[1] Oceanic variability on interannual, interdecadal, and longer timescales plays a key role in climate variability and climate change. Paleoclimatic records suggest major changes in the location and rate of deepwater formation in the Atlantic and Southern oceans on timescales from millennia to millions of years. Instrumental records of increasing duration and spatial coverage document substantial variability in the path and intensity of ocean surface currents on timescales of months to decades. We review recent theoretical and numerical results that help explain the physical processes governing the large-scale ocean circulation and its intrinsic variability. To do so, we apply systematically the methods of dynamical systems theory. The dynamical systems approach is proving successful for more and more detailed and realistic models, up to and including oceanic and coupled oceanatmosphere general circulation models. In this approach one follows the road from simple, highly symmetric model solutions, through a "bifurcation tree," toward the observed, complex behavior of the system under investigation. The observed variability can be shown to have its roots in simple transitions from a circulation with high symmetry in space and regularity in time to circulations with successively lower symmetry in space and less regularity in time. This road of successive bifurcations leads through multiple equilibria to oscillatory and eventually chaotic solutions. Key features of this

approach are illustrated in detail for simplified models of 34 two basic problems of the ocean circulation. First, a 35 barotropic model is used to capture major features of the 36 wind-driven ocean circulation and of the changes in its 37 behavior as wind stress increases. Second, a zonally 38 averaged model is used to show how the thermohaline 39 ocean circulation changes as buoyancy fluxes at the surface 40 increase. For the wind-driven circulation, multiple 41 separation patterns of a "Gulf-Stream like" eastward jet 42 are obtained. These multiple equilibria are followed by 43 subannual and interannual oscillations of the jet and of the 44 entire basin's circulation. The multiple equilibria of the 45 thermohaline circulation include deepwater formation near 46 the equator, near either pole or both, as well as intermediate 47 possibilities that bear some degree of resemblance to the 48 currently observed Atlantic overturning pattern. Some of 49 these multiple equilibria are subject, in turn, to oscillatory 50 instabilities with timescales of decades, centuries, and 51 millennia. Interdecadal and centennial oscillations are the 52 ones of greatest interest in the current debate on global 53 warming and on the relative roles of natural and 54 anthropogenic variability in it. They involve the physics 55 of the truly three-dimensional coupling between the wind- 56 driven and thermohaline circulation. To arrive at this three- 57 dimensional picture, the bifurcation tree is sketched out for 58 increasingly complex models for both the wind-driven and 59 the thermohaline circulation.

1. INTRODUCTION AND MOTIVATION

[2] Until a quarter of a century ago [Broecker and Van 67 Donk, 1970; Hays et al., 1976] the climates of the past 68 had been described mostly in qualitative terms. Since then 69 many techniques have become available to construct 70 climatic records from geological, biological, and physical 71 data [Bradley, 1999]. These proxy records show that 72 climate variations on different timescales have been very 73 common in the past. The enormous amount of instrumen-74

tal data that has been collected over the last century and one half contributes, in turn, to a more and more complete picture of the climate system's variability.

[3] The purpose of the present review paper is to describe the role of the ocean circulation in this variability and to emphasize that dynamical systems theory can contribute substantially to understanding this role. The intended audience and the way prospective readers can best benefit from this review are highlighted in Box 1/Appendix A1. To facilitate diverse routes through the paper, we have included a glossary of the principal symbols in Table 1 and a list acronyms in Table 2.

1.1. Climate Variability on Multiple Timescales

[4] An "artist's rendering" of climate variability on all timescales is provided in Figure 1a. The first version of Figure 1a was produced by *Mitchell* [1976], and many versions thereof have circulated since. Figure 1a is meant to summarize our knowledge of the spectral power $S = \frac{1}{2}$

 S_{ω} , i.e., the amount of variability in a given frequency 93 band, between ω and $\omega + \Delta\omega$; here the frequency ω is the 94 inverse of the period of oscillation and $\Delta\omega$ indicates a 95 small increment. This power spectrum is not computed 96 directly by spectral analysis from a time series of a given 97 climatic quantity, such as (local or global) temperature; 98 indeed, there is no single time series that is 10^7 years 99 long and has a sampling interval of hours, as Figure 1a 100 would suggest. Figure 1a includes, instead, information 101 obtained by analyzing the spectral content of many 102 different time series, for example, the spectrum 103 (Figure 1b) of the 335-year long record of Central 104 England Temperatures. This time series is the longest 105 instrumentally measured record of any climatic variable. 106 Given the lack of earlier instrumental records, one can 107 easily imagine (but cannot easily confirm) that the higher- 108 frequency spectral features might have changed, in am- 109 plitude, frequency, or both, over the course of climatic 110 history. 111

- [5] With all due caution in its interpretation, Figure 1a reflects three types of variability: (1) sharp lines that correspond to periodically forced variations at 1 day and 1 year; (2) broader peaks that arise from internal modes of variability; and (3) a continuous portion of the spectrum that reflects stochastically forced variations, as well as deterministic chaos [Ghil and Robertson, 2000; Ghil, 2002].
- [6] Between the two sharp lines at 1 day and 1 year lies the synoptic variability of midlatitude weather systems, concentrated at 3–7 days, as well as intraseasonal variability, i.e., variability that occurs on the timescale of 1–3 months. The latter is also called low-frequency atmospheric variability, a name that refers to the fact that this variability has lower frequency, or longer periods, than the life cycle of weather systems. Intraseasonal variability comprises phenomena such as the Madden-Julian oscillation of winds and cloudiness in the tropics or the alternation between episodes of zonal and blocked flow in midlatitudes [Ghil and Childress, 1987; Ghil et al., 1991; Haines, 1994; Molteni, 2002].
- [7] Immediately to the left of the seasonal cycle in Figure 1a lies interannual, i.e., year to year, variability. An important component of this variability is the El Niño phenomenon in the tropical Pacific: Once about every 4 years, the sea surface temperatures (SSTs) in the eastern tropical Pacific increase by a few degrees over a period of about 1 year. This SST variation is associated with changes in the trade winds over the tropical Pacific and in sea level pressures [*Bjerknes*, 1969; *Philander*, 1990]; an east-west seesaw in the latter is called the Southern Oscillation. The

combined El Niño/Southern Oscillation (ENSO) phenome- 142 non arises through large-scale interaction between the 143 equatorial Pacific and the atmosphere above. Equatorial 144 wave dynamics in the ocean plays a key role in setting 145 ENSO's timescale [Cane and Zebiak, 1985; Neelin et al., 146 1994, 1998; Dijkstra and Burgers, 2002].

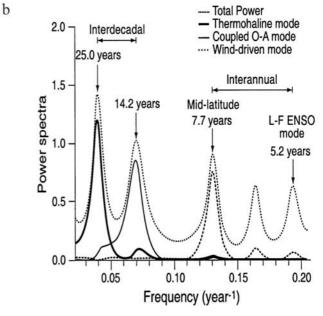

Figure 1. (a) An "artist's rendering" of the composite power spectrum of climate variability showing the amount of variance in each frequency range [from *Ghil*, 2002]. (b) Spectrum of the central England Temperature time series from 1650 to the present. Each peak in the spectrum is tentatively attributed to a physical mechanism; see *Plaut et al.* [1995] for details. - [8] The greatest excitement among scientists as well as the public is currently being generated by interdecadal variability, i.e., climate variability on the timescale of a few decades, the timescale of an individual human's life cycle [Martinson et al., 1995]. Figure 1b represents an upto-date "blowup" of the interannual-to-interdecadal portion of Figure 1a. The broad peaks are due to the climate system's internal processes: Each spectral component can be associated, at least tentatively, with a mode of interannual or interdecadal variability [Plaut et al., 1995]. Thus the rightmost peak, with a period of 5.2 years, can be attributed to the remote effect of ENSO's low-frequency mode, while the 7.7-year peak captures a North Atlantic mode of variability that arises from the Gulf Stream's interannual cycle of meandering and intensification. The two interdecadal peaks, near 14 and 25 years, are also present in global records, instrumental as well as paleoclimatic [Kushnir, 1994; Mann et al., 1998; Moron et al., 1998; Delworth and Mann, 2000; Ghil et al., 2002b].
- [9] Finally, the leftmost part of Figure 1a represents paleoclimatic variability. The information summarized here comes exclusively from proxy indicators of climate [Imbrie and Imbrie, 1986]. These include coral records [Boiseau et al., 1999] and tree rings for the historic past [Mann et al., 1998], as well as marine sediment [Duplessy and Shackleton, 1985] and ice core [Jouzel et al., 1991] records for the last 2 million years of Earth history, the Quaternary. Glaciation cycles, an alternation of warmer and colder climatic episodes, dominated the Quaternary era. The cyclicity is manifest in the broad peaks present in Figure 1a between roughly 1 kyr and 1 Myr. The two peaks at about 20 kyr and 40 kyr reflect variations in Earth's orbit, while the dominant peak at 100 kyr remains to be convincingly explained [Imbrie and Imbrie, 1986; Ghil and Childress, 1987; Gildor and Tziperman, 2001]. The glaciation cycles provide a fertile testing ground for theories of climate variability for two reasons: (1) They represent a wide range of climatic conditions, and (2) they are much better documented than earlier parts of climatic history.
- [10] Within these glaciation cycles, there are higherfrequency oscillations prominent in the North Atlantic paleoclimatic records. These are the Heinrich events [Heinrich, 1988] with a near periodicity of 6-7 kyr and the Dansgaard-Oeschger cycles that provide the peak at around 1-2.5 kyr in Figure 1a. Rapid changes in temperature, of up to one half of the amplitude of a typical glacial-interglacial temperature difference, occurred during Heinrich events, and somewhat smaller ones occurred over a Dansgaard-Oeschger cycle. Progressive cooling through several of the latter cycles followed by an abrupt warming defines a Bond cycle [Bond et al., 1995]. In North Atlantic sediment cores the coldest part of each Bond cycle is marked by a so-called Heinrich layer that is rich in ice-rafted debris. None of these higher-frequency oscillations can be directly connected to orbital or other periodic forcings.
- [11] In summary, climate variations range from the largeamplitude climate excursions of the past millennia to smaller-amplitude fluctuations on shorter timescales. Sev-

eral spectral peaks of variability can be clearly related to 206 forcing mechanisms; others cannot. In fact, even if the 207 external forcing were constant in time, that is, if no 208 systematic changes in insolation or atmospheric composi- 209 tion, such as trace gas or aerosol concentration, would 210 occur, the climate system would still display variability 211 on many timescales. This statement is clearly true for the 212 3–7 days synoptic variability of midlatitude weather, which 213 arises through baroclinic instability of the zonal winds, and 214 the ENSO variability in the equatorial Pacific, as discussed 215 above. Processes internal to the climate system can thus 216 give rise to spectral peaks that are not related directly to the 217 temporal variability of the forcing. It is the interaction of 218 this highly complex intrinsic variability with the relatively 219 small time-dependent variations in the forcing that is 220 recorded in the proxy records and instrumental data.

1.2. Role of the Ocean Circulation

- [12] We focus in this review on the ocean circulation as a 223 source of internal climate variability. The ocean moderates 224 climate through its large thermal inertia, i.e., its capacity to 225 store and release heat and its poleward heat transport 226 through ocean currents. The exact importance of the latter 227 relative to atmospheric heat transport, though, is still a 228 matter of active debate [Seager et al., 2001]. The large- scale ocean circulation is driven both by momentum fluxes 230 as well as by fluxes of heat and freshwater at the ocean- 231 atmosphere interface. The near-surface circulation is dom- 232 inated by horizontal currents that are mainly driven by the 233 wind stress forcing, while the much slower motions of the 234 deep ocean are mainly induced by buoyancy differences. 235
- [13] The circulation due to either forcing mechanism is 236 often described and analyzed separately for the sake of 237 simplicity. In fact, the wind-driven and thermohaline circu- 238 lation together form a complex three-dimensional (3-D) 239 flow of different currents and water masses through the 240 global ocean. The simplest picture of the global ocean 241 circulation has been termed the "ocean conveyor" [Gordon, 242 1986; Broecker, 1991]; it corresponds to a two-layer view 243 where the vertical structure of the flow field is separated 244 into a shallow flow, above the permanent thermocline at 245 roughly 1000 m, and a deep flow between this thermocline 246 and the bottom (i.e., between a depth of roughly 1000 m and 247 4000 m); see Figure 2. The unit of volume flux in the ocean 248 is $1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$, and it equals approximately the total 249 flux of the world's major rivers. MacDonald and Wunsch 250 [1996] and Ganachaud and Wunsch [2000] have provided 251 an updated version of this schematic representation of the 252 ocean circulation.
- [14] In the North Atlantic, for instance, the major current 254 is the Gulf Stream, an eastward jet that arises through the 255 merging of the two western boundary currents, the north-256 ward flowing Florida Current and the southward flowing 257 Labrador Current. In the North Atlantic's subpolar seas, 258 about 14 Sv of the upper ocean water carried northward by 259 the North Atlantic Drift, the northeastward extension of the 260 Gulf Stream, is converted to deepwater by cooling and 261 salinification. This North Atlantic Deep Water (NADW) 262

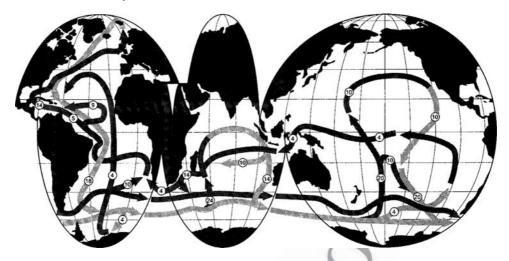

Figure 2. Sketch of the global ocean circulation as a "conveyor belt." Dark shaded paths indicate flow in the surface ocean; light shaded paths indicate flow in the deep ocean. Numbers indicate volume transport in sverdrup (1 Sv = 10^6 m³s⁻¹) (based on *Schmitz* [1995] but reprinted from *Bradley* [1999], with permission from Elsevier).

flows southward, crosses the equator, and joins the flows in the Southern Ocean. The outflow from the North Atlantic is compensated by water coming through the Drake Passage (about 10 Sv) and water coming from the Indian Ocean through the Agulhas Current system (about 4 Sv). Part of the latter "Agulhas leakage" may originate from Pacific water that flows through the Indonesian Archipelago. We refer to earlier reviews [Gordon, 1986; Schmitz, 1995; World Ocean Circulation Experiment (WOCE), 2001] for more complete information on the circulation in each major ocean basin as well as from one basin to another.

[15] Changes in the ocean circulation can influence climate substantially through their impact on both the meridional and zonal heat transport. This can affect mean global temperature and precipitation, as well as their distribution in space and time. Subtle changes in the North Atlantic surface circulation and their interactions with the overlying atmosphere are thought to be involved in climate variability on interannual and interdecadal timescales, as observed in the instrumental record of the last century [Martinson et al., 1995; Ghil, 2001]. Changes in the circulation may also occur on a global scale, involving a transition to different large-scale patterns. Such changes may have been involved in the large-amplitude climate variations of the past [Broecker et al., 1985].

1.3. Modeling Hierarchy

[16] The climate system is highly complex. Its main subsystems have very different characteristic times, and the specific phenomena involved in each one of the climate problems alluded to in sections 1.1 and 1.2 are quite diverse. It is inconceivable therefore that a single model could successfully incorporate all the subsystems, capture all the phenomena, and solve all the problems. Hence the concept of a hierarchy of climate models, from the simple to the complex, was developed about a quarter of a century ago

[Schneider and Dickinson, 1974; Ghil and Robertson, 299 2000].

[17] The simplest, spatially zero-dimensional (0-D) ocean 301 models are so-called box models, used to study the stability 302 [Stommel, 1961] and paleoevolution [Karaca et al., 1999] 303 of the oceans' thermohaline circulation or biogeochemical 304 cycles [Sarmiento and Toggweiler, 1984; Keir, 1988; 305 Paillard et al., 1993]. There are one-dimensional (1-D) 306 models that consider the vertical structure of the upper 307 ocean, whether the oceanic mixed layer only [Kraus and 308 Turner, 1967; Karaca and Müller, 1989] or the entire 309 thermocline structure.

[18] Two-dimensional (2-D) models of the oceans fall 311 into the two broad categories of "horizontal" and "verti- 312 cal." Models which resolve two horizontal coordinates 313 emphasize the study of the oceans' wind-driven circulation 314 [Cessi and Ierley, 1995; Jiang et al., 1995], while those that 315 consider a meridional section concentrate on the overturn- 316 ing, thermohaline circulation [Cessi and Young, 1992; Quon 317 and Ghil, 1992, 1995; Thual and McWilliams, 1992].

[19] As explained in section 1.2, the oceans' circulation is 319 essentially 3-D, and therefore general circulation models 320 (GCMs) of the ocean are indispensable in understanding 321 oceanic variability [McWilliams, 1996]. The Bryan-Cox 322 model [Bryan et al., 1974; Cox, 1987] has played a seminal 323 role for the development and applications of such models; 324 this role resembles the one played by the University of 325 California, Los Angeles, model [Arakawa and Lamb, 326 1977] in atmospheric modeling. A number of simplified 327 versions of the Bryan-Cox ocean GCM have been used in 328 exploratory studies of multiple mean flows [Bryan, 1986; 329 Marotzke et al., 1988] and oscillatory behavior [Weaver et 330 oceans. 332

[20] In confronting modeling results with observations 333 one has to realize that it is the largest scales that are best and 334 most reliably captured. This is certainly true in the atmo- 335

sphere, where global observing systems have existed for 337 half a century [Daley, 1991], and even more so in the oceans, where global coverage has been provided more 338 recently by satellites and long hydrographic sections [Ghil 339 and Malanotte-Rizzoli, 1991; Wunsch, 1996; WOCE, 2001]. 340 The variability of the large scales arises from two sources: 341 (1) the competition among the finite-amplitude instabilities 342 and (2) the net effects of the smaller scales of motion. In this 343 review, we concentrate mostly on the former. Dynamical 344 systems theory provides a perfect toolkit for this type of 345 study. 346

1.4. A Unifying Framework

[21] It is now widely understood that the climate system contains numerous nonlinear processes and feedbacks and that its behavior is rather irregular but not totally random. Dynamical systems theory studies the common features of such nonlinear systems. The theory is most fully developed for systems with a finite number of degrees of freedom [Smale, 1995], and the early and best known applications to atmospheric and ocean dynamics involved, not surprisingly, a small number of degrees of freedom [Stommel, 1961; Lorenz, 1963a, 1963b; Veronis, 1963, 1966]. This fact has led to a widespread perception that dynamical systems theory only applies to "low-order systems," and hence its concepts are not sufficiently well known or appreciated within the community of oceanographers, meteorologists, and other geoscientists.

[22] The dynamical systems main results that are most important for the study of climate variability have been summarized by *Ghil et al.* [1991]; they involve essentially bifurcation theory [*Guckenheimer and Holmes*, 1990] and the ergodic theory of dynamical systems [*Eckmann and Ruelle*, 1985]. Bifurcation theory studies changes in the qualitative behavior of a dynamical system as one or more of its parameters changes. The results of this theory permit one to follow systematically climatic behavior from the simplest kind of model solutions to the most complex, from single to multiple equilibria, and on to periodic, chaotic, and fully turbulent solutions. Ergodic theory connects the dynamics of a system with its statistics.

