Abstract. We present a Bayesian hierarchical model for reconstructing the continuous and dynamic evolution of relative sea-level (RSL) change with quantified uncertainty. The reconstruction is produced from biological (foraminifera) and geochemical ($\delta^{13}\text{C}$) sea-level indicators preserved in dated cores of salt-marsh sediment. Our model is comprised of three modules: (1) a new Bayesian transfer (B-TF) function for the calibration of biological indicators into tidal elevation, which is flexible enough to formally accommodate additional proxies; (2) an existing chronology developed using the Bchron age–depth model, and (3) an existing Errors-In-Variables integrated Gaussian process (EIV-IGP) model for estimating rates of sea-level change. Our approach is illustrated using a case study of Common Era sea-level variability from New Jersey, USA. We develop a new B-TF using foraminifera, with and without the additional ($\delta^{13}\text{C}$) proxy and compare our results to those from a widely used weighted-averaging transfer function (WA-TF). The formal incorporation of a second proxy into the B-TF model results in smaller vertical uncertainties and improved accuracy for reconstructed RSL. The vertical uncertainty from the multi-proxy B-TF is $\sim 28\%$ smaller on average compared to the WA-TF. When evaluated against historic tide-gauge measurements, the multi-proxy B-TF most accurately reconstructs the RSL changes observed in the instrumental record (mean square error = 0.003 m^2). The Bayesian hierarchical model provides a single, unifying framework for reconstruct-

ing and analyzing sea-level change through time. This approach is suitable for reconstructing other paleoenvironmental variables (e.g., temperature) using biological proxies.

1 Introduction

Paleoenvironmental reconstructions describe Earth's response to past climate changes and offer a context for current trends and analogs for anticipated future changes (e.g., Mann et al., 2009). Reasoning by analogy underpins the use of biological proxies for paleoenvironmental reconstructions (e.g., Rymer, 1978; Jackson and Williams, 2004; Bradley, 2015). The ecological preferences of biological proxies observed in modern environments are used to derive a paleoenvironmental reconstruction from their counterparts preserved in dated sediment cores under the assumption that their ecological preferences were unchanged through time (e.g., Juggins and Birks, 2012). This approach commonly utilizes data consisting of one environmental variable and counts from multiple proxy species (e.g., Imbrie and Kipp, 1971; Fritz et al., 1991; Birks, 1995). Numerical techniques known as transfer functions formalize the relationship between biological assemblages and the environmental variable. This step is termed calibration. To quantify environmental change through time it is necessary to combine the paleoenvironmental reconstruction with a chronology of sediment deposition and an

appropriate methodology to describe temporal trends. These three components can be developed and applied independently of one another or assimilated in a single framework.

Relative sea-level (RSL) reconstructions can constrain the relationship between temperature and sea level and reveal the long-term, equilibrium response of ice sheets to climate forcing (e.g., Dutton et al., 2015). Some of the most accurate and precise RSL reconstructions are produced from salt-marsh foraminifera. Foraminifera are used as sea-level proxies because species have different ecological preferences for the frequency and duration of tidal submergence, which is primarily a function of tidal elevation (e.g., Scott and Mediolini, 1978; Horton and Edwards, 2006; Edwards and Wright, 2015). Under conditions of RSL rise, salt-marshes accumulate sediment to maintain an elevation in the tidal frame. The resulting sedimentary sequence is an archive of past RSL changes that may be accessed by collecting sediment cores. After extraction, these sediment cores are sliced into layers (samples), from which foraminifera are counted. The transfer functions commonly used to reconstruct RSL impose a single ecological response to tidal elevation on all species of foraminifera (or other biological groups such as diatoms). Other analyses performed on the same layers can provide a multi-proxy approach to reconstructing RSL, although this often relies on informal approaches to combine results from independent proxies (e.g., Kemp et al., 2013a; Gehrels, 2000; Nelson et al., 2008). For example, on organogenic salt-marshes on the US Atlantic coast the primary source of organic carbon is *in situ* plant material and measurements of bulk sediment $\delta^{13}\text{C}$ reflect the dominant plant community (e.g., Kemp et al., 2012). Since salt-marsh plants are also sea-level proxies, the $\delta^{13}\text{C}$ values can be used to reconstruct RSL. Some sediment layers are dated using radiocarbon or recognition of pollution and vegetation clearance markers of known age. Since there are typically fewer dated layers than total layers, a statistical age–depth model is used to estimate the age of undated layers with uncertainty (e.g., Bronk Ramsey, 2008; Haslett and Parnell, 2008; Blaauw and Christen, 2011). Although Bayesian age–depth models and methods for estimating rates of sea-level change already exist, Bayesian methods are yet to be applied in the calibration phase of reconstructing RSL, preventing the appropriate propagation of uncertainties.