[23] Here we sketch the basic concepts of bifurcation theory for a general system of ordinary differential equations (ODEs) that can be written as

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}, \mathbf{p}, t). \tag{1}$$

[24] Here **x** is the state vector in the state space \mathbb{R}^n , where n indicates the number of degrees of freedom. The right-hand side **f** contains the model dynamics; it depends on **x** in a nonlinear fashion, on time t, and on the vector **p** of p parameters, where typically $p \ll n$. The ODE system (1) defines a dynamical system in continuous time, provided solutions exist and are unique for all times, $-\infty < t < \infty$. The system is called autonomous if **f** does not depend explicitly on time. A trajectory of the dynamical system,

starting at the initial state $\mathbf{x}(t_0) = \mathbf{x}_0$, is a curve $\Gamma = {\mathbf{x}(t): 391 - \infty < t < \infty}$ in the phase space that satisfies (1).

[25] A solution $\mathbf{x}(t) = \bar{\mathbf{x}}$ of an autonomous ODE system is 393 called a fixed point if

$$\mathbf{f}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) = 0, \tag{2}$$

and hence a trajectory for which $\mathbf{x}(t) = \bar{\mathbf{x}}$ at any time t will 396 remain there forever. Linear stability analysis of a particular 397 fixed point $(\bar{\mathbf{x}}, \bar{\mathbf{p}})$ considers infinitesimally small perturba-398 tions \mathbf{y} , i.e.,

$$\mathbf{x} = \bar{\mathbf{x}} + \mathbf{y};\tag{3}$$

linearization of (1) around $\bar{\mathbf{x}}$ then gives

$$\frac{d\mathbf{y}}{dt} = \mathbf{J}(\bar{\mathbf{x}}, \bar{\mathbf{p}})\mathbf{y},\tag{4}$$

where **J** is the Jacobian matrix 403

$$\mathbf{J} = \begin{pmatrix} \frac{\partial f_1}{\partial x_1} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \cdots & \cdots & \cdots \\ \frac{\partial f_n}{\partial x_1} & \cdots & \frac{\partial f_n}{\partial x_n} \end{pmatrix}.$$
 (5)

[26] The linear, autonomous ODE system (4) has solutions of the form $\mathbf{y}(t) = e^{\sigma t}\hat{\mathbf{y}}$. Substituting such a solution 407 into (4) leads to an eigenvalue problem for the complex 408 growth factor $\sigma = \sigma_r + i\sigma_i$, i.e.

$$\sigma \hat{\mathbf{y}} = \mathbf{J}(\bar{\mathbf{x}}, \bar{\mathbf{p}})\hat{\mathbf{y}}. \tag{6}$$

Those fixed points for which eigenvalues with $\sigma_r > 0$ exist 411 are unstable, since the perturbations are exponentially 412 growing. Fixed points for which all eigenvalues have $\sigma_r < 0$ 413 are linearly stable.

[27] Discretization of the systems of partial differential 415 equations (PDEs) that govern oceanic and other geophysical 416 flows [Gill, 1982; Pedlosky, 1987, 1996] leads to a system 417 of ODEs (1), with large n. In many cases the linearization 418 (3)–(5) yields solutions that are the classical linear waves of 419 geophysical fluid dynamics. These include neutrally stable 420 waves, like Rossby or Kelvin waves, or unstable ones, like 421 those associated with the barotropic or baroclinic instability 422 of ocean currents.

[28] If the number of solutions or their stability prop-424 erties change as a parameter is varied, a qualitative 425 change occurs in the behavior of the dynamical system: 426 The system is then said to undergo a bifurcation. The 427 points at which bifurcations occur are called bifurcation 428 points or critical points. A bifurcation diagram for a 429 particular system (1) is a graph in which the variation 430 of its solutions is displayed in the phase-parameter space. 431 Information on the most elementary bifurcations is pre-432 sented in Box 2/Appendix A2.

[29] Bifurcation theory goes beyond classical, linear 434 analysis in studying the nonlinear saturation of and inter- 435 actions between linear instabilities. When the interaction 436

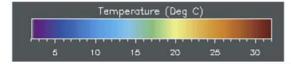

Figure 3. Composite, multipass image of the average sea surface temperature field in May 1996 within the Gulf Stream region. The infrared data used to obtain this picture were obtained from high-resolution (0.5° horizontally) observations from the advanced very high resolution radiometer (AVHRR) (see http://fermi.jhuapl.edu/avhrr/index.html). In a multipass image the "warmest" pixel is selected from each pass, 3 days apart.

between several instabilities leads to irregular, apparently random behavior, ergodic theory sheds light on the statistics of this behavior.

[30] In the early 1960s it was possible to compute the first one or two bifurcations analytically and one or two more by the modest computational means of that time, all this for systems with about 10 degrees of freedom or less [Lorenz, 1963a, 1963b; Veronis, 1963, 1966]. In the mid-1970s it became possible to do so for spatially 1-D energy balance models, either discretized by spectral truncation [Held and Suarez, 1974; North, 1975; North et al., 1983] or even by a full treatment of the governing PDEs [Ghil, 1976]. The numerical techniques to do so, so-called continuation techniques, are described elsewhere [Doedel and Tuckermann, 2000; Dijkstra, 2000]. Legras and Ghil [1985] were the first to apply a continuation method to a problem in geophysical fluid dynamics. Their atmospheric model had 25 spherical harmonics. In the last few years, bifurcation sequences have been computed for 2-D [Cessi and Young, 1992; Quon and Ghil, 1992, 1995; Speich et al., 1995; Dijkstra and Molemaker, 1997] and 3-D [Chen and Ghil, 1996; Ghil and Robertson, 2000; Dijkstra et al., 2001] climate models

with thousands or even tens of thousands of degrees of 460 freedom.

[31] Simplified GCMs, atmospheric, oceanic, and coupled, have thus become amenable to a systematic study of 463 their large-scale variability. For systems that have an even 464 larger number of degrees of freedom, such as full-scale 465 ocean and coupled ocean-atmosphere GCMs, with *n* larger 466 than 10⁶, bifurcation points can be inferred by performing 467 time-dependent forward integrations for several parameter 468 values and monitoring changes in qualitative behavior. This 469 type of "poor-man's continuation" has been applied successfully for models of the wind-driven [*Jiang et al.*, 1995; 471 *Chang et al.*, 2001] and thermohaline [*Quon aand Ghil*, 472 1992, 1995; *Chen and Ghil*, 1996] circulation.

2. WIND-DRIVEN CIRCULATION

[32] A central problem of oceanography is to understand 476 the physics of the near-surface ocean circulation and its 477 variability on timescales from several months to several 478 years. We focus in this section on the North Atlantic for two 479 reasons: (1) It is an ocean basin for which relatively many 480 observations are available, and (2) the circulation in this 481 basin is highly relevant to climate change over the surrounding, highly populated continental areas.

2.1. Observations

[33] The wind stress curl induced by the easterly winds in 485 very low and very high latitudes, on the one hand, and the 486 midlatitude westerlies, on the other, induces midlatitude 487 cellular flows, called gyres. The North Atlantic is typical 488 of several other ocean basins in exhibiting a dominant 489 anticyclonic cell, called the subtropical gyre, and a smaller 490 cyclonic cell, called the subpolar gyre. Each of these gyres 491 has a narrow, fast flowing western boundary current and a 492 slower, more diffuse eastern boundary current.

[34] Figure 3 gives a rough view of the near-surface flow 494 in the northwestern part of the North Atlantic basin, based 495 on a multipass image of the SST field, as obtained from 496 infrared sensing by satellite. Here orange colors indicate a 497 warm sea surface, with SSTs of typically 25°C in the Gulf 498 of Mexico and the Florida Straits. These warm waters are 499 advected northward, along the east coast of the United 500 States, by the strong Florida Current. After separation from 501 the coast near Cape Hatteras this current becomes the Gulf 502 Stream; typical temperatures near the separation point are 503 15°C. The northern boundary of the Gulf Stream is characterized by a strong meridional temperature gradient, which 505 is referred to as the north wall or cold wall.

[35] The mean position of the Gulf Stream in the North 507 Atlantic has fascinated oceanographers since its early de- 508 scription by Benjamin Franklin and Timothy Folger 509 [Richardson, 1980]. From the enormous amount of data 510 obtained since then, using ship observations and satellite 511 data, the time-mean path of the Gulf Stream is now well 512 known [Auer, 1987; Lee and Cornillon, 1995]. The Florida 513 Current (see Figure 3) flows almost parallel to the coastline 514 and, after separation, the Gulf Stream flows to the east- 515

northeast, approximately along 40°N. This nearly eastward jet is accompanied by vigorous recirculation regions north and south of it [Hogg et al., 1986; Feliks and Ghil, 1996]. Near Cape Hatteras the volume transport is estimated to be about 50-65 Sv, and it increases to a total of about 145 Sv at 60°W [Johns et al., 1995]. The position of the separation point is fairly stable, changing by less than about 50 km over several years.

[36] The variability of the Gulf Stream has been studied for decades through time-continuous in situ measurements, at a few locations, as well as by more detailed one-time-only hydrographic surveys. More recently, these data have been complemented with satellite-derived observations, which provide fairly complete and detailed spatiotemporal coverage [Vazquez et al.., 1990; Wang and Koblinsky, 1995]. Rossby waves form an important component of the temporal variability of the midlatitude oceans, and their analysis has attracted considerable attention in the last few decades [LeBlond and Mysak, 1978; Gill, 1982; Pedlosky, 1987]. Their signature can now be tracked through satellite altimetry [Chelton and Schlax, 1996] in the sea surface height field [Fu and Cheney, 1995] in spite of the fact that they might represent only a fairly small fraction of the total variance (5-15%) [cf. Gaspar and Wunsch, 1989].

[37] As the Gulf Stream penetrates farther east into the open ocean, it spreads out because of meandering. In this region, cutoff eddies are formed and move away from the main jet, generally in a westward or southwestward direction. Their average wavelength is about 100 km, and their propagation speed is of the order of 10 km d⁻¹. The scale of the eddies is related to an internal length scale of the ocean, the internal Rossby deformation radius [Robinson, 1983; Pedlosky, 1987]; both stratification and rotation effects contribute to define this radius [Feliks and Ghil, 1996]. In the oceans, motions with this horizontal scale are commonly referred to as mesoscale. Generally, the presence of mesoscale eddies causes variability on a subannual, 2- to 3-month timescale.

[38] The last decade has seen a huge increase in the observational information available on the oceans' basin and global scales [Wunsch, 1996; Ghil et al., 1997; WOCE, 2001]. As a result, attention has focused more and more on the temporal variability of the wind-driven circulation that is associated with these larger spatial scales [Fu and Smith, 1996] and involves lower frequencies [Pedlosky, 1996]. The eddy kinetic energy distribution determined by long-term ship drift and satellite-tracked drifter data shows a maximum of variability in the western part of the midlatitude ocean basins along the western boundary currents and their eastward extension [Wyrtki et al., 1976; Brugge, 1995]. Various observations, though limited in spatial and temporal coverage, suggest the existence of distinct scales of temporal variability from subannual [Lee and Cornillon, 1995] through seasonal [Ichikawa and Beardsley, 1993; Schott and Molinari, 1996] to interannual [Mizuno and White, 1993; Auer, 1987] scales.

[39] The sources of this low-frequency variability and of the associated spatiotemporal patterns have become an

object of intense scrutiny. The classical view is that the 574 overall red spectrum of the oceans' variability in time is due 575 to its "flywheel" integration of atmospheric white noise 576 [Hasselmann, 1976; Frankignoul and Hasselmann, 1977] 577 and that any peaks that rise above this broadband spectrum 578 also result primarily from changes in the external forcing, 579 especially in wind stress or buoyancy fluxes.

[40] The forced variability does not always account, 581 however, for all or even most of the observed variability. 582 For example, Niiler and Richardson [1973] noted a dis- 583 crepancy between the observed seasonal variability of the 584 Florida Current transport and the transport calculated as a 585 passive response to seasonally varying winds. Dommenget 586 and Latif [2000] have found that the spectrum of midlati- 587 tude SST variability in several coupled GCMs, each with a 588 fully dynamical ocean model, is significantly different from 589 a red noise process. Internal ocean dynamics, i.e., intrinsic 590 variability due to nonlinear interactions between two or 591 more physical processes that affect the wind-driven ocean 592 circulation, seems therefore to play an important role on 593 these timescales.

2.2. Classical Theory and Numerical Simulations

[41] The intensification of western boundary currents was 596 first explained using steady, linear, rectangular-basin models 597 [Stommel, 1948; Munk, 1950]. In the open ocean, away 598 from boundaries, the flow in these simple models is 599 dominated by Sverdrup [1947] balance between the wind 600 forcing and the latitudinally varying Coriolis forces, the so- 601 called β effect; here β is the meridional derivative of the 602 Coriolis parameter (see Gill [1982] or Pedlosky [1987]). 603 The β effect leads to east-west asymmetry in the flow 604 pattern, with streamlines more closely bunched near the 605 western rather than near the eastern boundary [Stommel, 606 1951]. In the boundary layer that forms near the former, 607 lateral as well as bottom friction counteracts the increased 608 shear; the inclusion of the one or the other leads to the 609 Munk and Stommel boundary layer structures, respectively. 610

[42] The wind-driven flows are susceptible to barotropic 611 and baroclinic instability, which lead to time-dependent 612 behavior. The growth of perturbations and their interaction 613 with the background state, as well as with each other, lead to 614 a modification of the mean state and to the prevalence of the 615 time-dependent mesoscale features that were discussed in 616 section 2.1. High-resolution ocean GCMs, with realistic 617 continental geometry and bathymetry, have been run either 618 globally or for the Atlantic region [Semtner and Chervin, 619] 1992; Stammer et al., 1996; New et al., 1995; Chao et al., 620 1996; McWilliams, 1996; Smith et al., 2000]. The results of 621 these numerical simulations show large internal variability 622 on a wide range of space scales and timescales and the 623 influence of the eddies on the mean flow. The GCM results 624 are, however, not always easier to interpret than the obser- 625 vations, with which they share many physical processes and 626 scales of motion. 627

[43] For example, model resolution strongly affects the 628 mean flow path of the Gulf Stream, in particular its 629 separation near Cape Hatteras. In models with a horizontal 630

mesh size of 1° or larger [Holland and Bryan, 1994; Gerdes and Köberle, 1995; Chassignet et al., 2000], separation of the Gulf Stream is very diffuse, being spread out between Cape Hatteras and Newfoundland, and no recirculation regions are present: The stream north of Cape Hatteras appears as a rather broad band that continues to follow the coastline. For higher-resolution models with a horizontal mesh size of $1/3^{\circ}-1/6^{\circ}$ [Beckmann et al., 1994; Bryan et al., 1995; Chao et al., 1996] the time-mean state shows a sizable anticyclonic gyre northeast of Cape Hatteras, but the actual separation still occurs north of the observed position, and the simulated ocean heat transport is therefore incorrect. Only at a very high horizontal resolution, of 0.1° or higher, at which eddies are well simulated, does the Gulf Stream tend to separate at the correct position [Smith et al., 2000]. The root-mean-square sea surface height variability simulated at this resolution is also in good agreement with the one reconstructed by blending altimeter data from the TOPEX-Poseidon and the ERS-1 and ERS-2 satellites [Le Traon et al., 1998].

[44] These GCM simulations clearly show that it is necessary to have a mesh size that is well below the Rossby deformation radius in order to obtain Gulf Stream separation at the correct location. Still, it is far from clear which physical processes control the separation process. Haidvogel et al. [1992] and Dengg et al. [1996] have reviewed the problem of Gulf Stream separation. Both external factors (such as bottom topography or the wind stress field) and internal ones (such as adverse pressure gradients [Schlichting, 1968; Tansley and Marshall, 2001; Ghil et al., 2004] or the outcropping of isopycnals [Gangopadhyay et al., 1992; Chassignet and Bleck, 1993]) play an important role. Several studies using idealized models have tried to isolate only one or two factors as decisive, but the relation between these results and those obtained by using more realistic models and observations is hard to establish. The tools of bifurcation and ergodic theory are thus essential to explore systematically the results of the full hierarchy of ocean models.

[45] The fact that the wind-driven circulation of the major ocean basins typically contains a subtropical gyre that greatly exceeds in size and strength the subpolar gyre has led to applying these tools to two types of idealized models. Single-gyre models study the subtropical gyre only, while double-gyre models study a subtropical and a subpolar gyre of equal or nearly equal strength. In a sense, the two types of models bracket the midlatitude ocean basins' real circulation.

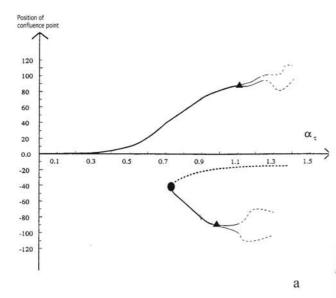

2.3. Successive Bifurcations in Equivalent-Barotropic Models

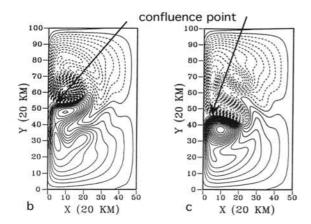

[46] Following the pioneering work of *Veronis* [1963, 1966], a systematic analysis of bifurcations in the winddriven ocean circulation has been carried out by several authors in the mid-1990s. Cessi and Ierley [1995], in particular, used a quasi-geostrophic (QG) barotropic model, while Jiang et al. [1993, 1995] used a reduced-gravity shallow water model (see Box 3/Appendix A3).

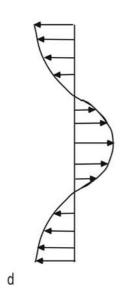

- [47] Jiang et al. [1995] computed transient double-gyre 688 flow for different values of the nondimensional wind stress 689 forcing strength α_{T} , using a horizontal resolution of 20 km. 690 For each value of α_{τ} they monitored the position of the 691 confluence point, i.e., the merging point of the two sepa- 692 rated western boundary currents, and its variability in time. 693 For small values of α_{τ} a unique, nearly symmetric flow is 694 found for which the confluence point is displaced slightly 695 northward of the basins' mid axis. This solution is neces- 696 sarily stable to small perturbations, since it is attained by 697 forward integration.
- [48] For larger values of α_{τ} , multiple stable equilibria 699 were found: A second steady state solution has its conflu- 700 ence point lying south of the mid basin axis. Spatial patterns 701 of the stable stationary thickness field h = h(x, y) for both 702 types of solutions are shown in Figures 4b and 4c for $\alpha_{\rm T} = 703$ 0.9. The bifurcation diagram proposed by Jiang et al. 704 [1995] is shown in Figure 4a, and the solution structure 705 corresponds to that of an imperfect pitchfork bifurcation 706 (see Box 2/Appendix A2 and Figure 3). In Figure 4a the 707 bold solid lines represent actually computed values of the 708 steady state confluence point, while the bold dashed lines 709 represent an inferred branch of unstable steady states.
- [49] Both stable equilibria become unstable at larger wind 711 stress strength, and stable periodic solutions arise from 712 either solution branch. One of these two limit cycles has a 713 period of about 2.8 years and is characterized by an 714 oscillation of the confluence point over a distance of about 715 100 km. This variation in the meridional position of the 716 eastward jet is accompanied by a periodically varying 717 strength of the recirculation regions. For larger values of 718 α_{τ} , aperiodic solutions are obtained for which the position 719 of the confluence point makes even larger excursions. 720
- [50] Speich et al. [1995] followed up on the Jiang et al. 721 [1995] work by studying the bifurcation structure of their 722 1.5-layer shallow water model using continuation tech- 723 niques (see section 1.4 and references there). The exact 724 position of the saddle-node bifurcation point in Figure 4a 725 could thus be calculated explicitly. Moreover, the Hopf 726 bifurcations (see Box 2/Appendix A2) that destabilize both 727 steady state branches were determined and so were the 728 spatial patterns of the linear oscillatory modes that lead to 729 these instabilities. These authors used singular-spectrum 730 analysis (SSA [Ghil and Vautard, 1991; Ghil et al., 731 2002b]) to compare the periods of these modes to those 732 obtained for the Gulf Stream and Kuroshio axis in Com- 733 prehensive Ocean-Atmosphere Data Set (COADS) data. 734 The results above raise a number of fundamental questions, 735 such as the physical origin of the multiple equilibria, the 736 nature of the oscillatory instabilities, and the transition route 737 to irregular behavior for large wind stress forcing.

2.3.1. Origin of Multiple Steady States

[51] The shallow water model can be simplified further 740 when the Rossby number ϵ is sufficiently small (see Box 3/741 Appendix A3). Under these conditions, QG theory is an 742 adequate approximation of the flow dynamics [Pedlosky, 743 1987]. Cessi and Ierley [1995] computed stationary solu- 744 tions of the single-layer QG equations in a small rectangular 745

basin by using a Newton-Raphson method. Multiple equi- 746 libria were found when the value of lateral friction coeffi- 747 cient A_H was decreased, with as many as seven occurring in 748 a small area of the parameter plane investigated. 749

[52] Dijkstra and Katsman [1997], using continuation 750 techniques, determined the detailed bifurcation structure of 751 the [Cessi and Ierley, 1995] QG model. At large values of 752 lateral friction A_H , there is only one steady state, which is 753 the antisymmetric double-gyre pattern. When A_H is decreased, this flow undergoes a perfect pitchfork bifurcation, 755 and two stable asymmetric states appear. The existence of 756 the perfect pitchfork bifurcation was already shown by 757 Jiang et al. [1993, 1995] in a low-order truncated QG 758 model (see Box 3/Appendix A3). The multiple equilibria 759 arise by spontaneous symmetry breaking: The solutions on 760 the asymmetric branches have the jet displaced either 761 southward or northward, similar to those in Figure 4, but 762 the two QG solutions that coexist for exactly the same 763 parameter values are now perfect mirror images of each 764 other.

[53] The shallow water equations are not invariant under 766 reflection symmetry with respect to the basins' mid axis, 767 and hence no perfect pitchfork bifurcation can occur. Small 768 deviations from the equilibrium thermocline depth, even at 769 low forcing or high lateral friction, induce an imperfection 770 which perturbs the pitchfork bifurcation. *Dijkstra and* 771 *Molemaker* [1999] worked out explicitly the connection 772 between the bifurcation diagrams of the QG and shallow 773 water models and showed that the occurrence of multiple 774 equilibria in the shallow water model does have its origin 775 in the QG model's symmetry breaking, as conjectured by 776 *Jiang et al.* [1995].

[54] Barotropic processes dominate the physical mecha778 nism of the instability. *Dijkstra and Katsman* [1997] ob779 served this in their two-layer QG model, which included 780 baroclinic processes but exhibited essentially the same 781 primary pitchfork bifurcation as the barotropic QG model 782 of *Cessi and Ierley* [1995]. *Ghil et al.* [2002a] used a QG 783

Figure 4. (a) Bifurcation diagram for the solutions found in an 1.5-layer shallow water model by forward time integration. The meridional position of the confluence point is plotted on the ordinate in kilometers away from the symmetry axis; on the abscissa a nondimensional measure α_{τ} of the wind stress strength is shown. Markers indicate bifurcation points, with a circle for the saddle-node bifurcation and a triangle for either Hopf bifurcation. Bold solid and dashed lines indicate steady states, stable and unstable, respectively. Thin solid and dashed lines give the range of variability for the periodic and aperiodic solutions, respectively. (b and c) Patterns of the thickness field h = h(x,y) of the upper, active layer's thickness for the two stable steady state solutions at $\alpha_{\tau} = 0.9$. Thicknesses h > D =500 m are solid; those with h < D are dashed; contour interval is 5 m. The position of the confluence point is indicated in both Figures 4a and 4b. The nondimensional friction coefficient is $\alpha_A = 1.3$ in Figures 4a–4c (from *Jiang* et al. [1995]). (d) Sketch of the wind stress forcing for the idealized double-gyre problem.

model in which the vertical stratification was captured by projection onto the two leading eigenmodes of the vertical structure equation [Flierl, 1978; Feliks and Ghil, 1996]. Flierl and Feliks and Ghil showed explicitly that the first baroclinic mode exhibits the same horizontal pattern as the barotropic mode at the point of symmetry breaking.

2.3.2. Origin of Temporal Variability

[55] Hopf bifurcations destabilize the steady solutions as the forcing increases (see Figure 4a) or lateral friction decreases [see Jiang et al., 1995, Figure 4]. The spatiotemporal pattern of the most unstable oscillatory mode Φ (t) can be determined from the solution of the linear stability problem (6). The complex eigenvalue $\sigma = \sigma_r + i\sigma_i$ and associated eigenfunction $\hat{\mathbf{x}} = \hat{\mathbf{x}}_r + i\hat{\mathbf{x}}_i$ provide the mode $\Phi(t)$,

$$\Phi(t) = e^{\sigma_r t} [\hat{\mathbf{x}}_r \cos(\sigma_i t) - \hat{\mathbf{x}}_i \sin(\sigma_i t)], \tag{7}$$

with angular frequency σ_i and growth rate $\sigma_r > 0$, which destabilizes the steady state. The period \mathcal{P} of the oscillatory 800 factor in (7) is given by $\mathcal{P} = 2\pi/\sigma_i$.

[56] For the one- and two-layer QG and shallow water models, three classes of modes may destabilize the steady states. Jiang et al.'s [1995] 1.5-layer shallow water model captures only equivalent-barotropic processes. In this model, two of these three classes arise at the Hopf bifurcations shown in Figure 4a. The upper branch becomes unstable through a so-called (recirculation) gyre mode [Speich et al., 1995]. The two centers of action of this mode are located within the vigorous recirculation regions near the confluence point of the two separated boundary currents, and the pattern straddles the time-mean axis of the eastward jet. Simonnet and Dijkstra [2002] have shown that the gyre modes do arise ultimately by a merger between stationary modes. The unstable, purely exponential modes that merge are both related to the symmetry-breaking pitchfork bifurcation. The destabilization mechanism is a shear instability and is essentially independent of Rossby wave dynamics.

[57] The lower branch in Figure 4a becomes unstable through a mode that has a subannual oscillation period; such modes are referred to as (Rossby) basin modes [Pedlosky, 1987]. The latter are basically a superposition of free westward propagating Rossby waves, whose sum satisfies the boundary conditions. The gravest barotropic ocean basin mode has a one-cell spatial structure in both horizontal directions; its period is about 20 days, which is only slightly increased by the presence of friction. These otherwise neutral basin modes are destabilized through the presence of horizontal shear and lead therewith to variability on this very short timescale of a month or less. Similar oscillatory instabilities are found in the equivalent-barotropic version of Dijkstra and Katsman's [1997] QG model and are closely linked to those in the shallow water model [Dijkstra and Molemaker, 1999]. Chang et al. [2001] found that such a basin mode plays an important role in a barotropic QG model at high values of the forcing and in a fairly turbulent

[58] In two-layer [Dijkstra and Katsman, 1997] and twomode [Ghil et al., 2002a] models, additional baroclinic instabilities occur, whose spatial patterns resemble those 840 that destabilize a zonal eastward jet [Eadv, 1949; Pedloskv, 841 1987]. This third class of oscillatory instabilities has sub- 842 annual periods and represents classical baroclinic modes, 843 modified to some extent by the geometry of the mean flow. 844

2.4. Low- and Ultralow-Frequency Results

[59] The results in section 2.3 describe the lowest 846 branches of the bifurcation tree, where steady state behavior 847 with highly symmetric spatial patterns changes into richer 848 spatiotemporal behavior of the flow, once the forcing 849 increases or the friction decreases. The periods associated 850 with these first few bifurcations, from months to years, are 851 typically comparable to or longer than those associated with 852 mesoscale variability. How does this bifurcation structure 853 relate to time-dependent flows obtained by numerical sim- 854 ulations using similar or somewhat more detailed models? 855

[60] McCalpin and Haidvogel [1996] investigated the 856 time-dependent solutions of an equivalent-barotropic QG 857 model for a basin of realistic size (3600 × 2800 km), as well 858 as the sensitivity of solutions to the magnitude of the wind 859 stress and its meridional profile. They classified solutions 860 according to their basin-averaged kinetic energy and found 861 three persistent states in their simulations (Figure 5a). High- 862 energy states are characterized by near symmetry with 863 respect to the mid axis, weak meandering, and large jet 864 penetration into the basin interior (Figure 5b, left plot). 865 Low-energy states have a strongly meandering jet that 866 extends but a short way into the basin (Figure 5b, right 867 plot), while intermediate-energy states resemble the time- 868 averaged flow and have a spatial pattern somewhere 869 between high- and low-energy states (not shown). The 870 persistence of the solutions near either state is irregular 871 but can last for more than a decade of simulated time 872 (Figure 5a). Compared to the interannual periods obtained 873 by Hopf bifurcations, we shall refer to this type of variabil- 874 ity as (inter)decadal or ultralow frequency. Berloff and 875 McWilliams [1999] studied a two-layer QG model with a 876 constant-in-time, symmetric double-gyre forcing. They also 877 found that, at relatively low values of the lateral friction 878 coefficient, the flow patterns hover for extended intervals 879 near three states, each with a distinct total energy.

[61] The ultralow-frequency variability has been attributed 881 to the interaction of mesoscale eddies [Berloff and 882 McWilliams, 1999], to regime switches associated with 883 transitions between different steady states [Primeau, 1998, 884 2002], and, most recently, to the existence of global 885 bifurcations [Meacham, 2000; Chang et al., 2001; Nadiga 886 and Luce, 2001]. Chang et al. [2001] and Simonnet et al. 887 [2003b] provide fairly convincing numerical evidence for 888 the existence of a so-called homoclinic bifurcation in OG 889 models. For high forcing their upper branch, high-energy 890 time-dependent solutions are destabilized through this glob- 891 al bifurcation and give rise to a lower branch, low-energy 892 state. Nadiga and Luce [2001] analyzed in detail such a 893 global bifurcation in a 1.5-layer QG model and associated 894 the transition to aperiodic behavior in it with the so-called 895 [Shilnikov, 1965] phenomenon of successive homoclinic 896

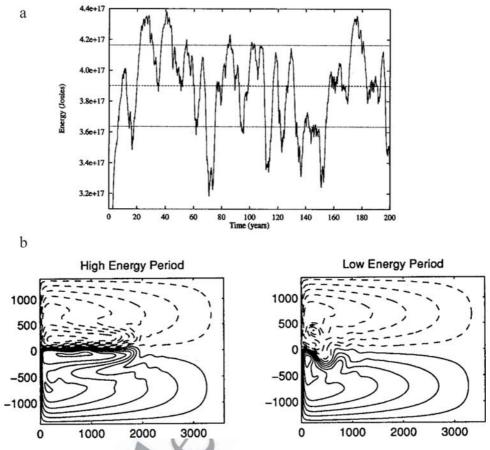

Figure 5. (a) Typical variation of the kinetic energy of the double-gyre flow in a large basin for the high-forcing or low-dissipation regime.(b) Typical patterns of the stream function for the (left) high-energy state and the (right)low-energy state [from *McCalpin and Haidvogel*, 1996].

bifurcations [Ghil and Childress, 1987; Guckenheimer and Holmes, 1990].

[62] To summarize, many of the idealized models used so far to study the low-frequency behavior of the wind-driven double-gyre circulation exhibit very similar bifurcation behavior. This behavior helps in understanding the complex dynamics in the high-forcing, low-dissipation regime that best describes the observed ocean circulation, insofar as basin-scale, subannual, and interannual variability is concerned. The dynamical origin of the ultralow-frequency, decadal, and interdecadal variability is still under dispute. This variability appears to be associated with alternations between two or three states that are characterized by different basin-scale energy levels and jet penetration scales, but the mechanism of the transitions between these states requires further clarification.

[63] In this section we consider two kinds of asymmetries: (1) the forcing by a wind stress field that leads to a single-gyre circulation and (2) the asymmetry due to the coastal geometry of the North Atlantic basin.

2.5.1. Forcing Asymmetries

[64] We saw in section 2.3.1 that, in a QG model, a purely zonal wind stress with a meridional profile that is

symmetric about the mid basin axis of a rectangular basin 921 leads to a perfect pitchfork bifurcation. As soon as the wind 922 stress has the slightest asymmetric component, this pitch- 923 fork bifurcation breaks up and the branches become dis- 924 connected [*Jiang et al.*, 1995]. As one proceeds toward a 925 single-gyre situation, one of the two disconnected branches 926 totally disappears [*Ierley and Sheremet*, 1995; *Kamenkovich* 927 et al., 1995].

[65] Sheremet et al. [1997] plotted the bifurcation dia-929 gram for the single-gyre problem as the maximum nondi-930 mensional transport Q versus the Reynolds number Re (see 931 Box 3/Appendix A3). For small Re the unique stable branch 932 tends to the Munk-Sverdrup solution [Sverdrup, 1947; 933 Munk, 1950]. Multiple equilibria appear through emergence 934 of two back-to-back saddle-node bifurcations, as Re 935 increases. Pedlosky [1996] refers to the high Q values and 936 associated strong recirculation on the upper branch of this 937 S-shaped bifurcation curve as "inertial runaway."

[66] Sheremet et al. [1997] found five classes of internal 939 modes in single-gyre flows. The first class is the Rossby 940 basin modes, of which several can exhibit positive growth 941 rates for sufficiently large Re. Wall-trapped modes are 942 associated with boundary layer instability. There are two 943 types of modes that are mainly confined to the inertial 944 recirculation gyres, stationary recirculation modes and os- 945

cillatory recirculation zone modes. A fifth class of modes arises from a resonant interaction between the recirculation gyre and certain Rossby basin modes. A number of eddies on the southern flank of the recirculation gyre are prominent in this mode's spatial pattern. Chang et al. [2001] clarified the connection between this resonance mode of Sheremet et al. [1997] in the single-gyre problem and the gyre mode of Speich et al. [1995] in the double-gyre problem.

[67] Berloff and Meacham [1997, 1998] studied in detail the time-dependent behavior of the single-gyre flows. The connection between this behavior and the bifurcation structures and instability modes is, however, not as complete as for the double-gyre problem. The connection between the oscillatory modes in the single- and double-gyre flows would also bear a more systematic investigation than the tentative parallels drawn so far.

2.5.2. Geometric Asymmetries

[68] Dijkstra and Molemaker [1999] and Schmeits and Dijkstra [2000] performed numerical bifurcation studies for realistic basin geometry and wind stress forcing. Dijkstra and Molemaker [1999] have shown in a β plane shallow water model that the perturbed pitchfork bifurcation found in the double-gyre flows within a rectangular basin remains robust, given a more realistic geometry. Schmeits and Dijkstra [2000] considered the North Atlantic basin over the domain $(5^{\circ}-85^{\circ}W, 10^{\circ}-65^{\circ}N)$ within a barotropic shallow water model on the sphere, with constant depth D = 1000 m. The bifurcation diagram obtained at a horizontal resolution of 0.5° is shown in Figure 6a, by plotting the maximum dimensional northward transport versus the Ekman number $E = A_H/(2\Omega r_0^2)$.

[69] Figure 6a demonstrates that a more realistic continental geometry does not alter the existence of a perturbed pitchfork bifurcation. Two solution branches are found for $E < 2.2 \times 10^{-7}$, both of which are unstable. A solution on the lower branch is shown as a contour plot of layer thickness anomalies for $E = 1.6 \times 10^{-7}$ in Figure 6b. It displays the double-gyre circulation, typical for the North Atlantic Ocean, with a "deflected" Gulf Stream which separates too far north compared to the observed. The southern recirculation in this solution is weak, and at this value of E the transport is about 46 Sv, considerably smaller than observed (see section 3.1).

[70] The upper branch exists only for $E < 2.2 \times 10^{-7}$. The solution at $E = 1.6 \times 10^{-7}$ (Figure 6c) shows a "separated" Gulf Stream that actually seems to separate twice, once near Cape Hatteras and also off the Great Banks. The circulation patterns outside the western boundary current and the recirculation regions are very similar, so that the multiple equilibria are related to the different separation behavior of the Gulf Stream. On the upper branch the recirculation off Cape Hatteras is much more vigorous, and the northward transport equals or exceeds the

[71] On the lower branch in Figure 6a a Hopf bifurcation 1000 1001 occurs at $E = 2.5 \times 10^{-7}$ and is marked with H_1 . The linear 1002 oscillatory instability is shown at two phases, one-quarter 1003 period apart, in Figures 6d and 6e. The maximum amplitude of the mode is located near the axis of the western boundary 1004 current, and it propagates upstream. The perturbation has a 1005 period of 6 months and a wavelength of about 550 km; its 1006 cross-stream components cause the Gulf Stream to meander. 1007

[72] Schmeits and Dijkstra [2000] computed a regime 1008 diagram that separates steady from oscillatory behavior and 1009 has the layer thickness D as the second parameter. The 1010 spatial pattern of the neutral mode does not change much as 1011 D is varied over a range of about 100 m, but the period of 1012 the subannual oscillation increases from 6 to 11 months. 1013 This range of periods brackets the 9-month period in 1014 meandering intensity found by Lee and Cornillon [1995] 1015 in SST observations.

2.6. Relevance to the North Atlantic Circulation

[73] A hierarchy of equivalent-barotropic models shows 1018 that multiple mean flows seem dynamically possible for the 1019 North Atlantic wind-driven circulation. The existence of 1020 multiple mean Gulf Stream paths can be traced back to its 1021 dynamic origin: a symmetry-breaking pitchfork bifurcation 1022 within the equivalent-barotropic OG double-gyre flow in a 1023 rectangular basin. Numerical bifurcation methods have 1024 helped demonstrate the persistence of qualitative behavior 1025 across this hierarchy of models from QG to shallow water 1026 and from rectangular to realistic geometry. The two stable 1027 equilibria in both the QG and shallow water models can be 1028 dubbed the "jet-up" and "jet-down" solutions. They de- 1029 form into solutions with different separation behavior of the 1030 Gulf Stream near the North American coast in shallow 1031 water models with more realistic basin geometry.

[74] One underlying optimistic idea in our approach is 1033 that stationary equilibria do play an important role in 1034 determining the time-mean state of the real system. The 1035 reasoning follows that outlined by Ghil and Childress 1036 [1987] for a similar application of dynamical systems 1037 methods to large-scale atmospheric flows. Steady states 1038 may be unstable to one or a few modes; these define 1039 directions in state space along which trajectories diverge 1040 from the unstable steady state. However, they are still stable 1041 in most other directions, along which trajectories are 1042 attracted toward the given steady state. In this way, multiple 1043 steady states act as "ghost equilibria" to guide the trajectory 1044 of a time-dependent model. If this is indeed the case, one 1045 may be able to find the signature of multiple equilibria in 1046 eddy-resolving ocean models and observations, as discussed 1047 already in section 2.4 in the context of ultralow-frequency 1048 variability.