We develop a Bayesian transfer function (B-TF) to reconstruct RSL using foraminifera (expressed as raw counts) and measurements of bulk sediment $\delta^{13}\text{C}$ from salt-marsh sediment. This model allows each species of foraminifera to have a different ecological response to tidal elevation and provides a formalized approach to combine multiple proxies and consequently reduce reconstruction uncertainty. Following the framework of Parnell et al. (2015) we combine this new B-TF with an existing chronology module (Bchron), and an existing Errors-In-Variables Integrated Gaussian Process (EIV-IGP) Cahill et al. (2015) to create a holistic Bayesian hierarchical model. Through application of the model to a case

study of Common Era and RSL change in New Jersey (USA), we compare the utility of the B-TF with an existing weighted averaging transfer function (WA-TF) approach.

2 Previous calibration methods

Transfer functions are empirically derived equations for reconstructing past environmental conditions from the abundance of multiple species. The term refers not to a single numerical method, but to a range of regression-based techniques that are classified into two categories depending on whether the underlying model maps environmental variables to species abundances (classical calibration) or vice versa (inverse calibration). Classical approaches are underpinned by the ecologically intuitive assumption that the distribution of species is driven by environmental variables (e.g., Birks, 2012). Inverse approaches initially gained popularity because of their reduced computational complexity (e.g., Birks, 2010) resulting in quicker processing compared to classical methods. Furthermore, inverse methods often demonstrate equal or superior performance when compared to classical approaches (e.g., Toivonen et al., 2000; ter Braak and Juggins, 1993; Korsman and Birks, 1996). The parameters in transfer functions are estimated using empirical data (a modern training set) from environments likely to be analogous to those encountered in core material (e.g., Juggins and Birks, 2012) and are treated as fixed and known. Studies seeking to reconstruct RSL from salt-marsh sediment employ transfer functions developed using a modern training set of paired observations of tidal elevation and microfossil assemblages (most commonly foraminifera or diatoms) to reconstruct RSL from their counterparts preserved in sediment cores (e.g., Horton et al., 1999; Gehrels, 2000; Edwards and Horton, 2006; Kemp et al., 2013b; Barlow et al., 2014). Although the different types of transfer function have advantages and weaknesses compared to one another, these regression-based techniques share the limitations of applying a single response form to all species and treating model parameters as fixed and known. Applying a single response form can result in misleading or inaccurate paleoenvironmental reconstructions if the response curve is not appropriate for all species (Greig-Smith, 1983) and does not account for the inherent uncertainty in model parameters that results from ecological noise and the influence of secondary environmental variables, which in RSL reconstructions can include salinity, pH and sediment texture and composition (e.g., Shennan et al., 1996; Zong and Horton, 1999; Horton et al., 1999).

Bayesian calibration methods are inherently classical and have recently been given growing attention to produce paleoenvironmental reconstructions using biological proxies (e.g., Toivonen et al., 2000; Vasko et al., 2000; Haslett et al., 2006; Li et al., 2010; Tingley et al., 2012; Tolwinski-Ward et al., 2013, 2015; Parnell et al., 2015). Toivonen et al. (2000) and Vasko et al. (2000) developed a Bayesian model to re-

construct temperature from chironomid counts. Haslett et al. (2006) adopted elements of the model proposed by Toivonen et al. (2000) in a more complex Bayesian hierarchical model for reconstructing multivariate climate histories from pollen counts. Li et al. (2010) proposed a Bayesian hierarchical model to reconstruct temperature from pollen using a multi-proxy approach. Similarly, Tingley et al. (2012) considered a Bayesian hierarchical space-time model for inferring climate processes. More recently, Tolwinski-Ward et al. (2013, 2015) and Parnell et al. (2015) expanded on the aforementioned approaches of Haslett et al. (2006) and Tingley et al. (2012) for reconstructing climate variables. To date, Bayesian methods have not been used for reconstructing RSL using biological proxies.