[75] Schmeits and Dijkstra [2001] detected transitions 1050 between two different Gulf Stream paths in output from a 1051 high-resolution simulation of the Parallel Ocean Climate 1052 Model (POCM) [Stammer et al., 1996]. One quasi-steady 1053 state turned out to be very similar to the deflected Gulf 1054 Stream solution (Figure 6b) in the equivalent-barotropic 1055 shallow water model on the sphere, while the other one 1056 resembles to a large extent the same model's separated Gulf 1057 Stream solution (Figure 6c). The transitions occur on 1058 interannual timescales, and the distinct signatures of the 1059 two Gulf Stream paths are visible in the deeper layers of the 1060

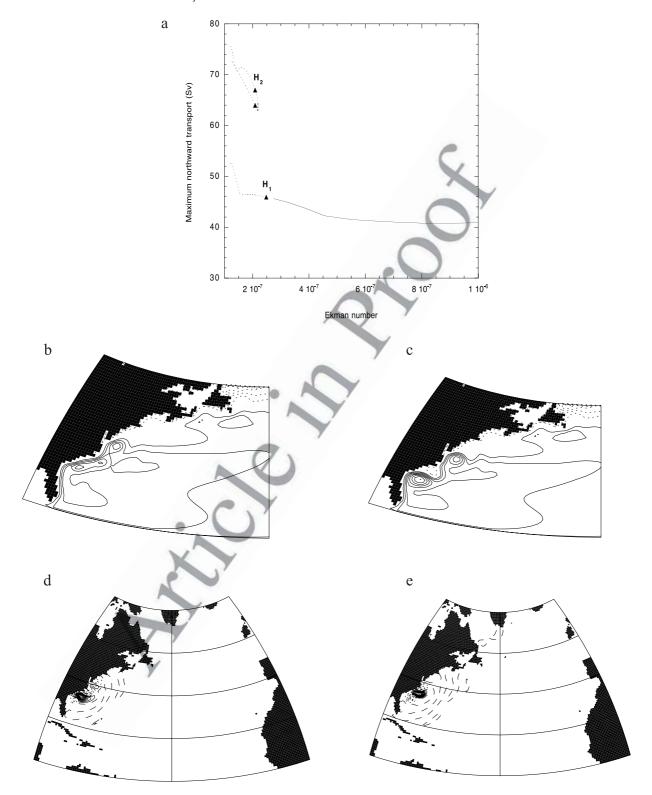

Figure 6. (a) Bifurcation diagram for a barotropic shallow water model of the North Atlantic with the Ekman number as control parameter. The nondimensional Ekman number, $E = A_H/(2\Omega r_0^2)$, where Ω and r_0 are the angular frequency and radius of the Earth, respectively, is plotted on the abscissa, while the maximum northward volume transport is plotted on the ordinate. Solid (dotted) branches indicate stable (unstable) steady states, as usual, whereas the Hopf bifurcation points are indicated by triangles. (b and c) Contour plots of the layer thickness anomaly for two coexisting unstable solutions at $E = 1.6 \times 10^{-7}$. The contour levels are scaled with respect to the maximum value of the field; only a small part of the domain, $(85^{\circ}W-45^{\circ}W, 24^{\circ}N-51^{\circ}N)$, is shown: "deflected" (Figure 5b) and "separated" Gulf Stream (Figure 5c). (d and e) Spatial pattern of the linear oscillatory mode at H_1 in Figure 6a. Layer thickness anomalies for the real (Figure 6d) and imaginary part (Figure 6e) are shown. From *Schmeits and Dijkstra* [2000].

1145

1155

1061 POCM temperature field. This indicates that the transition 1062 between the two patterns is a barotropically controlled 1063 phenomenon, as predicted by the simple and intermediate 1064 model studies (see Dijkstra and Katsman [1997], Ghil et al. 1065 [2002a], and section 2.3.1). Thus the multiple equilibria of 1066 the intermediate models seem to persist in a state-of-the-art 1067 GCM such as POCM. Bane and Dewar [1988] have also 1068 found bimodal behavior in the Gulf Stream path off South 1069 Carolina during the Gulf Stream Deflection and Meander 1070 Energetics Experiment (1981–1982); transitions between a 1071 weakly and a strongly deflected state seem to occur on a 1072 subannual timescale.

[76] For the barotropic component of the North Atlantic 1074 circulation the modes of variability that arise as oscillatory 1075 instabilities are easily identified across our hierarchy of the 1076 QG and shallow water models. In the range of parameters 1077 studied, only two classes of modes contribute to the 1078 variability: the barotropic Rossby basin modes and the gyre 1079 modes. Their timescale and even their spatial pattern depend 1080 only weakly on the continental geometry and details of the 1081 wind stress. An important reason for this robustness can be 1082 found in the rectangular geometry studies, where the gyre 1083 modes are strongly localized within the high-shear regions 1084 of the recirculation gyre; this feature changes but little 1085 across the hierarchy of models. The basin modes have a 1086 much broader footprint but still seem to be affected only 1087 moderately by the changes in basic flow and detailed basin 1088 geometry. In the baroclinic case other modes, associated 1089 with baroclinic instability of the current system, become 1090 important.

[77] Applying dynamical systems theory to the temporal 1092 variability of the climate system requires a similarly opti-1093 mistic assumption, to wit, that each mode of temporal 1094 variability can be traced back to a specific Hopf bifurcation. 1095 This bifurcation can then be studied in isolation, and the 1096 physics of the mode can be clarified in detail. Subsequent 1097 modifications in a model that incorporates a more complete 1098 set of physical processes and spatial detail are then traced by 1099 studying time-dependent solutions of the latter model. The 1100 barotropic basin mode, with its subannual timescale, is 1101 present throughout the whole model hierarchy, and one 1102 thus may be able to detect its signal in output from eddy-1103 resolving models and observations.

[78] Preliminary comparison of some of the models' 1105 interannual variability with observed spatiotemporal SST 1106 patterns in the North Atlantic [Moron et al., 1998] is quite 1107 encouraging. The 7- to 8-year mode in the observations is 1108 strongest in the northwestern part of the subtropical gyre, 1109 with a weaker center of opposite polarity in the subpolar 1110 gyre and substantial weakening of features toward the east 1111 and the south. It thus seems to have noteworthy similarities 1112 with the interannual gyre mode [Simonnet et al., 2003a, 1113 2003b].

[79] Multichannel SSA (M-SSA) [Plaut and Vautard, 1115 1994; Ghil et al., 2002b]) was applied to sea surface height 1116 and SST observations in the Gulf Stream region to deter-1117 mine dominant variability patterns. Schmeits and Dijkstra 1118 [2000] isolated a propagating mode of variability with a timescale close to 9 months. This timescale corresponds to 1119 the dominant variability in the Gulf Stream's meandering 1120 intensity [Lee and Cornillon, 1995].

[80] Simonnet et al. [2003b] performed a 100-year sim- 1122 ulation of a 2.5-layer shallow water model in a North 1123 Atlantic-shaped domain and compared the results with 1124 the actual variability of the Gulf Stream axis, as inferred 1125 from COADS (see Figure 7). The meridional excursions of 1126 the jet axis along the 50°W meridian appear in Figure 7a. 1127 The power spectrum of the interannual portion of this 1128 variability is plotted in Figure 7b, while Figure 7c shows 1129 an interannual power spectrum of model-simulation results. 1130 The two spectra are strikingly similar in structure: Each 1131 exhibits four peaks between 1 and 10 years in period, whose 1132 spacing in frequency and relative sizes is roughly the same. 1133 The longest period is about 7 years in both spectra, close to 1134 the 6 years obtained by Speich et al. [1995], as well as to the 1135 observed 7.7-year peak in Figure 1b [see also Moron et al., 1136 1998].

[81] The main results of this section are summarized in 1138 Table 3. It appears that both the subannual mode in the 1139 observations, with a period of about 9 months, and the 1140 interannual one, with a period of about 7-8 years [Da Costa 1141 and Colin de Verdière, 2004] can be explained by the model 1142 hierarchy results reviewed herein.

3. THERMOHALINE CIRCULATION

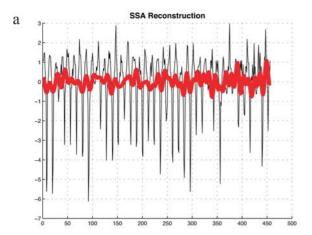

[82] The buoyancy fluxes at the ocean surface give rise to 1146 gradients in temperature and salinity, which produce, in 1147 turn, density gradients. These gradients are, overall, sharper 1148 in the vertical than in the horizontal and are associated 1149 therefore with an overturning or thermohaline circulation 1150 (THC). Since the Atlantic is the most active basin in the 1151 global ocean circulation, the sensitivity of its THC to 1152 perturbations and to changes in forcing is a topic of active 1153 research. 1154

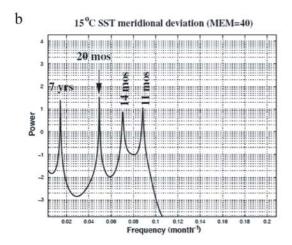

3.1. Observations

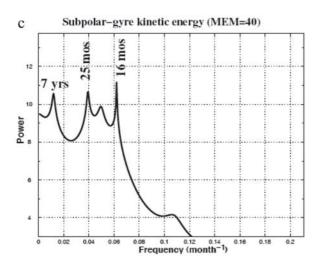

[83] The downward annual mean heat flux into the ocean 1156 [e.g., Oberhuber, 1988] indicates that, on average, there is 1157 net heat input near the equator and net heat loss at higher 1158 latitudes. In the North Atlantic and North Pacific, high 1159 losses to the atmosphere (exceeding 150 W m⁻²) occur 1160 near the western boundary currents and their eastward 1161 extensions.

[84] The freshwater flux indicates high-precipitation 1163 areas near the equator that are associated with the Intertrop- 1164 ical Convergence Zone, especially throughout the tropical 1165 Indo-Pacific Ocean; the highest values (exceeding 200 mm 1166 month⁻¹) occur in the western tropical Pacific and the South 1167 Pacific Convergence Zone. In the North Atlantic and North 1168 Pacific basins the subtropical gyres show net excess of 1169 evaporation over precipitation, with values of 100 mm 1170 month⁻¹ and more off the west coast of Africa, while the 1171 subpolar gyres show a net excess of precipitation. The 1172 zonally averaged profile of the freshwater flux does not 1173 exhibit any strong asymmetry with respect to the equator, 1174 1175 although the data from different sources show substantial 1176 variations [*Zaucker et al.*, 1994].

1177 [85] The heat and freshwater fluxes together determine 1178 the surface buoyancy flux that acts to force the oceans' 1179 THC. There are also direct cryospheric influences through 1180 the presence of sea ice and icebergs. Because sea ice has a 1181 considerably lower salt content than the ocean water on 1182 which it grows, there is a net salt flux into the ocean. When

icebergs melt, the surface of the ocean is enriched with 1183 freshwater, decreasing its salinity.

- [86] There are other, more localized fluxes that may be 1185 important, such as river outflow, but these are not considered further here. The transport of salt and heat by the THC 1187 is advection-dominated, since lateral mixing is small overall, while vertical mixing is, for the most part, restricted to 1189 the upper ocean and near rough topography. Because of the 1190 limited amount of mixing the concept of individual water 1191 masses, which are separated from each other, has been 1192 introduced in classical oceanography [Sverdrup et al., 1193 1946]. Such a water mass is often characterized by its 1194 (potential) temperature and salinity at formation, although 1195 recent work has shown that probability density functions for 1196 related variables, such as tracer transit times, are, in fact, 1197 broader than previously thought [Holzer and Hall, 2000]. 1198
- [87] The North Atlantic Deep Water, mentioned in section 1.2, forms in the subpolar North Atlantic and can be 1200 identified as the water having a potential temperature θ of 1201 about 3°C in a recently obtained north-south section [Talley, 1202 1999] from the World Ocean Circulation Experiment 1203 (WOCE) at 24°W (Figure 8). The Antarctic Bottom Water 1204 (AABW) forms mainly in the Weddell Sea and enters the 1205 Atlantic from the south. It is even denser than NADW, 1206 having a potential temperature of about 0.5°C, and thus 1207 penetrates below the latter (Figure 8). The outflow of 1208 NADW from the Atlantic is, in addition to the deep inflow 1209 of AABW, also compensated by surface inflow from the 1210 Indian Ocean and through the Drake Passage [Schmitz, 1211 1995]. The layering of these water masses produces strong 1212 vertical stratification in the Atlantic.
- [88] The total meridional heat transport due to the ocean 1214 circulation is difficult to measure directly. It can, however, 1215

Figure 7. (a) Time evolution of the mean monthly meridional displacement of the position of the sea surface temperature (SST) isotherm $T = 15^{\circ}$ C away from the latitude 41°N at 50°W, January 1960 to December 1997. The SST field has been spatially interpolated by cubic splines in the interval 30°N-60°N in order to compute the deviation from its mean latitude position; the data are derived from the Comprehensive Ocean-Atmosphere Data Set. Both the raw data (thin line) and data adaptively lowpass-filtered signal (bold line) are shown; the latter is based on singular-spectrum analysis (SSA) with a 16-year window, which retains the eight modes with lowest frequencies, after filtering out the annual and subannual signals. (b) Maximum entropy spectrum of the low-passfiltered time series shown in Figure 7a, given in log linear coordinates. The order of the maximum entropy method (MEM) is 40; only the powers of 10 are indicated on the ordinate. (c) Results from a 100-year simulation with a 2.5layer shallow water model within a basin that approximates the North Atlantic in size and shape, using an idealized wind stress. Maximum entropy spectrum of the subpolargyre kinetic energy is shown. The SSA window length is 20 years, the number of modes retained is 12, and the MEM order is 40. Coordinates and labeling are the same as in Figure 7b. From Simonnet et al. [2005].

1216 be inferred from estimates of the atmospheric transports and 1217 constraints on the global energy balance. It is thus estimated 1218 that the ocean and atmospheric circulation each carry about 1219 half of the total poleward heat transport. In the Atlantic the 1220 meridional transport is northward over the whole basin 1221 because of a strongly asymmetric meridional overturning 1222 circulation; in situ hydrographic measurements yield 1.2 PW 1223 at 24°N [Hall and Bryden, 1982]. In the Pacific the heat 1224 transport is believed to be mainly through wind-driven 1225 currents, with a local estimate of 0.8 PW at 24°N [Bryden 1226 et al., 1991]. The heat transport in the Indian Ocean is 1227 mainly southward and is estimated to be 0.4 PW at 30°S 1228 [Robbins and Toole, 1997; Ganachaud and Wunsch, 2000]. 1229 Held [2001] has provided interesting theoretical arguments for the partition between atmospheric and oceanic transport 1231 in low latitudes.

1232 [89] Estimates of freshwater transport through the ocean 1233 are even harder to obtain from direct observations. There is 1234 net precipitation in the tropical, middle-, and high-latitude 1235 regions and net evaporation in the subtropics. This leads to a 1236 net buoyancy flux at the ocean surface that is nearly 1237 symmetric about the equator with positive extrema at the 1238 equator and negative ones at about 25°N. The ocean must 1239 transport freshwater into the evaporative regions and away 1240 from precipitation regions for compensation. Wijffels et al. 1241 [1992] present estimates of this freshwater transport and 1242 demonstrate the importance of the Bering Strait through 1243 flow. The Pacific experiences net precipitation overall, with

much of this gain occurring between 0° and 15°N, the 1244 location of the Intertropical Convergence Zone. On the 1245 other hand, the Atlantic and Indian oceans are evapora- 1246 tion-dominated basins. Over the whole North Atlantic, there 1247 is southward transport of freshwater with a maximum of 1248 about 1 Sv at 45°N [Schmitt et al., 1989].

[90] The THC varies on timescales of decades or longer, 1250 as far as we can tell from instrumental and paleoclimatic 1251 data [Martinson et al., 1995]. For example, sediment core 1252 records in the North Atlantic indicate that changes in 1253 deepwater temperatures occurred during Dansgaard- 1254 Oeschger oscillations and were, in all likelihood, related 1255 to changes in NADW and AABW formation. Few contin- 1256 uous instrumental records with any spatial resolution and 1257 useful accuracy exist, however, on these timescales. The 1258 largest number of such records is available for the North 1259 Atlantic Ocean. These records include measurements of the 1260 overflow from the Nordic Seas [Dickson and Brown, 1994], 1261 convective activity [Schlösser et al., 1991], repeated ship 1262 measurements over the same section [Bryden et al., 1996], 1263 and ocean weather stations [Sy et al., 1997; Joyce and 1264 *Robbins*, 1995].

[91] There exist, however, fairly long SST data sets, such 1266 as COADS, from which near-surface patterns of variability 1267 on interannual to decadal timescales can be inferred; these 1268 patterns may be related to THC variability. *Deser and* 1269 *Blackmon* [1993] have used empirical orthogonal function 1270 (EOF) analysis [*Preisendorfer*, 1988] to determine the 1271

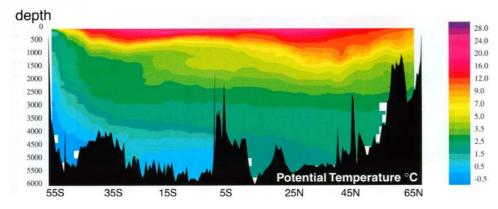

Figure 8. Potential temperature (θ) section at 24°W in the Atlantic. North Atlantic Deep Water (NADW) is characterized by $\theta \approx 3$ °C, while Antarctic Bottom Water (AABW) is characterized by $\theta \approx 0.5$ °C. From *Talley* [1999].

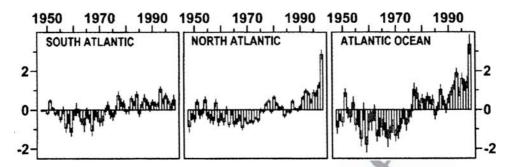

Figure 9. Time series of ocean heat content (10^{22}J) in the upper 300 m of the Atlantic for the half century 1948–1998. From *Levitus et al.* [2000].

1272 dominant spatial variability patterns of SST in the North 1273 Atlantic. The first EOF displays a basin-scale SST pattern of 1274 essentially one sign; the strongest anomalies are equal to 1275 about 1°C and occur in the Gulf Stream region. The time 1276 series that represents the "amplitude" of this pattern, i.e., 1277 the leading principal component, indicates that in the first 1278 half of the 20th century this region was colder than normal, 1279 whereas during the century's second half it has been 1280 warmer.

[92] Kushnir's [1994] statistical analysis of SST and sea level pressure data indicates that THC variations are in- volved in the North Atlantic's interdecadal variability. The least dominant pattern of variability he found is basin-wide, less strongest in winter, and shows maxima in the vicinity of leeland and the Labrador Sea. The high-amplitude SST variability in these areas has been linked to variations in less convective activity. It is known that deep convection was interrupted in the Labrador Sea over the time interval lego 1968–1982 because of the presence of the so-called Great Salinity Anomaly [Dickson et al., 1988]. A low-salinity lego patch of water traveled along a cyclonic path south of Greenland and finally ended up in the North Atlantic, influencing the velocity field along its way.

1295 [93] *Moron et al.*'s [1998] spatiotemporal analysis of the 1296 global SST record for the 20th century used M-SSA and 1297 showed that global warming in the early part of the century 1298 started in the subpolar North Atlantic. The same is true of 1299 the current cooling trend that started in the early 1970s and 1300 is now shared by most of the North Atlantic and much of the 1301 North Pacific; trends in this work were defined by subtract-1302 ing interannual and interdecadal oscillatory modes.

1303 [94] The change in the ocean's heat content over the 1304 upper 300 m, as compiled by *Levitus et al.* [2000], is plotted 1305 in Figure 9 for the North, South, and whole Atlantic over 1306 the last half century. Figure 9 clearly shows the warming 1307 trend of the upper ocean over the last century. For compar-1308 ison, the seasonal cycle of upper ocean heat content for the 1309 North Atlantic has an amplitude of about 5.6×10^{22} J 1310 [*Levitus et al.*, 2000], while the interdecadal range is of 1311 about 3.8×10^{22} J. The difference patterns in the North 1312 Atlantic's heat content between the pentads 1988-1992 and 1313 1970-1974 for two reference depths (300 m and 3000 m, 1314 not shown) are strongly aligned with the Gulf Stream: The 1315 heat content decreases north of it and increases south of it.

[95] The processes that control these changes on inter- 1316 decadal timescales are poorly understood so far. To study 1317 possible modes of variation of the THC, we review a 1318 hierarchy of models.

3.2. Box Models and Their Multiple Equilibria

[96] The North Atlantic experiences heat input in low 1321 latitudes and heat loss at high latitudes; this induces a 1322 poleward density gradient. On the other hand, there is 1323 substantial evaporation in low latitudes, which increases 1324 the salinity of the water there and hence its density. The 1325 surface freshwater flux and heat flux have opposite effects 1326 on the large-scale ocean circulation: What happens as the 1327 relative importance of the two surface fluxes varies?

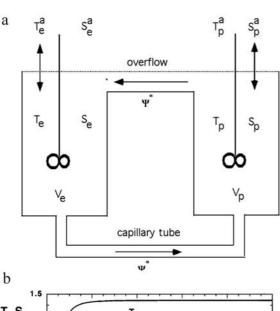

[97] Stommel [1961] proposed a minimal model that can 1329 be used to study this problem in its simplest form. Two 1330 vessels, called boxes, have volumes V_p and V_e and contain 1331 well-mixed water of temperature and salinity (T_e, S_e) and 1332 (T_p, S_p) ; the subscripts "e" and "p" indicate the equatorial 1333 and polar box, respectively. The boxes are connected at the 1334 surface by an overflow region and at the bottom by a 1335 capillary tube to keep the volume in each box constant 1336 (Figure 10a). The flow rate Ψ is directed from high to low 1337 pressure and is taken to be directly proportional to the 1338 density difference between the two boxes; a linear equation 1339 of state is also assumed. The exchange of properties does 1340 not depend on the sign of Ψ , because it only matters that 1341 properties from one box are transported to the other box; the 1342 pathway, either through the overflow or through the capil- 1343 lary, is thus of no importance because mass is conserved. 1344

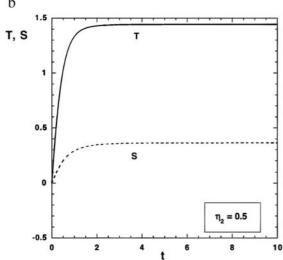

[98] Exchange of heat and salt between each box and the 1345 atmosphere above is modeled through relaxation to a 1346 prescribed surface temperature and salinity (T^a , S^a). The 1347 freshwater flux is usually converted into an equivalent salt 1348 flux of the opposite sign. Under appropriate scaling the 1349 dimensionless equations become 1350

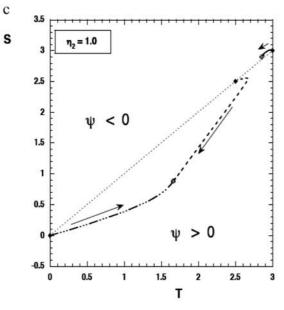

$$\frac{dT}{dt} = \eta_1 - T(1 + |T - S|), \tag{8a}$$

$$\frac{dS}{dt} = \eta_2 - S(\eta_3 + \mid T - S \mid); \tag{8b}$$

1354 here T and S monitor the equatorial-to-pole temperature and 1355 salinity difference, $\Psi = T - S$ is the flow rate, and t 1356 indicates time. The parameters η_1 and η_2 represent the 1357 strength of the thermal and freshwater forcing, respectively,

and η_3 is the ratio of the thermal-versus-freshwater restoring 1358 timescales, as discussed below. 1359

[99] Starting from the initial state (T = 0, S = 0), the time 1360 evolution of a solution T = T(t), S = S(t) of (8) is shown in 1361 Figure 10b for the case $\eta_1 = 3.0$, $\eta_2 = 0.5$ and $\eta_3 = 0.3$. In 1362 this case the freshwater forcing is relatively small, and the 1363 flow evolves to a steady state with sinking in the north, 1364 called a thermally dominated or TH state, since $\Psi = T - 1365$ S > 0. It turns out that for these parameter values the 1366 same steady state is reached for all initial states; that is, 1367 the TH state is the unique stable equilibrium for this set 1368 of parameters.

[100] We now proceed to investigate how this asymptotic 1370 behavior of the solutions changes as the parameters are 1371 changed. To this effect we increase the salinity flux forcing 1372 and plot in Figure 10c three trajectories in the (T, S) plane 1373 for the case $\eta_2 = 1.0$, while η_1 and η_3 have the same values 1374 as before. The trajectories starting at the initial states (0, 0) 1375 and (2.5, 2.5) approach a steady state with sinking in the 1376 polar box, similar to the one pictured in Figure 10b. 1377 However, the trajectory starting at (3.0, 3.0) approaches a 1378 steady state with sinking in the equatorial box, called a 1379 salinity-dominated or SA state, since $\Psi = T - S < 0$. In this 1380 case, there are multiple stable equilibria for the same 1381 forcing.

[101] Thus TH and SA steady states can coexist in this 1383 model if the salinity flux is large enough. Is there a limiting 1384 value of η_2 at which these multiple equilibria appear? This 1385 question motivates us to look at the steady state equations 1386 and solve directly for the equilibria as a function of the 1387 parameters.

[102] We show typical results in Figure 11a, where Ψ is 1389 plotted versus η_2 for $\eta_1 = 3.0$ and $\eta_3 = 0.3$. The two 1390 eigenvalues $\sigma_{1,2}$ of the Jacobian matrix of (8) control the 1391 stability of each steady state along the three branches and 1392 are both real throughout. We indicate the positive or 1393 negative sign of the two eigenvalues along each branch. 1394 For values of η_2 up to the point L_1 , only the TH solution is 1395 linearly stable, while for values beyond L_2 , only the SA 1396 solution is stable. On the branch that connects the solutions 1397 at L_1 and L_2 , one of the eigenvalues is positive and hence 1398 this solution is unstable. Between the points L_1 and L_2 the 1399 TH and SA solutions coexist and are both stable. For 1400

Figure 10. (a) Sketch of the two-box model setup of *Stommel* [1961]. Two reservoirs contain well-mixed water and are connected through an overflow and a capillary tube. The circulation is driven by density gradients between the boxes; these are due to heat and salinity fluxes at the surface. The direction of flow between boxes corresponds to a thermally dominated solution, with $\Psi > 0$ and implied sinking in the polar and rising in the equatorial box. (b) Evolution of T(t) and S(t) for a solution with zero initial data, T(0) = S(0) = 0, $\eta_1 = 3.0$, $\eta_2 = 0.5$, and $\eta_3 = 0.3$. (c) Trajectories in the (T, S) plane for three different initial states (shown by diamonds) that can lead to two different steady states (shown by crosses). Here $\eta_2 = 1.0$, while $\eta_1 = 3.0$ and $\eta_3 = 0.3$, as in Figure 10b.

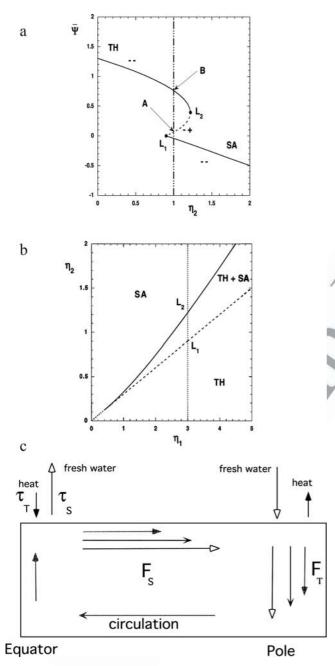

Figure 11. (a) Bifurcation diagram for the flow Ψ versus the salinity flux η_2 , with fixed $\eta_1 = 3.0$ and $\eta_3 = 0.3$. The labels TH and SA indicate the thermally driven and salinity driven solutions, respectively. (b) Regime diagram, showing the locus of the saddle-node bifurcations L_1 and L_2 of Figure 11a in the (η_1, η_2) parameter plane for $\eta_3 = 0.3$. (c) Sketch of the physics of the salt-advection feedback. The mean circulation is indicated by the normal pointed arrows. The upper ocean temperature and salinity fields can be inferred from the surface forcing of heat and freshwater. A perturbation which strengthens the circulation leads to a poleward salt transport (F_S) , which causes an amplification (open-headed arrows); it also leads to increased heat transport (F_T) , which damps the original perturbation (solid-headed arrows).

instance, when the point A (Figure 11) is taken as an initial 1401 state, the trajectory finally ends up at state B.

[103] The saddle-node bifurcations L_1 and L_2 (see Box 2/ 1403 Appendix A2) represent exact bounds for the region of 1404 multiple equilibria for the given values of η_1 and η_3 . When 1405 the position of these points is determined for other values of 1406 η_1 , at fixed η_3 , the area in the (η_1, η_2) parameter plane where 1407 both TH and SA solutions occur is bounded by two smooth 1408 curves (Figure 11b). To the right of the L_1 curve the polarsinking (TH) solution is unique, whereas to the left of the L_2 1410 curve the equatorial-sinking (SA) solution is unique. Between 1411 the two curves the TH and SA solutions coexist and are both 1412 stable. Such a plot is referred to as a regime diagram: It helps 1413 in understanding the difference between Figures 10b and 10c. 1414 For $\eta_1 = 3.0$ and $\eta_2 = 0.5$, as in Figure 10b, the system always 1415 tends to the unique stable TH solution. For $\eta_1 = 3.0$ and $\eta_2 = 1416$ 1.0 the system is in the regime in which stable TH and SA 1417 states coexist, and hence trajectories with different initial 1418 states may approach either steady state.

[104] The multiple equilibria arise because of a positive 1420 feedback between the flow and the salt transport, called the 1421 salt-advection feedback [Walin, 1985; Welander, 1986; 1422 Marotzke et al., 1988; Cessi and Young, 1992; Quon and 1423 Ghil, 1992; Thual and McWilliams, 1992; Vellinga, 1996; 1424 Dijkstra and Molemaker, 1997]. Figure 11c shows a zonally 1425 averaged overturning circulation that is thermally driven. 1426 The surface forcing salts and warms the low-latitude region, 1427 while it freshens and cools the high-latitude region. If the 1428 circulation strengthens, then more salt is transported pole- 1429 ward; this is indicated by the arrows labeled F_S in 1430 Figure 11c. This enhanced salt transport will further increase 1431 the density in high latitudes and consequently amplify the 1432 original perturbation of the circulation, because of increased 1433 deepwater formation there. The strengthening of the circulation also transports more heat northward, as indicated by the 1435 arrows labeled F_T ; this will weaken the flow by lowering the 1436 density in high latitudes. Heat transport therefore provides a 1437 negative feedback on the circulation. Multiple equilibria 1438 occur when the positive feedback wins out.

[105] In addition to the salt-advection feedback the exis- 1440 tence of multiple steady states in the THC also depends 1441 crucially on the different response times of ocean salinity τ_S 1442 and temperature τ_T to changes in surface forcing. The 1443 atmosphere exerts quite a strong control on SST anomalies, 1444 but ocean water salinity does not affect the freshwater flux 1445 at all. In general, distinct surface boundary conditions for 1446 temperature and salinity are referred to as mixed boundary 1447 conditions [Haney, 1971; Welander, 1986; Tziperman et al., 1448 1994]. The extreme case is to prescribe surface temperature 1449 on the one hand and surface freshwater flux on the other. In 1450 this case the response time τ_T is zero, while τ_S is not. The 1451 parameter η_3 in (8b) is the ratio of τ_T and τ_S .

[106] Welander [1986] and Thual and McWilliams [1992] 1453 have studied an extension of the [Stommel, 1961] box 1454 model to include two polar boxes on either side of the 1455 equatorial one. When the forcing is symmetric with respect 1456 to the equator, the equations possess a reflection symmetry 1457 that makes north and south indistinguishable in the model. 1458

1553

1459 The presence of this symmetry has a striking influence on 1460 the structure of the steady solutions and their stability.

[107] For small salt-forcing strength a single symmetric 1462 solution exists; it is of TH type, with upwelling at the 1463 equator and sinking at both poles. This solution (not shown) can be viewed as being the sum of two TH solutions of the 1465 Stommel model that mirror each other. It is a two-cell 1466 solution, with one overturning cell in each hemisphere. 1467 When the salt forcing is large enough, a symmetry-breaking 1468 pitchfork bifurcation occurs (see Box 2/Appendix A2). The 1469 TH solution becomes unstable, and two asymmetric solu-1470 tions, labeled NPP and SPP, appear. The NPP solution has a 1471 single, pole-to-pole overturning cell, with no equatorial 1472 upwelling nor downwelling: Downwelling occurs in the 1473 northern box, and upwelling occurs in the southern box. The 1474 SPP solution is just the reflection of the NPP solution in the 1475 equator, with downwelling in the southern and upwelling in 1476 the northern box.

[108] Box models have also been used to illustrate a 1477 1478 convective feedback that may be responsible for multiple 1479 equilibria [Welander, 1982; Lenderink and Haarsma, 1994]. 1480 Consider a box model with two vertically stacked boxes: One represents the surface ocean that exchanges heat and 1482 freshwater with the overlying atmosphere, and the other box 1483 is the deep ocean. Convective exchange between these 1484 boxes occurs if the surface water becomes denser than the 1485 deep water; the latter is assumed to possess constant 1486 temperature and salinity, as the deep-ocean box is much 1487 larger than the near-surface box.

[109] Suppose, initially, that the upper ocean is less dense 1489 than the deep ocean and no convective exchange occurs, but the upper box is being cooled and freshened through atmospheric exchange. When the situation of colder and fresher 1492 water above warmer and saltier water becomes marginally 1493 stable, a finite-amplitude, positive-density perturbation in the upper box will induce convection, which mixes warmer and saltier water to the surface. The heat in the surface layer is 1496 quickly lost to the atmosphere, but the surface salinity is 1497 increased, and hence convection is maintained, leading to a convective state. Convective and nonconvective states may 1499 thus coexist over a certain parameter range.

[110] Within simple box models, two types of oscillatory 1501 phenomena can also be found. One is associated with 1502 propagation of salinity perturbations along the mean ther-1503 mohaline flow and is referred to as a loop oscillation 1504 [Welander, 1986]. The other is associated with repeated 1505 transitions between convective and nonconvective states. 1506 The most elementary box model which includes both types 1507 of oscillations is the four-box model originally used by 1508 Huang et al. [1992] and analyzed in greater detail by 1509 Tziperman et al. [1994]. This model includes two deep-1510 ocean boxes, two near-surface boxes, and vertical as well as 1511 horizontal exchanges of heat and salt.

1512 3.3. Two-Dimensional Models and Their Relaxation 1513 Oscillations

[111] The next step in the modeling hierarchy, as de-1515 scribed in section 1.3, is models that focus on overturning

flows in the meridional plane. In 2-D Boussinesq models 1516 [Cessi and Young, 1992; Quon and Ghil, 1992; Thual and 1517 McWilliams, 1992], rotation and wind stress forcing are 1518 neglected a priori (see Box 4/Appendix A4).

[112] THC solutions within the 2-D Boussinesq models 1520 were first obtained for the simplest case of isotropic eddy 1521 diffusivities ($R_{HV}^M = R_{HV}^T = 1$, see Box 4/Appendix A4) and 1522 relatively large depth-to-width ratio A compared to the real 1523 ocean [Quon and Ghil, 1992; Thual and McWilliams, 1992]: 1524 $A \approx 0.1$ in the models versus $A = 10^{-3}$ in the Atlantic, say. 1525 Since the vertical length scale of the flow is still consider- 1526 ably smaller than the horizontal scale, isotropic diffusivities 1527 imply that vertical diffusion is the dominant transport 1528 mechanism.

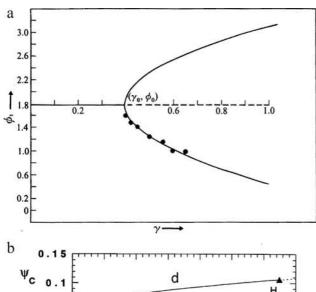

[113] Quon and Ghil [1992] derived the freshwater flux 1530 F_S (see Box 4/Appendix A4) from model steady states 1531 obtained under restoring conditions for both temperature 1532 and salinity. The parameter γ was used to measure the 1533 strength of this freshwater flux. Still, given equatorially 1534 symmetric forcing, a symmetric flow pattern is expected, 1535 i.e., the TH pattern, with upwelling near the equator and 1536 downwelling near either high-latitude end of the rectangular 1537 domain. Steady states were computed by forward 1538 integration, and their symmetry was measured by the 1539 difference ϕ_1 between the intensity of the overturning on 1540 either side of the equator. A two-parameter parabola was 1541 then least squares fitted to the asymmetric steady states, as 1542 shown in Figure 12a.

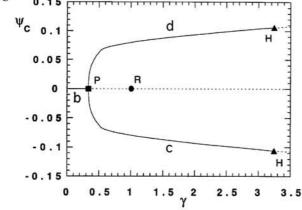

[114] Dijkstra and Molemaker [1997] recomputed the 1544 bifurcation diagram by more accurate continuation tech- 1545 niques and for slightly different lateral boundary conditions, 1546 and their results are shown in Figure 12b. The value of the 1547 meridional plane stream function at the rectangle's center 1548 point, which is zero for equatorially symmetric solutions, is 1549 shown on the ordinate. The solution at the point labeled b is 1550 the thermally driven two-cell TH state, while the solutions 1551 at points c and d are single-cell, pole-to-pole solutions, SPP 1552 and NPP, respectively.

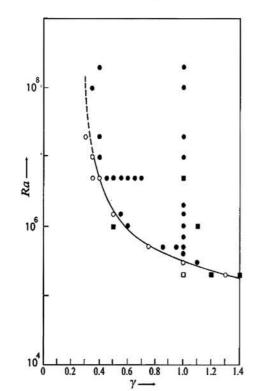

[115] The agreement between the two bifurcation dia- 1554 grams in Figures 12a and 12b is excellent, given the 1555 differences in lateral boundary conditions: The point P in 1556 Figure 12b has $\gamma = 0.36$, while $\gamma_0 = 0.40$ in Figure 12a. In 1557 fact, Dijkstra and Molemaker [1997] used somewhat less 1558 constraining boundary conditions than Quon and Ghil 1559 [1992]. This is expected to shift the pitchfork bifurcation 1560 to slightly smaller values, as found in Figure 12b. By 1561 varying the value of Ra, Quon and Ghil [1992] obtained a 1562 regime diagram shown here as Figure 12c; the neutral 1563 stability curve that separates the unique TH equilibria from 1564 the multiple, pairwise mirror symmetric ones is the locus of 1565 the pitchfork bifurcations in the (γ, Ra) plane.

[116] Thual and McWilliams [1992] computed similar 1567 bifurcation diagrams and systematically compared these 1568 diagrams for box models and for the 2-D Boussinesq model. 1569 They found that the simplest "plumbing scheme" that 1570 yields the same bifurcation diagram for the ODE system 1571 governing a box model as for the (numerically discretized) 1572 PDE system in Box 3/Appendix A3 has five boxes: one 1573

c

equatorial box and two pairs of polar boxes, near-surface 1574 and deep-ocean boxes. There are six pipes that connect each 1575 polar surface box to the equatorial one, each deepwater box 1576 to the equatorial one, and the two boxes stacked at either 1577 pole with each other in the vertical.