3 A Bayesian hierarchical model for reconstructing and analyzing former sea levels

We now describe our statistical model, which produces estimates of RSL and associated rates from raw inputs including foraminifera counts and radiocarbon dates (or dates produced from recognition of pollution and vegetation clearance markers of known age) from a sediment core. There are two advances from existing approaches:

1. A B-TF model using a penalized spline (P-spline) as a non-parametric model of the multinomial response of foraminifera counts to tidal elevation. The multinomial distribution can take account of the fact that large counts give reduced uncertainty and the P-spline model allows for multi-modal and non-Gaussian species response to environmental variables;
2. A full hierarchical model which incorporates the B-TF, a chronology model accounting for time uncertainty, and a rich stochastic process for quantifying sea-level rate changes.

We use the JAGS package (Just Another Gibbs Sampler; Plummer, 2003) to fit the model via Gibbs sampling.

We start by outlining our notation:

- \mathbf{y} are the observed foraminifera (expressed as raw counts) from the sediment core. y_{il} is the count of species l in layer i . We denote \mathbf{y}_i the L -vector of foraminifera counts for each layer i in the sediment core, where $i = 1, \dots, N$ layers and $l = 1, \dots, L$ species;
- \mathbf{r} are the observed radiocarbon dates in the sediment core. r_k is the k th radiocarbon date, $k = 1, \dots, K$. Usually $K \ll N$. Due to the nature of radiocarbon, these are given in radiocarbon years rather than calendar years. A known calibration curve is used to transform the radiocarbon ages into calendar ages as part of the chronology model;
- \mathbf{d} are the observed depths in the sediment core. d_i is the depth associated with layer i ;

- e is paleo-marsh elevation (PME), which is the tidal elevation at which a layer originally accumulated. e_i is the PME for sediment core layer i ;
- s is RSL. s has a deterministic relationship with e and d given some fixed parameters ω so that $s = g_\omega(e, d)$. Producing s will require correcting PME for sample tidal elevation (a function of sediment core depth). s_i is the RSL for sediment core layer i ;
- \mathbf{t} represents the calendar ages (in years before present (1950); BP) of all layers in the sediment core. It is unknown and estimated with uncertainty as part of the chronology module from the radiocarbon dates r (and non radiocarbon dates) and observed depths d . t_i represents the age of sediment core layer i ;
- \mathbf{y}^m are the observed modern foraminifera counts. y_{jl}^m is the abundance of species l in surface sample j . \mathbf{y}_j^m is an L -vector of modern foraminifera counts for modern sample j with $j = 1, \dots, J$ modern samples. $T_j = \sum_{l=1}^L y_{jl}^m$ are the row totals of species counts for calibration sample j in the matrix of species abundances;
- \mathbf{e}^m are the observed modern tidal elevations. e_j^m is the tidal elevation for surface sample j . Together \mathbf{y}^m and \mathbf{e}^m are used to calibrate the relationship between foraminifera abundance and tidal elevation;
- \mathbf{z} is the sediment core $\delta^{13}\text{C}$ where z_i is the $\delta^{13}\text{C}$ for layer i . We include this as a secondary proxy though it is an optional part of the model and can be removed if unavailable in other sediment cores;
- $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$ are a set of parameters governing the relationship between foraminifera (expressed as raw counts) and tidal elevation and $\delta^{13}\text{C}$ and tidal elevation respectively;
- $\boldsymbol{\psi}$ are a set of parameters governing the sedimentation process (i.e., linking age and depth);
- $\boldsymbol{\phi}$ are a set of parameters governing the RSL process, including its smoothness and variability;