[117] Cessi and Young [1992] provided an important 1579 verification of the numerical results for the isotropic case 1580 in the limit of infinite Prandtl number (see Box 4/Appendix 1581 A4), $Pr \to \infty$, and vanishing aspect ratio, $A \to 0$. An 1582 asymptotic expansion of the PDE equations in Box 4/ 1583 Appendix A4 in a very thin domain yields an ODE for 1584 the vertically averaged salinity \hat{S} :

$$\hat{S}'' + \mu_1^2 \left[\hat{S}' (\hat{S}' - T_S')^2 \right]' + \mu_2 F_S = \delta^2 \hat{S}''''. \tag{9}$$

Here μ_1 and μ_2 measure the strength of the thermal and 1587 freshwater forcing, respectively, and the primes indicate 1588 differentiation with respect to y. The parameter δ allows for 1589 the presence of boundary layers with sharp gradients in the 1590 N-S direction. *Cessi and Young* [1992] obtained analytical 1591 results for $\delta \to 0$, but their solutions are not globally defined 1592 on the whole y interval. *Dijkstra and Molemaker* [1997] 1593 computed numerical solutions for nonzero δ in the whole 1594 rectangular domain, verified the bifurcation diagrams, and 1595 showed that they approached *Cessi and Young*'s [1992] 1596 analytical ones for $\delta \to 0$.

[118] In reality, the aspect ratio is very small, A=1598 $\mathcal{O}(10^{-3})$, but the ratio R_{HV} of vertical and horizontal 1599 diffusivities is very small too. Quon and Ghil [1995] 1600 explored 2-D Boussinesq flows in a rectangular domain 1601 with small A and $R_{HV} \ll 1$. For a choice of $R_{HV}^M = R_{HV}^T = A = 1602$ 0.01 the model behavior was investigated for two different 1603 sets of surface boundary conditions. The pitchfork bifurcation from symmetric to asymmetric steady states in this case 1605 is similar to the diffusive case. Each branch of asymmetric 1606 steady states undergoes a Hopf bifurcation to oscillatory 1607 solutions with a period equivalent to thousands of years in 1608 dimensional time. In the oscillatory solutions, small-scale 1609 convective "chimneys" appear close to the polar wall of the

Figure 12. Bifurcation and regime diagrams for a 2-D Boussinesq model of the thermohaline circulation (THC). (a) Approximate pitchfork bifurcation diagram obtained by a "poor-man's continuation method." The solid circles indicate steady state solutions obtained by forward integration. 1611 stronger cell. For a broad range of parameters the oscilla-1612 tions are strongly nonlinear, with a slow, diffusive warming 1613 phase and a sudden flush that reestablishes full-strength 1614 overturning.

[119] Weijer et al. [1999] studied systematically the 16151616 impact of lateral heat and salt fluxes on the Atlantic over-1617 turning. They showed that either a shift in the distribution of 1618 the intermediate and thermocline water, which together 1619 compensate for NADW export, or a change in their water 1620 mass characteristics might influence the Atlantic overturn-1621 ing's strength considerably. Dijkstra and Neelin [1999] 1622 considered the effects of asymmetry in the distribution of 1623 land masses. This leads to a surface freshwater flux that has 1624 slightly larger values in high northern than in high southern 1625 latitudes but also leads to an asymmetry in the area of 1626 ocean-atmosphere interaction and hence in the surface heat 1627 flux [Chen and Ghil, 1995].

[120] These asymmetric effects introduce an imperfection 1628 1629 into the pitchfork bifurcation diagram of the equatorially 1630 symmetric case. The branch of northern-sinking solutions is 1631 preserved when the N-S asymmetry of the freshwater flux is 1632 increased, while the branch of southern-sinking solutions 1633 eventually disappears. Hence asymmetry of either air-sea 1634 interaction or freshwater flux with respect to the equator 1635 induces a preference for northern sinking due mainly to 1636 larger salinification in the North Atlantic.

[121] In the 2-D Boussinesq models above, the effects 1638 of wind stress forcing and rotation were completely 1639 neglected. In some of them, moreover, solutions were 1640 obtained that contain regions with an unstable density 1641 stratification. The reason for such an unrealistic result is 1642 that many models of this type do not resolve the small 1643 scales at which the nonhydrostatic processes included in 1644 the Boussinesq approximation become important. We 1645 review next a class of 2-D, zonally averaged models in 1646 which the effects of rotation and wind are parameterized. 1647 In these ocean models, moreover, explicit procedures are 1648 used to remove the static instabilities; these procedures 1649 are collectively referred to as "convective adjustment" 1650 [Marotzke, 1991].

[122] When the 3-D primitive equations that govern ocean 1652 GCMs [Gill, 1982; Pedlosky, 1987, 1996; McWilliams, 1653 1996] are averaged with respect to longitude, a closure has 1654 to be found for several variables, in particular for the zonal 1655 pressure difference, in terms of zonally averaged quantities 1656 alone [Marotzke et al., 1988]. Wright and Stocker [1992] and 1657 Wright et al. [1998] drop the zonal momentum balance and 1658 propose a so-called "geostrophic" closure, which postulates 1659 the existence of a linear relation between the zonal density 1660 difference across the basin and the meridional density gradi-1661 ent. Wright and Stocker [1992] have shown the usefulness of 1662 this closure by a comparison with 3-D model results. In a 1663 more rigorous analysis based on vorticity dynamics, Wright et 1664 al. [1995] have shown that a relation between the east-west 1665 density difference and the zonally averaged meridional den-1666 sity gradient does indeed exist. In principle, other 2-D models 1667 [Marotzke et al., 1988; Sakai and Peltier, 1995; Vellinga, 1668 1996] can be considered as special cases of zonally averaged

models by taking the zonal velocity and all zonal derivatives 1669 equal to zero.

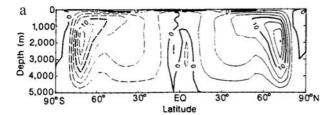

[123] Vellinga [1996] performed a bifurcation analysis for 1671 several types of zonally averaged models. The pitchfork 1672 bifurcation is quite robust in these models, although the TH 1673 solutions lose their stability for slightly different values of 1674 the strength of the salt flux forcing. This qualitatively 1675 similar behavior in 2-D models that have completely dif- 1676 ferent momentum balances suggests that the essentials of 1677 symmetry breaking of the thermally dominated THC do not 1678 reside in the dynamics but in the transport equations for heat 1679 and salt. To break the symmetry, it suffices to have a strong 1680 enough meridional velocity response to a meridional density 1681 gradient.

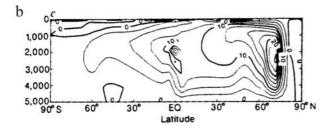

[124] For stronger overturning flows the "convective 1683 adjustment" that replaces small-scale nonhydrostatic flow 1684 in low-resolution 2-D models [Wright and Stocker, 1992], 1685 as well as in most ocean GCMs [Cox, 1984; Rahmstorf, 1686 1995b], can lead to the appearance of spurious saddle- 1687 node bifurcations. Vellinga [1998] investigated the origin 1688 of these artificial multiple steady states. They arise 1689 because of the possibility of "convective adjustment" at 1690 arbitrary grid points. This feature of several 2-D and 3-D 1691 models of the THC demonstrates their extreme sensitivity 1692 to finite-amplitude perturbations, since the convective 1693 adjustment procedure only mixes heat and salt locally 1694 downward. This sensitivity can already be deduced from 1695 the simple [Welander, 1982] two-box model, where a 1696 finite-amplitude perturbation can induce a transition be- 1697 tween a quiescent and a convective state, given only 1698 vertical transport; it is absent from 2-D Boussinesq 1699 models that resolve chimneys explicitly [Quon and Ghil, 1700 1995].

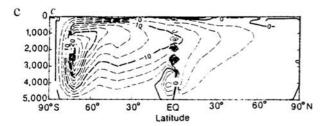

3.4. Three-Dimensional Models

[125] To understand more fully the 3-D aspects of the 1703 THC, and eventually its interaction with the wind-driven 1704 circulation, more elaborate 3-D models are necessary. These 1705 models include ocean GCMs; this term is typically reserved 1706 for 3-D models with fairly realistic bathymetry and equation 1707 of state. Until recently, though, spatial resolution has been 1708 fairly limited, even in such GCMs, to about 4° × 4° 1709 horizontally and 12 levels.

[126] Several types of ocean GCMs are reviewed by 1711 McWilliams [1996] and Chassignet et al. [2000]. The 1712 modular ocean model (MOM) [Pacanowski, 1996] and 1713 the Parallel Ocean Program (POP) [e.g., Smith et al., 1714 2000] are improved descendants of the original Bryan- 1715 Cox model. The large-scale geostrophic (LSG) model was 1716 suggested by Hasselmann [1982] and subsequently devel- 1717 oped, tested, and used by Maier-Reimer et al. [1993]. The 1718 idea behind the LSG model is to filter out the fast phenom- 1719 ena that do not affect, to first order, changes in the ocean on 1720 large spatial scales and long timescales. In frictional geo- 1721 strophic models (FGMs) the inertia terms and the local 1722 accelerations are neglected, while using a rigid-lid surface 1723 condition. In the momentum equations, additional simplifi- 1724 cations are usually made in the form of linear friction 1725

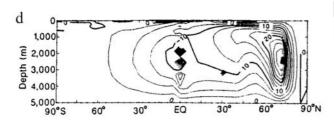

Figure 13. Steady states obtained in an ocean GCM limited to an idealized 60° wide sectorial configuration, subject to mixed boundary conditions. Zonal averages of the velocity field are plotted as a meridional plane stream function field. (a) Reference state obtained with equatorially symmetric, restoring boundary conditions. (b) Circulation obtained after adding a negative salinity perturbation of 1 psu south of 45°S. (c) Circulation after adding a positive salinity perturbation of 2 psu south of 45°S. (d) Circulation after adding a positive salinity perturbation of 2 psu north of 45°N. From Bryan [1986], used with permission from Nature (http://www.nature.com).

1726 [Salmon, 1986; Colin de Verdière, 1988], and no details of basin geometry and bottom topography are included.

1728 3.4.1. Multiple Equilibria

[127] Bryan [1986] used the MOM model to address the 1730 issue of multiple equilibria in 3-D ocean models in a full-1731 basin setup. He first obtained the solution of a single-1732 hemispheric, sectorial version of the model under restoring 1733 conditions, using observed salinity over the domain (0-1734 60°E, 0-90°N). This solution and the corresponding sur-1735 face forcing were reflected across the equator to provide a 1736 full-basin solution as an initial state (Figure 13a). The freshwater flux of this state was diagnosed and used in 1737 subsequent runs for which mixed boundary conditions were 1738 prescribed. 1739

[128] When a negative salinity anomaly of 1 psu is 1740 suddenly added poleward of 45°S, the deep convection in 1741 the Southern Hemisphere is interrupted. The residence time 1742 of water parcels in the surface layer increases and leads 1743 through the convective feedback to a collapse of the over- 1744 turning circulation in the Southern Hemisphere; a pole-to- 1745 pole circulation is reached within 50 years (Figure 13b), 1746 with sinking in high northern latitudes only. This collapse is 1747 referred to as the polar halocline catastrophe and is associ- 1748 ated with the equatorward spreading of a tongue of low- 1749 salinity water.

[129] Adding a positive salinity anomaly of 2 psu in the 1751 same region, poleward of 45°S, induces an intensification of 1752 the meridional overturning; this leads, through the advective 1753 feedback mechanism, to a southern-sinking solution in 1754 about 200 years (Figure 13c). An initial state with a positive 1755 salinity anomaly of 2 psu in the northern subpolar region 1756 gave a northern-sinking solution (Figure 13d) similar to that 1757 in Figure 13b.

[130] Klinger and Marotzke [1999] used a "poor-man's 1759 continuation method" to determine bifurcation diagrams of 1760 the 3-D double-hemispheric configuration by calculating 1761 steady states within the MOM model for many parameter 1762 values. In the equatorially symmetric case the multiplicity 1763 of their model's equilibria appears to arise through a 1764 subcritical pitchfork bifurcation. Weijer and Dijkstra 1765 [2001] used pseudo arc length continuation to perform a 1766 bifurcation study of the double-hemispheric case. They 1767 showed that (1) there is a qualitative similarity between 1768 the steady state structure in the 2-D and the 3-D case, given 1769 mixed boundary conditions, and (2) the location of the 1770 pitchfork bifurcation point responsible for the multiple 1771 equilibria can be characterized by energy considerations 1772 alone. This characterization helps demonstrate that the 1773 physical mechanism of symmetry breaking is essentially 1774 the same in the 2-D and 3-D case.

[131] Marotzke and Willebrand [1991] studied the global 1776 THC in an idealized configuration of the MOM model; in it, 1777 two similar ocean basins mimicked the Atlantic and Pacific 1778 oceans. The two rectangular basins are connected at their 1779 southern end by a channel with specified transport that 1780 represents the Antarctic Circumpolar Current (ACC) and 1781 induces a prescribed north-south asymmetry. Given mixed 1782 boundary conditions, four different types of equilibria were 1783 found: (1) a solution with northern sinking in both rectan- 1784 gular basins; (2) a conveyor belt circulation, with the THC 1785 in the "Pacific" basin being driven by that in the "Atlan- 1786 tic"; (3) an inverse-conveyor solution, with the roles of the 1787 "Pacific" and "Atlantic" interchanged; and (4) a state with 1788 southern sinking for both ocean basins.

[132] Weaver and Hughes [1994] used a similar MOM 1790 configuration but included a fully prognostic ACC channel 1791 flow. Their numerical experiments were set up exactly as 1792 done by Marotzke and Willebrand [1991], and three differ- 1793 ent solutions were found. For all three equilibria the Pacific 1794

1845

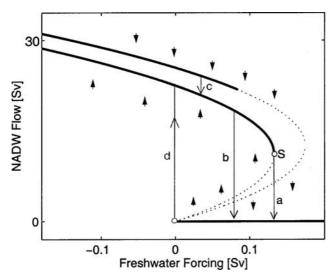

Figure 14. Model response to transient forcing, presented as a schematic bifurcation diagram. The amount of NADW in the solution is plotted versus the amplitude of the perturbation in freshwater forcing. This schematic diagram is obtained by indirect reasoning applied to results of timedependent numerical experiments with a particular spatial pattern and rate of change in time of the forcing perturbation for a global ocean GCM. See Rahmstorf [2000] for the heuristic interpretation of the solid and dotted segments, various types of arrows, and other symbols. From Rahmstorf [2000, Figure 2], republished with kind permission of Springer Science and Business Media.

1795 circulation is quite the same; it is only the Atlantic's THC 1796 that is comparable to that observed, weaker or stronger. 1797 They found no northern sinking nor an inverse-conveyor 1798 solution, probably because of a more limited northward 1799 extension of their Pacific basin.

[133] Rahmstorf [1995a] used a global version of the 1801 MOM model, with realistic continental outlines and ba-1802 thymetry, to study the stability of the global THC. In his 1803 work the circulation is driven by a prescribed freshwater 1804 flux and wind stress; instead of a prescribed surface air 1805 temperature a simple model of ocean-atmosphere interac-1806 tion [Rahmstorf, 1995b] was used. The freshwater forcing 1807 was changed by adding slowly varying perturbations at 1808 different locations, and the response of the overturning flow 1809 to these perturbations in forcing was monitored. Rahmstorf 1810 [2000] interpreted the response to a perturbation in the 1811 northern North Atlantic with an inflow of 0.05 Sv per 1812 1000 years with the help of the diagram shown in Figure 14. 1813 With increasing freshwater forcing the strength of the 1814 overturning circulation decreases, and at some point 1815 (indicated by S in Figure 14) the overturning collapses. When 1816 the freshwater input is reversed, hysteresis occurs, and it takes 1817 a negative freshwater input to start the overturning again 1818 (shown by the light arrow labeled d in Figure 14).

[134] Manabe and Stouffer [1988] first used the coupled 1820 ocean-atmosphere model of NOAA's Geophysical Fluid 1821 Dynamics Laboratory (GFDL) for climate studies. The 1822 global coupled model was further improved by Manabe and Stouffer [1993, 1995], who reported and analyzed longtime integrations of this model. While the spatial resolution 1824 used in the early climate studies was still quite low $(4^{\circ} \times 4^{\circ})$ 1825 horizontally), the model's water mass formation and distribution was fairly realistic [England, 1992, 1993]. Manabe 1827 and Stouffer found two different equilibrium states; they 1828 differ considerably in the amount of northern overturning, 1829 which is about 12 Sv for one of the states but nearly zero for 1830 the other. As expected, the two states also display a very 1831 substantial difference in surface temperature and salinity 1832 patterns, with the weak overturning state having a smaller 1833 surface density in the North Atlantic. Tziperman [1997] 1834 showed that this coupled model has, in fact, a wide range of 1835 equilibria with weak THC; any of these equilibria may 1836 rapidly change, because of finite-amplitude perturbations, to 1837 either collapse entirely or undergo rapid oscillations.

[135] In summary, the appearance of multiple equilibria is 1839 pervasive in models ranging from simple box models to 1840 complex coupled ocean-atmosphere models. As we know 1841 already from section 2, multiple equilibria are but the first 1842 step in describing and understanding the effects of nonlin- 1843 earity on the ocean's variability.

3.4.2. Temporal Variability

[136] To understand in depth the variability of THC 1846 flows, 3-D model configurations that correspond to a single, 1847 more or less idealized basin have been extensively analyzed 1848 using the MOM model [Marotzke, 1991; Weaver and 1849 Sarachik, 1991]. Weaver et al. [1993] found signatures of 1850 decadal-to-interdecadal variability in their simulations; its 1851 mechanism is associated with large changes in convective 1852 activity in the model's Labrador Sea region, which leads to 1853 changes in the meridional heat transport near the basin's 1854 western boundary [Weaver et al., 1994]. This model vari- 1855 ability is insensitive to the freshwater flux and wind stress 1856 forcing and seems to be caused by processes involving the 1857 surface heat flux, regional convection, and the large-scale 1858 overturning circulation; the details, however, remain to be 1859 clarified.

[137] Greatbatch and Zhang [1995] described a similar 1861 type of oscillation in an FGM; they found a slightly longer 1862 period of 50 years, versus the 22-year periodicity found by 1863 Weaver et al. [1993, 1994]. Chen and Ghil [1995] analyzed 1864 in detail the physical mechanisms of variability in their 1865 15-level MOM ocean model with rectangular basin geometry. 1866 They showed that a robust interdecadal oscillation occurs 1867 when higher-density water is generated in high latitudes, 1868 either by cooling or by salinity increase. They emphasized 1869 that the net salt flux in the subpolar North Atlantic is positive, 1870 as brine rejection by sea ice formation overcomes the 1871 freshening by precipitation. Colin de Verdière and Huck 1872 [1999] and Huck et al. [1999] showed that this oscillatory 1873 behavior occurs through an instability of the steady single- 1874 basin flow when the horizontal heat diffusivity is decreased. 1875 These authors attributed the propagation of the temperature 1876 anomalies to traveling baroclinic waves.

[138] Te Raa and Dijkstra [2002] performed a systematic 1878 study of THC stability in a single basin. Two types of 1879 oscillatory modes can destabilize the steady buoyancy- 1880

1881 driven flows in such a basin. One class of modes has an 1882 interdecadal timescale, and the other has a centennial 1883 timescale; both modes are damped when restoring rather 1884 than mixed boundary conditions are applied. Subject to 1885 prescribed surface buoyancy flux conditions, the interdeca-1886 dal modes are destabilized through a Hopf bifurcation, as 1887 suggested by Chen and Ghil's [1995] results, when the 1888 horizontal mixing of heat becomes small enough. Te Raa and Dijkstra [2002] showed that the destabilization mechanism is related to an out-of-phase response of the zonal and meridional overturning to propagating temperature anoma-1892 lies [see also Colin de Verdière and Huck, 1999].

[139] Chen and Ghil [1996] used a hybrid coupled model 1894 to clarify further whether the interdecadal climate oscillation 1895 that appears to be mainly driven by THC variability in the 1896 North Atlantic is of predominantly oceanic origin or truly 1897 involves both atmosphere and ocean as coequal partners. As 1898 mentioned in section 1.3, such models play an important 1899 role in bridging the gap between simple box and 2-D 1900 models on the one hand and fully coupled GCMs on the 1901 other. The hybrid model of these authors couples a hori-1902 zontally 2-D atmospheric energy balance model (EBM) 1903 with the low-resolution ocean GCM already used by Chen 1904 and Ghil [1995] to model the North Atlantic in a simplified, 1905 rectangular geometry.

[140] This hybrid model's regime diagram is shown in 1907 Figure 15a. A steady state is stable for high values of the 1908 air-sea coupling parameter λ_{ao} or of the EBM's diffusion 1909 parameter d. Interdecadal oscillations with a period of 40-1910 50 years are self-sustained and stable for low values of these 1911 two parameters. The transition from a stable equilibrium to 1912 a stable limit cycle via Hopf bifurcation was computed by 1913 "poor-man's continuation." The hybrid coupled model's 1914 self-sustained oscillations are characterized by a pair of 1915 vortices of opposite sign that grow and decay in quadrature 1916 with each other in the ocean's upper layers. The evolution of 1917 this pattern in SST anomalies is shown in Figures 15b-15e, 1918 where four stages of the oscillation, each 5.5 years apart, are 1919 plotted; they cover about one half of the oscillation's period, 1920 while the other half period corresponds to an approximate 1921 inversion of the anomalies' sign. The centers of the anoma-1922 lies follow each other anticlockwise through the northwest-1923 ern quadrant of the model domain.

[141] Delworth et al. [1993] focused on interdecadal 1924 1925 variability within the global coupled GFDL model. Starting 1926 from a quasi-equilibrium state, determined as in the work of 1927 Manabe and Stouffer [1988], the model was integrated 1928 for 600 "upper ocean" years. In this model version the 200-year mean of the overturning stream function attained 1930 about 18 Sv. The model variability was monitored by a 1931 THC index that equals the annual mean of the meridional 1932 overturning stream function's maximum value in the North 1933 Atlantic. Delworth et al. [1993] found pronounced variabil-1934 ity in this THC index, with an average period of about 1935 50 years; see Figure 16a. The difference in annual mean 1936 model SSTs between 4 decades of high THC index and 4 of 1937 low THC index is shown in Figure 16b. This pattern has 1938 a dipole-like appearance, with maxima off the North

American coast. It resembles the SST pattern obtained from 1939 observations [Kushnir, 1994] as the difference between 1940 relatively warm years (1970–1984) and relatively cold ones 1941 (1950-1964), which is plotted here in Figure 16c [see also 1942 Moron et al., 1998, Figure 3]. 1943

[142] Relations between the different atmospheric and 1944 oceanic fields and the heat and salt budgets point to the 1945 oscillation's being mainly of an oceanic origin: It appears to 1946 be driven by density anomalies in the sinking region of the 1947 subpolar North Atlantic, combined with smaller density 1948 anomalies of the opposite sign in the broad, rising region. 1949 Delworth and Greatbatch [2000] attributed this variability 1950 to a stable oscillatory THC mode, which is excited by noise 1951 in the GFDL model [see Griffies and Tziperman, 1995]. 1952 Both the period and the spatiotemporal characteristics of 1953 Chen and Ghil's [1996] interdecadal oscillation are thus 1954 rather similar to those seen in Delworth et al.'s [1993] fully 1955 coupled GCM with realistic geometry. They resemble, in 1956 turn, quite closely those found by Chen and Ghil [1995] in 1957 their purely oceanic, single-basin model, as well as the 1958 patterns of the interdecadal modes in the single-basin ocean 1959 models of Colin de Verdière and Huck [1999] and Te Raa 1960 and Dijkstra [2002].

[143] The LSG model's variability was investigated by 1962 Mikolajewicz and Maier-Reimer [1990]. The model was 1963 spun up using restoring conditions on the surface salinity 1964 and temperature and momentum forcing by the annual mean 1965 wind stress. The freshwater flux was derived from the 1966 situation after 3800 years of spin-up, and the simulation 1967 was continued using mixed boundary conditions from that 1968 point on. The model's circulation is stable for this experi- 1969 mental setup. Subsequently, a stochastic component was 1970 added to the freshwater flux, and the response of the 1971 NADW outflow at 30°S was monitored. Low-frequency 1972 variability is then present in the model and was attributed to 1973 the integration of the stochastic component in the surface 1974 forcing by the ocean [Hasselmann, 1976]. However, at a 1975 timescale of about 300 years, there is more energy in the 1976 spectrum than can be expected from pure low-pass filtering 1977 of noise. The salinity anomalies associated with this vari- 1978 ability show a dipole pattern that is advected with the 1979 Atlantic's THC.

3.5. Relevance to the North Atlantic and Global THC 1981

[144] Here we compare the results from bifurcation 1982 studies of 2-D and 3-D models of the oceans' THC with 1983 those of more traditional GCM studies. The phenomenon of 1984 multiple equilibria found in GCMs appears to be either 1985 related to equatorial symmetry breaking or to saddle-node 1986 bifurcations.

[145] The equatorially symmetric setup is the clearest 1988 case: The emergence of asymmetric pole-to-pole solutions 1989 is due to symmetry breaking, which occurs across the entire 1990 hierarchy of models [Rooth, 1982; Bryan, 1986; Welander, 1991 1986; Quon and Ghil, 1992; Thual and McWilliams, 1992; 1992 Weijer and Dijkstsra, 2001]. The associated physical 1993 mechanism is the salt-advection feedback; this mechanism 1994 only requires that there exist a meridional velocity response 1995

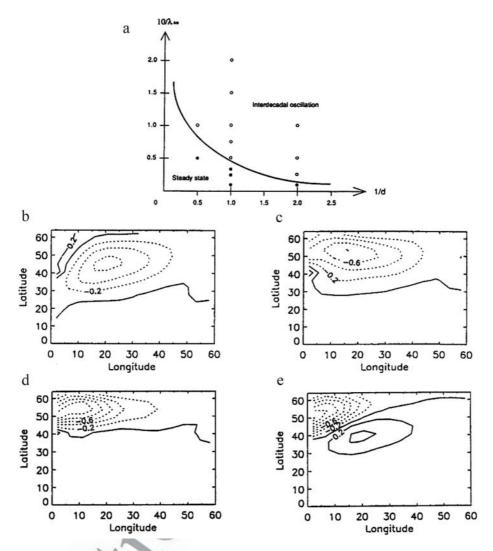

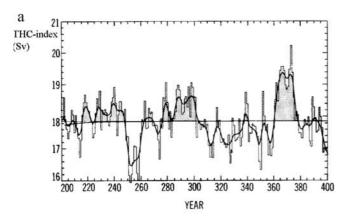

Figure 15. (a) Regime for a hybrid coupled model. The parameters d and λ_{oa} are the atmospheric EBM's thermal diffusivity and the proportionality constant for the air-sea heat flux, respectively. Solid circles in both diagrams indicate numerically computed steady states; open circles indicate periodic solutions. From *Chen and Ghil* [1996]. (b–e) Interdecadal oscillation in the hybrid coupled model. SST anomaly patterns are shown at intervals of about 5.5 years to cover roughly half the period of the 44-year oscillation.

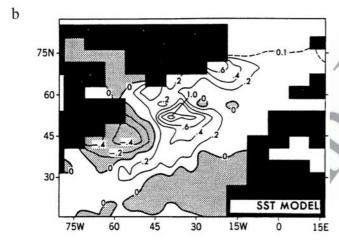

1996 to a change in the meridional density profile, given a strong 1997 enough meridional salinity gradient. Imperfections of the 1998 equatorially symmetric situation, due to either asymmetric 1999 freshwater forcing or continental asymmetry, lead to dis-2000 connected branches of equilibria. These asymmetries may 2001 explain the multiple equilibria, or lack thereof, in more 2002 realistic situations [Weijer et al., 1999; Dijkstra and Neelin, 2003 2000].

2004 [146] Ganopolsky et al. [2001] carried out climate model 2005 simulations in which the ocean circulation is represented by 2006 a zonally averaged flow in each basin in order to examine 2007 the mechanism of Dansgaard-Oeschger cycles. In their 2008 model, two stable steady states exist for the modern climate, 2009 one with high and the other with nearly zero meridional 2010 overturning, while in the glacial climate there is only one 2011 stable circulation pattern. A time-dependent variation in the 2012 freshwater flux forcing can, however, induce rapid transi-

tions between this cold state and an unstable warm state. 2013 Hence the loss of stability of the THC equilibrium, combined with variable surface fluxes, can lead to oscillations 2015 that resemble Dansgaard-Oeschger cycles. 2016

[147] Overturning mean flows in the oceans seem to be 2017 subject to several modes of oscillatory instability; see 2018 Table 4. These range from relaxation oscillations, characterized by millennial periodicities with long intervals of 2020 weak THC that alternate with sudden flushes, through 2021 centennial oscillations, which correspond to the loop 2022 advection of density anomalies, all the way to decadal 2023 and interdecadal oscillations. It is the latter that are of the 2024 greatest interest in distinguishing natural from anthropogenic variability on the timescale of human life [, ,]. 2026 What role, if any, do the interdecadal oscillatory modes 2027 described in this section play in the ocean's observed 2028 interdecadal variability?

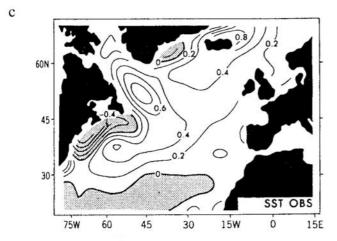

Figure 16. Interdecadal variability in the Geophysical Fluid Dynamics Laboratory coupled ocean-atmosphere model. From *Delworth et al.* [1993]. (a) Time series of annual mean THC index over 200 years of integration. (b) SST pattern obtained as the difference of four model-simulated decades of high-THC-index states and four model simulated low-THC-index states. (c) Pattern of interdecadal SST anomalies obtained as the difference between two 15-year long intervals: the relatively warm interval 1950–1964 and the relatively cold interval 1970–1984 (last panel from *Kushnir* [1994]).

[148] A similar question was discussed, with respect to 2030 the wind-driven circulation and interannual variability, in 2031 section 2.6. The answer, again, can only be given by 2032 studying the spatiotemporal patterns and physical mech- 2033 anisms of these interdecadal modes across a hierarchy of 2034 models and the various, albeit incomplete, observational 2035 data sets [Ghil and Robertson, 2000; Ghil, 2001]. Evi- 2036 dence is mounting that the 14- to 15-year and 25- to 2037 27-year peaks in temperature spectra (see Ghil and Vautard 2038 [1991] and Figure 1b) are indeed due to THC modes, as 2039 conjectured by Plaut et al. [1995]. This evidence includes 2040 the similarity between the interdecadal mode of Chen and 2041 Ghil's [1996] simplified hybrid coupled model and that of 2042 Delworth et al.'s [1993] fully coupled global GCM, as well 2043 as that between the latter and the observational results of 2044 Kushnir [1994] and Moron et al. [1998].

[149] It does not matter in this context whether these THC 2046 modes are due to damped or self-sustained instabilities, 2047 since the modes can always be excited by stochastic noise 2048 [Griffies and Tziperman, 1995; Rivin and Tziperman, 2049 1997]. The forcing of the ocean by atmospheric variability 2050 has a wide range of timescales. High-frequency forcing may 2051 lead to low-frequency response in the coupled system, 2052 according to the scenario of Hasselmann [1976] and 2053 Mitchell [1976], while low-frequency forcing can lead to 2054 direct changes in the ocean circulation. The latter may be 2055 resonantly amplified by the presence of an oscillatory 2056 instability, even if this mode is damped, in the absence of 2057 atmospheric "noise." Moreover, coupled modes of variabil- 2058 ity may also exist, where feedbacks between the ocean and 2059 atmosphere act in concert to amplify perturbations [Latif 2060 and Barnett, 1994, 1996]. The ocean's interactions with sea 2061 ice may contribute to even richer types of variability [Yang 2062 and Neelin, 1993; Kravtsov and Ghil, 2004].

[150] It thus appears that an understanding of elementary 2064 bifurcations does help explain the changes in the oceans' 2065 THC on timescales of decades and longer. The results are, 2066 however, less conclusive than those in section 2.

4. OUTLOOK 2069

[151] Until about 2 decades ago the tools of analytical and 2070 numerical bifurcation theory could be applied only to 0-D 2071 THC models [Stommel, 1961; Rooth, 1982] or to 0-D and 2072 1-D climate models [Held and Suarez, 1974; Ghil, 1976; 2073 North et al., 1981]. We have illustrated in this review, by 2074 considering a few oceanic flow problems on different time- 2075 scales, that the general theory can be combined with powerful 2076 numerical tools to study successive bifurcations across the 2077 hierarchy of climate models, all the way from 0-D global or 2078 box models (see section 3.2) to 2-D and 3-D models: 2079 atmospheric [Legras and Ghil, 1985; Strong et al., 1995], 2080 oceanic [Quon and Ghil, 1992, 1995; Thual and McWilliams, 2081 1992; Dijkstra and Molemaker, 1997], and coupled [Chen 2082 and Ghil, 1996; Te Raa and Dijkstra, 2003].

[152] Each bifurcation is associated with a specific linear 2084 instability of a relatively simple climate state: oscillatory in 2085 the case of Hopf bifurcations and purely exponential in the 2086

TABLE 4. Oscillations in the Oceans' Thermohaline Circulation: Timescales and Mechanisms^a

Timescale	Phenomena	Mechanism	Reference	
Decadal	local migration of surface anomalies due to surface cooling	localized surface-density anomalies due to surface coupling	Chen and Ghil [1995]	
Decadal	advection of density anomalies at midlatitudes	gyre advection	Weaver et al. [1991]	
Interdecadal	westward propagation of temperature anomalies	generalized baroclinic instability	Colin de Verdière and Huck [1999] and Delworth et al. [1993],	
Interdecadal	advection of density anomalies and convection changes	combined gyre and overturning advection	Delworth and Greatbatch [2000] and Te Raa and Dijkstra [2002]	
Centennial	loop-type, meridional circulation	conveyor belt advection of density anomalies	Mikolajewicz and Maier-Reimer [1990] and Winton and Sarachik [1993]	
Millennial	flushes and superimposed decadal fluctuations	bottom water warming	Chen and Ghil [1995] and Weaver et al. [1993]	

2087 case of saddle-node or pitchfork bifurcations. The nonlinear 2088 saturation of each instability leads to more complicated 2089 spatiotemporal patterns. Following the bifurcation tree, 2090 from one rung of the modeling hierarchy to the next, 2091 permits us therefore to study with increasing detail and 2092 realism the basic physical mechanisms that lead to low-2093 frequency variability of the ocean circulation.

[153] Typically, the first one or two bifurcations will be 2094 2095 captured fairly well by a lower-order or otherwise very 2096 simple model of the ocean circulation problem of interest. 2097 As the model's number of degrees of freedom or other 2098 aspects of its complexity increase, more complicated and 2099 realistic regimes of behavior will appear. These regimes can 2100 be reached by studying the additional bifurcations that 2101 intervene. The task of following bifurcations numerically 2102 off solution branches with greater and greater complexity 2103 becomes more and more challenging. Continuation methods 2104 [Keller, 1977; Seydel, 1994; Doedel and Tuckermann, 2000] 2105 are now applied to follow steady state and periodic solution 2106 branches of more and more highly resolved atmospheric 2107 [Legras and Ghil, 1985; Strong et al., 1995; Keppene et al., 2108 2000], 2-D oceanic [Speich et al., 1995; Dijkstra and 2109 Molemaker, 1997; Simonnet et al., 2003a, 2003b], and 2110 3-D oceanic [Te Raa and Dijkstra, 2002] models. Projected 2111 increase of computer power and developments in numerical 2112 algorithms should make it possible to apply such methods 2113 to currently available GCMs in the near future.

2114 [154] Results from GCMs, atmospheric, oceanic, and 2115 coupled, provide solutions to ocean circulation and climate 2116 dynamical problems that have the greatest spatiotemporal 2117 detail and, one hopes, the greatest degree of physical 2118 realism. These solutions provide, in turn, the best opportu-2119 nity for evaluating our theories of low-frequency variability 2120 of the ocean circulation, developed by climbing the lower 2121 rungs of the modeling hierarchy, against the observational 2122 evidence, to the extent that the latter is available.

2123 [155] Such an evaluation, given the irregular character of 2124 the observed oceanic variability, needs to be informed by 2125 the ergodic theory of dynamical systems [*Eckmann and* 2126 *Ruelle*, 1985], which can describe this irregular behavior in

a consistent way. The basic ideas of the latter theory have 2127 led, in the climate context, to the development of advanced 2128 statistical tools, such as clustering methods [Ghil and 2129 Robertson, 2002], as well as singular-spectrum analysis 2130 [Ghil and Vautard, 1991; Plaut and Vautard, 1994] and 2131 other advanced spectral methods [Ghil et al., 2002b]. These 2132 tools have to be applied in parallel to the GCMs' simulations and to the relevant observational data sets.

[156] Studying the observed and simulated ocean variability with the same sophisticated tools can help pinpoint 2136 the aspects of this variability that we have understood, and 2137 can therefore predict with confidence, and those that we 2138 have not. Fortunately, there are many more of the latter, and 2139 much work remains to be done. It is the authors' hope that 2140 the tools and points of view presented here will help to 2141 solve certain ocean-related climate-variability problems, as 2142 well as possibly suggest some new ones.

APPENDIX A 2145

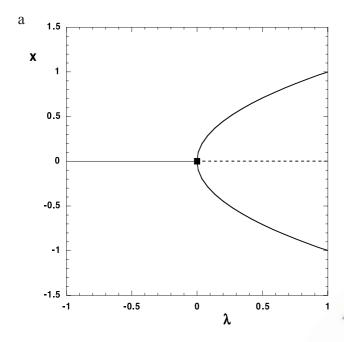

A1. Intended Audience and Corresponding Reading Routes

[157] The material covered by this review has attracted 2148 increasing interest from a broad audience. This audience 2149 includes, of course, oceanographers but also atmospheric 2150 and other geoscientists and climate change researchers, as 2151 well as fluid dynamicists and applied mathematicians. The 2152 purpose of the review is therefore to satisfy the curiosity of 2153 and provide a research tool to this broad audience to the 2154 extent possible within the space allowed.

[158] Obviously, some parts of the material will be more 2156 familiar to certain readers than to others. Much of sections 2157 1.2, 2.1, 2.2, and 3.1 can be skipped by all oceanographers, 2158 as well as by many of the other geoscientists. Likewise, Box 2159 2/Appendix A2, on elementary bifurcation theory, will be 2160 well known to all applied mathematicians and to many 2161 interested fluid dynamicists and geoscientists but not to all. 2162 [159] The methods of bifurcation theory are applied in 2163

section 2 to the wind-driven circulation and in section 3 to 2164

2181

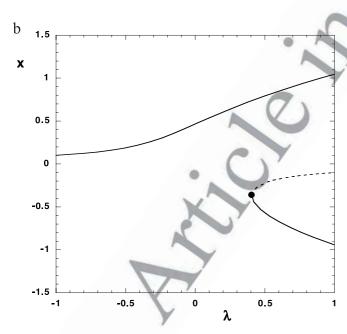

Figure A1. (a) Bifurcation diagram of the pitchfork bifurcation in the system $f(x, \lambda) = \lambda x - x^3$. (b) Perturbed pitchfork bifurcation diagrams for the system $f(x, \lambda) = \epsilon + \lambda x - x^3$ for $\epsilon = 0.1$. Solid lines indicate stable solutions, and dashed lines indicate unstable ones. The bifurcation points are marked by a circle and square.