Using the notation above we create a Bayesian hierarchical model to produce a posterior distribution of our parameters given data:

$$p(\mathbf{s}, \mathbf{e}, \mathbf{t}, \boldsymbol{\theta}, \boldsymbol{\psi}, \boldsymbol{\phi}, \boldsymbol{\alpha} | \mathbf{y}^m, \mathbf{e}^m, \mathbf{y}, \mathbf{r}, \mathbf{d}, \boldsymbol{\omega}, \mathbf{z}) \propto$$

$$\underbrace{p(\mathbf{y} | \mathbf{e}, \boldsymbol{\theta}) p(\mathbf{z} | \mathbf{e}, \boldsymbol{\alpha})}_{\text{Fossil Data Model}} \times \underbrace{p(\mathbf{y}^m | \mathbf{e}^m, \boldsymbol{\theta})}_{\text{Modern Calibration Model}} \times \underbrace{p(\mathbf{r} | \mathbf{t}, \boldsymbol{\psi}, \mathbf{d})}_{\text{14C Calibration}} \times \underbrace{p(\mathbf{t} | \mathbf{d}, \boldsymbol{\psi})}_{\text{Chronology Model}}$$

$$\times \underbrace{p(\mathbf{s} | \mathbf{e}, \mathbf{d}, \mathbf{t}, \boldsymbol{\phi}, \boldsymbol{\omega})}_{\text{Sea level Model}} \times \underbrace{p(\boldsymbol{\theta})}_{\text{Modern Calibration Prior}} \times \underbrace{p(\boldsymbol{\psi})}_{\text{Chronology Prior}} \times \underbrace{p(\boldsymbol{\phi})}_{\text{Sea Level Prior}} \times \underbrace{p(\boldsymbol{\alpha})}_{\delta^{13}\text{C Prior}}$$

Before describing the components of the model that we use, we note that this is an extremely complex and computationally demanding model to fit, being of very high dimension

with rich stochastic processes being required for many of the sub-models. We follow Parnell et al. (2015) in making some simplifying assumptions. First, we assume that the calibration parameters θ can be learnt solely from the modern calibration data y^m and e^m . Thus, the sediment core data contain no further information about this relationship. This is a common assumption in many paleoclimate studies (e.g., Haslett et al., 2006; Tolwinski-Ward, 2015). Second, we assume that the model can be modularized into three parts: the aforementioned calibration, chronology and process modules. This is a conservative assumption and follows from the restriction on the calibration parameters.

Following these assumptions, we obtain the three modules:

$$\begin{aligned} p(\theta|y^m, e^m) &\propto p(y^m|e^m, \theta)p(\theta) \text{ calibration module} \\ p(t, \psi|r, d) &\propto p(r|d, t, \psi)p(t|d, \psi)p(\psi) \text{ chronology module} \\ p(s, e, t, \theta, \psi, \phi, \alpha|y^m, e^m, y, r, d, \omega, z) &\propto \\ p(y|e, \theta)p(\theta|y^m, e^m)p(t, \psi|r, d)p(s|e, \omega, d, t, \phi)p(\phi) \\ p(z|e, \alpha)p(\alpha) &\text{ process module.} \end{aligned}$$

We note that if there is no additional $\delta^{13}\text{C}$ proxy information then z and α and hence the last two terms on the right-hand side of the process module are removed from the equation.

3.1 The calibration module: multinomial P-splines (B-TF)

In this module we aim to estimate the parameters θ that govern the relationship between foraminifera and tidal elevation by using the model as specified in the Sect. 3. The probability density function $p(y_j^m|e_j^m, \theta)$ used as the likelihood here provides the data-generating mechanism from which foraminifera abundances can be simulated given tidal elevation. The likelihood we use for the modern model is

$$y_{j1}^m, y_{j2}^m, \dots, y_{jL}^m | T_j, p_{j1}, p_{j2}, \dots, p_{jL} \sim \quad (1)$$

$$\text{Multinomial}(p_{j1}, p_{j2}, \dots, p_{jL}, T_j), \quad (2)$$

where $p_j = \{p_{j1}, p_{j2}, \dots, p_{jL}\}$ is the vector containing the probability of finding species l at the tidal elevation associated with sample j .