2165 the thermohaline circulation. These two sections are fairly 2166 self-contained. An outlook on the future of this approach in 2167 oceanographic and climate studies concludes the paper. 2168 Therefore, depending on the reader's interest and back-2169 ground, they can skip either section 2 or 3 in proceeding 2170 from section 1 to section 4. The principal results of section 2 2171 appear in Table 3, and those of section 3 are shown in the 2172 corresponding Table 4.

A2. Elementary Bifurcations

[160] The simplest, most robust, and oft encountered 2174 bifurcations occur when a single parameter, say λ , is varied. 2175 The type of bifurcation depends on how the eigenvalues σ 2176 of the Jacobian matrix $\bf J$ in (5) cross the imaginary axis. 2177 Since $\bf J$ has real coefficients, it is either a real eigenvalue or 2178 a complex conjugate pair of eigenvalues that crosses this 2179 axis.

A2.1. A Single Zero Eigenvalue

[161] The first example is that of the saddle-node 2182 bifurcation, also called limit point or turning point. The 2183 simplest dynamical system in which this bifurcation 2184 occurs has

$$f(x,\lambda) = \lambda - x^2. \tag{A1}$$

Fixed points $\bar{x}=\pm\sqrt{\lambda}$ exist when $\lambda>0$, and no solutions 2187 exist for $\lambda<0$. The stability of these states is determined by 2188 the sign of the unique eigenvalue $\sigma=-2\bar{x}$ of the Jacobian 2189 matrix. Hence the solution $\bar{x}=\sqrt{\lambda}$ is stable, while the 2190 solution $\bar{x}=-\sqrt{\lambda}$ is unstable. The saddle-node bifurcation 2191 is characterized by a sudden appearance or disappearance of 2192 solutions in the parameter space. Well-known examples in 2193 atmospheric and climate dynamics include energy balance 2194 models [*Ghil*, 1976; *North et al.*, 1983] and the *Charney* 2195 and *DeVore* [1979] model of bistability of blocked and 2196 zonal flows.

[162] A second important example, a so-called pitchfork 2198 bifurcation, arises in the presence of mirror symmetry; such 2199 a symmetry can be written in general, see equation (1), as 2200 $\mathbf{f}(-\mathbf{x}) = -\mathbf{f}(\mathbf{x})$. The simplest system in which this bifurcation occurs has

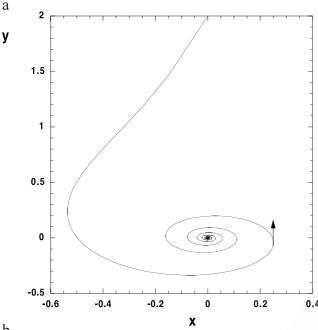

$$f(x,\lambda) = \lambda x - x^3. \tag{A2}$$

For $\lambda < 0$, there is only one steady solution (or fixed point) 2204 $\bar{x} = 0$, but for $\lambda > 0$, three fixed points exist: $\bar{x} = 0$ and $\bar{x} = 2205$ $\pm \sqrt{\lambda}$. Hence the number of fixed points changes from one to 2206 three as λ crosses zero. Since $J = \lambda - 3$ \bar{x}^2 , $\sigma = \lambda$ for $\bar{x} = 0$ 2207 and hence $\bar{x} = 0$ is stable for $\lambda < 0$ but unstable for $\lambda > 0$. 2208 The two additional fixed points that exist for $\lambda > 0$ have $\sigma = 2209 - 2\lambda$, so that these are both stable (Figure A1a). This 2210 bifurcation is actually called a supercritical pitchfork bifurcation, since the two mirror-symmetrical nonzero solutions 2212 exist for $\lambda > 0$. For the system $f(x, \lambda) = \lambda x + x^3$, three 2213 solutions coexist for negative λ and a subcritical pitchfork 2214 bifurcation occurs. The latter type arises, for example, in the 2215 Lorenz [1963a] system.

[163] What happens when the mirror symmetry of $f(x, \lambda)$ 2217 in the bifurcation equation (A2) is slightly perturbed: Does 2218 the solution structure change, and if so, can one determine a 2219 priori how? Slight perturbations from the symmetry can be 2220 represented as as

$$f(x,\lambda) = \epsilon + \lambda x - x^3 \tag{A3}$$

for some (small) ϵ . When $\epsilon = 0$, a pitchfork bifurcation 2222 occurs at $(\bar{x} = 0, \lambda = 0)$, but for $\epsilon \neq 0$, the pitchfork 2224

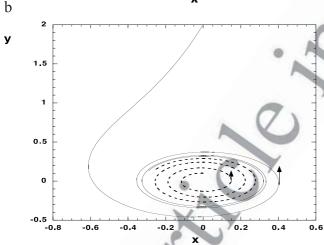

Figure A2. Trajectories of the reduced equations (A4) for the Hopf bifurcation: (a) before the bifurcation at $\lambda = 0$ ($\lambda = -0.1$) and (b) after the bifurcation ($\lambda = 0.1$). The secondary parameter value is $\omega = 1.0$, and both graphs show a trajectory that starts at the point (0, 2). In Figure A2b an additional trajectory starting at (0, 0.1) is shown as the dashed curve. Arrows indicate the tangent at that point in the direction of evolution along the given curve.

2225 bifurcation is no longer present because the reflection 2226 symmetry is broken: $f(-x, \lambda) \neq -f(x, \lambda)$. The bifurcation 2227 diagram for $\epsilon \neq 0$ is referred to as an imperfect pitchfork 2228 bifurcation. Such a diagram has a connected branch, which 2229 is present over the entire parameter range, and a 2230 disconnected branch, which exhibits a saddle-node bifurca-2231 tion (see Figure A1b for $\epsilon > 0.1$).

2232 A2.2. A Single Complex Conjugate Pair of Eigenvalues

2233 [164] In the saddle-node and pitchfork bifurcations, the 2234 number of fixed points changes as a parameter is varied. We 2235 now consider a bifurcation in which the character of the 2236 unique solution changes from steady to oscillatory. The simplest example of this type of bifurcation, called Hopf 2237 bifurcation, is given by 2238

$$\frac{dx}{dt} = \lambda x - \omega y - x(x^2 + y^2)$$

$$\frac{dy}{dt} = \lambda y + \omega x - y(x^2 + y^2).$$
(A4)

It can be easily checked that, at $\lambda = 0$, the Jacobian matrix **J** 2240 associated with the trivial solution $\bar{x} = \bar{y} = 0$ has a complex 2241 conjugate pair of eigenvalues $\sigma = \pm i\omega$.

[165] Transformation of (A4) to polar coordinates x = r 2243 $\cos \theta$, $y = r \sin \theta$ yields the more transparent form 2244

$$\frac{dr}{dt} = \lambda r - r^3$$

$$\frac{d\theta}{dt} = \omega.$$
(A5)

Comparing (A5) with (A2), it can be seen that a pitchfork 2246 bifurcation occurs at $\lambda=0$ in the (r,λ) plane. For $\lambda<0$, 2247 only one stable fixed point, $\bar{r}=0$, exists; it corresponds to a 2248 steady solution of the original equations. For $\lambda>0$, 2249 however, the nontrivial stable fixed points given by $r=\pm\sqrt{\lambda}$ 2250 now represent a periodic solution of the original equations, 2251 with a period of $2\pi/\omega$. Hence a transition from steady to 2252 periodic behavior occurs as λ crosses zero.

[166] The emergence of the periodic orbit can be seen 2254 explicitly by computing trajectories of the equations (A4) 2255 for a subcritical value of $\lambda=-0.1$ and a supercritical value 2256 of $\lambda=0.1$. In the subcritical case (Figure A2a), the 2257 trajectory spirals in and finally ends up at the stable fixed 2258 point (0, 0). In the supercritical case (Figure A2b), however, 2259 it spirals onto the periodic orbit with $\bar{r}=1.0/\sqrt{10}$ that arises 2260 through the Hopf bifurcation.

[167] A trajectory starting at (0, 0.1) is also plotted as the 2262 dashed curve in Figure A2b and demonstrates that the origin 2263 has become an unstable fixed point; this trajectory spirals 2264 out to approach asymptotically the periodic orbit from 2265 within.

[168] The stable periodic orbits that arise by a Hopf 2267 bifurcation are called limit cycles. They represent the 2268 nonlinear saturation of a linear oscillatory instability. 2269 Well-known examples of Hopf bifurcations in atmo- 2270 spheric dynamics include baroclinic instability [Lorenz, 2271 1963b; Pedlosky, 1987] and oscillatory topographic 2272 instability [Legras and Ghil, 1985; Ghil and Vautard, 2273 1991].

A3. The 1.5-Layer Shallow Water Model

[169] Consider a rectangular ocean basin of dimensions 2277 $L \times 2L$ on a midlatitude β plane with Coriolis parameter f=2278 $f_0+\beta_0 y$; x and y are eastward and northward pointing 2279 Cartesian coordinates. An active layer of mean depth D with 2280 density ρ_0 is situated above a slightly heavier layer that has a 2281 density $\rho_0+\Delta\rho$ and is supposed to be motionless. The 2282 interface between the two layers is conceptually identified 2283 with the permanent thermocline. It is able to deform, and 2284 the reduced gravity g' that acts on the upper layer is given 2285

2286 by $g' = g\Delta\rho/\rho_0$. Such a shallow water model is commonly 2287 referred to as a 1.5-layer model.

2288 [170] The flow is driven by a wind stress $\tau(x, y) = \tau_0(\tau^x, 2289 \ \tau^y)$ with amplitude τ_0 , assumed to be constant in time, and 2290 spatial pattern (τ^x, τ^y) . Lateral friction, with coefficient A_H , 2291 and bottom friction, with coefficient R, are the only dissi-2292 pative mechanisms. The stratification, i.e., the vertical 2293 structure of the density and flow fields and the description 2294 of subgrid-scale mixing processes are thus highly 2295 simplified.

2296 [171] The velocities in the eastward and northward direc-2297 tions are denoted by $\mathbf{v} = (u, v)$, and h = h(x, y, t) is the 2298 thickness of the upper layer, which takes the equilibrium 2299 value D in the absence of forcing. The upper layer mass flux 2300 vector \mathbf{V} is given by $\mathbf{V} = (U, V) = (hu, hv)$, and the equations 2301 describing the flow are [Jiang et al., 1995]

$$\begin{split} \frac{\partial U}{\partial t} + \nabla \cdot (\mathbf{v}U) - fV &= -g'h \frac{\partial h}{\partial x} + A_H \nabla^2 U - RU + \alpha_\tau \frac{\tau_0 \tau^x}{\rho_0}, \\ \frac{\partial V}{\partial t} + \nabla \cdot (\mathbf{v}V) + fU &= -g'h \frac{\partial h}{\partial y} + A_H \nabla^2 V - RV + \alpha_\tau \frac{\tau_0 \tau^y}{\rho_0}, \\ \frac{\partial h}{\partial t} &= -\frac{\partial U}{\partial x} - \frac{\partial V}{\partial y}. \end{split} \tag{A6}$$

2303 No-slip conditions are specified on the boundary, and an 2304 idealized wind stress, given by

$$\tau^{x}(y) = -\cos\left(\frac{k\pi y}{2L}\right) \quad \tau^{y} = 0, \quad 0 \le y \le 2L,\tag{A7}$$

2306 forces the circulation within the basin. Double-gyre forcing 2307 studies use a wind forcing with k = 2, whereas single-gyre 2308 studies have used k = 1. The double-gyre forcing, as well as 2309 the boundary conditions, have mirror symmetry about the 2310 mid-axis of the basin, located at y = L.

2311 [172] To help understand the bifurcation behavior of the 2312 shallow water model, *Jiang et al.* [1995] introduced a 2313 highly truncated QG model, with only two modes:

$$\frac{dA}{dt} - \mu AB + \nu A = \eta_1$$

$$\frac{dB}{dt} + \mu A^2 + \nu B = \eta_2.$$
(A8)

2315 Here A and B are the symmetric and antisymmetric 2316 components, respectively, of the flow, while μ and ν are 2317 positive constants, with μ proportional to the Rossby 2318 number and ν proportional to the characteristic width of 2319 the western boundary layer. The wind stress forcing is 2320 represented by its antisymmetric and symmetric parts, η_1 2321 and η_2 .

2322 [173] In fact, there are two distinct boundary layer thick-2323 nesses, the Munk thickness $\delta_M = (A_H/\beta_0)^{1/3}$ and the inertial 2324 boundary layer thickness $\delta_I = (\bar{U}/\beta_0)^{1/2}$; here is a character-2325 istic depth-averaged horizontal velocity. Two important 2326 nondimensional numbers that characterize the flow are the 2327 Rossby number $\epsilon = \bar{U}/(f_0L)$ and the Reynolds number $Re = 2328 \ (\delta_I/\delta_M)^3$.

A4. The 2-D Boussinesq Equations

[174] The simplest 2-D model employs a Cartesian coor- 2330 dinate system, with meridional coordinate $0 \le y \le L$ and 2331 vertical coordinate $0 \le z \le H$, where H and L are the depth 2332 of the fluid and the meridional extent of the basin, respectively. For 2-D flow fields, which do not depend on the 2334 zonal coordinate, the equations governing the meridional 2335 velocity v, vertical velocity w, pressure p, density p, temperature p, and salinity p are 2337

$$\frac{\partial u}{\partial t} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{1}{\rho_0} \frac{\partial p}{\partial y} = A_H \frac{\partial^2 v}{\partial y^2} + A_V \frac{\partial^2 v}{\partial z^2},$$

$$\frac{\partial w}{\partial t} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{1}{\rho_0} \frac{\partial p}{\partial z} + \frac{\rho}{\rho_0} g = A_H \frac{\partial^2 w}{\partial y^2} + A_V \frac{\partial^2 w}{\partial z^2},$$

$$0 = \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z},$$

$$\frac{\partial T}{\partial t} + v \frac{\partial T}{\partial y} + w \frac{\partial T}{\partial z} = K_H \frac{\partial^2 T}{\partial y^2} + K_V \frac{\partial^2 T}{\partial z^2},$$

$$\frac{\partial S}{\partial t} + v \frac{\partial S}{\partial y} + w \frac{\partial S}{\partial z} = K_H \frac{\partial^2 S}{\partial y^2} + K_V \frac{\partial^2 S}{\partial z^2}.$$
(A9)

(A6) [175] The simplest equation of state is a linear dependence of density on temperature and salinity, i.e., $\rho=2341$ d an $\rho_0[1-\alpha_T(T-T_0)+\alpha_S(S-S_0)]$, while the Boussinesq 2342 approximation for thermosolutal convection allows the 2343 density to vary only in the buoyancy term of (A9). Here 2344 $A_{H/V}$ and $K_{H/V}$ are the diffusivities of momentum and of 2345 heat and salt, respectively. Since we are interested in a 2346 thin layer, $H/L \ll 1$, we consider eddy diffusivities that 2347 may take very different values in the vertical and horizontal directions [*Quon and Ghil*, 1995]. The rectangular 2349 flow domain is typically assumed to be symmetric about 2350 the equator.

[176] The boundary conditions for temperature and salin- 2352 ity at the ocean surface z = H become, in the limit of 2353 restoring temperature conditions and prescribed freshwater 2354 flux, 2355

$$T(y,H) = T_S(y)\Delta T,$$

$$K_V \frac{\partial S}{\partial z}(y,H) = F_0 F_S(y),$$
(A10)

where both T_S and F_S are prescribed dimensionless 2357 functions and ΔT is a typical meridional temperature 2358 difference. The freshwater flux has again been converted 2359 into an equivalent salt flux [*Huang*, 1993]. Salinity and heat 2360 fluxes are assumed to be zero at the bottom, and lateral 2361 boundaries and free-slip conditions are applied at all 2362 boundaries.

[177] When these equations are nondimensionalized, a 2364 number of parameters appear that depend on the type of 2365 scaling. For example, scales L_* , K_H/L_* , $\rho_0 K_H$ A_H/H^2 , ΔT , 2366 and ΔS for length, velocity, pressure, temperature and 2367 salinity can be used, with ΔS being a characteristic merid-2368 ional salinity difference. In this case the Prandtl number Pr, 2369 the thermal Rayleigh number Ra, the buoyancy ratio $\overline{\lambda}$, the 2370 aspect ratio A, the salt flux strength γ , the ratios of vertical 2371 and horizontal diffusivities for momentum R_{HV}^M and for heat 2372

2373 and salt R_{HV}^T appear. These nondimensional parameters are 2374 defined as

$$Pr = \frac{A_H}{K_H}, \quad Ra = \frac{g\alpha_T \Delta T L_*^3}{A_H K_H}, \quad A = \frac{H}{L_*}, \quad \gamma = \frac{F_0 H}{K_V},$$
$$R_{HV}^M = \frac{A_V}{A_H}, \quad R_{HV}^T = \frac{K_V}{K_H}, \quad \overline{\lambda} = \frac{\alpha_S \Delta S}{\alpha_T \Delta T}.$$

[178] The system of dimensionless equations thus con-2378 tains seven parameters. However, if the salinity is rescaled 2379 with λ , only six of the original seven parameters remain. 2380 Usually, the product $\gamma \overline{\lambda}$ is taken as the parameter that 2381 measures the strength of the freshwater flux. The scale 2382 invariance of physical laws permits one to determine 2383 rigorously the number of independent parameters in a 2384 fluid-dynamical problem. This result is often called Buck-2385 ingham's Π-theorem [Barenblatt, 1987; Ghil et al., 2002a] 2386 and its application to the 2-D THC does yield the number 2387 six above.

[179] **ACKNOWLEDGMENTS.** It is a pleasure to thank many 2389 colleagues who shared ideas and preprints with us. We are grateful to 2390 all our associates who worked with us on the low-frequency 2391 variability of the oceans: Y. Chao, K.-I. Chang, S. Drijfhout, 2392 S. Jiang, F.-F. Jin, F. Chen, Y. Feliks, K. Ide, M. Karaca, C. Katsman, 2393 C.-C. Lai, H. Le Treut, G. Loeper, J. C. McWilliams, M. J. 2394 Molemaker, J. Nauw, J. D. Neelin, H. Öksüzŏglu, D. Paillard, 2395 Z. Pan, C. Quon, L. te Raa, W. de Ruijter, M. Schmeits, E. Simonnet, 2396 L. U. Sushama, R. Temam, P. van der Vaart, S. Wang, W. Weijer, 2397 A. Wirth, and F. W. Wubs. The paper benefited from careful reading 2398 and many constructive comments by P. DeMenocal, E. Tziperman, 2399 and several anonymous reviewers. This work was supported by the 2400 Netherlands Organization for Scientific Research (NWO) under a 2401 NWO-PIONIER grant (H.D.) and by NSF grants ATM00-83121 and 2402 OCE02-221066 and DOE grant DE-FG02-01ER63251 (M.G.).

[180] The Editor responsible for this paper was Peter B. 2404 deMenocal. He thanks two anonymous reviewers and one anony-2405 mous cross-disciplinary reviewer.