The probability vectors p_j are estimated from a latent response λ_{jl} (i.e., the response of species l for sample j) which is a function of tidal elevation e_j^m . λ_l is a J -vector including the latent response of species l for all samples j . The relationship between probability of foraminifera species occurrence and tidal elevation is expected to be nonlinear so we model these using P-splines (De Boor, 1978; Dierckx, 1993) via a softmax transformation. The softmax transformation is given as

$$p_{jl} = \frac{\exp(\lambda_{jl})}{\sum_{l=1}^L \exp(\lambda_{jl})}, \quad (3)$$

where λ_l are given P-spline prior distributions. P-splines are created from B-spline basis functions penalized to produce a smooth curve. The B-spline basis functions are constructed from piecewise polynomial functions that are differentiable to a given degree q , here cubic. The component cubic B-spline basis functions look like individual Gaussian curves, however, they will be non-zero only over the range of $q+2$ knots; this has numerous computational advantages. We refer to the B-spline matrix as \mathbf{B} . The columns of \mathbf{B} are the tidal elevations e^m , transformed by the appropriate basis function. The resulting relationship is

$$\lambda_l = \mathbf{B}\beta_l + \epsilon_l. \quad (4)$$

\mathbf{B} is a $J \times M$ matrix of basis functions where M is the number of knots, and J is the number of modern samples. To obtain the penalized smooth behavior for λ_l we apply a prior such that the first differences of β_l are normally distributed with mean 0 and precision τ_β . The parameter τ_β controls how close the weights are related to each other and will therefore control smoothness.

An error term, $\epsilon_l \sim N(0, \nu_l)$, is added to the mean for λ_l here to ensure that we do not encounter problems with over-dispersion by under or over-estimating the variance in the observed data. We do not assume a constant variance; to account for the changing variation in the data the precision parameters ν_l are also estimated using P-splines, i.e., $\nu_l = \exp(\mathbf{B}\gamma_l)$. This allows the variance to adapt given the data and will allow it to increase/decrease where necessary. Similarly to Eq. (4), the basis functions are penalized by parameters γ_l to produce ν_l and we apply a prior such that the first differences of γ_l are normally distributed with mean 0 and precision τ_γ . Therefore, the calibration model has parameters $\theta = \{\beta_l, \gamma_l, \tau_\gamma, \tau_\beta; l = 1, \dots, L\}$, which can be fitted in a single Bayesian model for all species simultaneously.

The B-TF produces posterior estimates for the multinomial probability vector p_j for each modern sample. For each species of foraminifera, we compare the probability of species occurrence (at each modern observed tidal elevation) estimated from the B-TF, with the empirical probability of foraminifera species occurrence estimated from the observed data. The model vs. empirical probability comparison provides evidence to support the validity of the model. The comparison indicates whether the model is capable of capturing the within-species variability of occurrence probabilities across changing tidal elevations. Once run, the B-TF can produce estimates of PME for each layer in the sediment core from this relationship. A uniform prior is supplied for unknown PME suggesting that all elevations in a given range are equally likely. For our New Jersey case study we chose a range of 0 to 150 SWLI. This range is specific to this case study and would need to be updated at different locations.

We evaluate the performance of the B-TF via 10-fold cross-validation on the modern data, where the data are divided up into 10 randomly drawn equal size sections (known as folds) which are removed in turn. We create predictions for

the removed sections repeatedly until every observation has an out-of-sample prediction value. To allow direct and meaningful comparison between models, we also cross-validated the WA-TF using the same approach on the same randomly drawn folds.

3.2 The inclusion of a secondary proxy

In cases where the secondary $\delta^{13}\text{C}$ proxy is available, the posterior estimated for e_i will include the likelihood $p(z|e, \alpha)$. This is a normal likelihood $z_i \sim N(\mu_i, \tau_z)$ where the precision τ_z is constant and μ_i will correspond to the dominant $\delta^{13}\text{C}$ value at e_i . $\delta^{13}\text{C}$ reflect dominant plant communities on a marsh and the observed modern boundaries between communities can correspond to a tidal datum (TD). As a result $\delta^{13}\text{C}$ measured in bulk sediment can be related to tidal elevation as follows:

$$\mu_i = \begin{cases} \mu_1, & \text{if } e_i \leq \text{TD} \\ \mu_2, & \text{if } e_i \geq \text{TD} \\ \mu_3, & \text{otherwise,} \end{cases}$$

where μ_i are given informative uniform priors with upper and lower limits corresponding to the maximum and minimum $\delta^{13}\text{C}$ values represented in a given elevational range. The prior information required here is location specific. For example, for the New Jersey case study sites the TD is MHHW. At these sites $\delta^{13}\text{C}$ can range anywhere from -28 to -22‰ at elevations above MHHW and anywhere from -18.9 to -12‰ at elevations below MHHW. Therefore, the prior for $\mu_1 \sim U(-28, -22)$ and $\mu_2 \sim U(-18.9, -12)$. In cases where $\delta^{13}\text{C}$ values fall in the range -21.9 to -19‰ they cannot provide information about elevation in relation to MHHW, thus $\mu_3 \sim U(-21.9, -19)$.

3.3 The chronology module: Bchron

The chronology module is concerned with estimating the ages t of the foraminifera in the sediment core. These ages will necessarily be uncertain, since the radiocarbon dates r (and non-radiocarbon dates) are observed with uncertainty. An interpolation step is then required to obtain estimated ages at all depths, which adds further uncertainty. A useful constraint is that age must increase with depth (the law of superposition; Steno, 1669) so a monotonic stochastic process is used. Bchron (Haslett and Parnell, 2008) assumes that the integrated sedimentation rate (i.e., the accumulation of sediment over a fixed period of time) arises as the realization of a compound Poisson–Gamma (CPG) process. Bchron calibrates the radiocarbon (and non-radiocarbon) dates, estimates the parameters of the CPG (here ψ) and identifies outliers. Other age–depth models are available (see Parnell et al., 2011 for a review), but Bchron was designed specifically for use in paleoenvironmental reconstructions.

Once Bchron has been run, we obtain a joint posterior distribution of ages for every layer in the sediment core,

which we denote as $p(t|r, \mathbf{d}, \psi)$. Each individual chronology sample from Bchron satisfies the law of superposition. However, we approximate the age of each layer in the posterior – i.e., $p(t_i|r, \mathbf{d}, \psi)$ as a normal distribution – so that $t_i|r, \mathbf{d}, \psi \sim N(\mu_{t_i}, \sigma_{t_i}^2)$. This may seem like a severe relaxation, since the ages of layers may now overlap, but we find this has minimal effect on the resulting RSL reconstructions since the ages are further updated during the process module. Further simulations justifying this assumption have been carried out using chronological models in late Holocene sea-level reconstructions from salt-marsh sediments (Parnell and Gehrels, 2015).

3.4 The process module: Errors-In-Variables integrated Gaussian process (EIV-IGP)

Our final step is to transform PME, e_i into RSL, s_i via the relationship $s_i = g_\omega(e_i, d_i)$. We then have a set of bivariate probability distributions for each layer consisting of pairs (t_i, s_i) which represent the raw layer-by-layer estimates of RSL and age. To use these in the EIV-IGP framework of Cahill et al. (2015), we approximate each bivariate probability distribution as bivariate Gaussian. The model makes use of two well-known statistical approaches. Firstly, the EIV approach (Dey et al., 2000) accounts for measurement error in the explanatory variable, here time. The EIV approach is necessary when dealing with proxy reconstructions that include temporal uncertainty from dating the sediment core. Secondly, the Gaussian process approach (Rasmussen, 2006) is useful for nonlinear regression problems and is a practical approach to modeling time series data. A Gaussian process is fully specified by a mean function (set to zero) and a covariance function that relates the observations to one another.

We use an integrated Gaussian process approach (Holsclaw et al., 2013; Cahill et al., 2015). A Gaussian process prior is placed on the rates of sea-level change and the mean of the distribution assumed for the observed data is derived from the integral of the rate process. This integrated approach is useful when there is interest in the rate process as the analysis allows for estimates of instantaneous rates of RSL change. Furthermore, the current RSL estimate is derived as the integral of all the previous RSL rates that have occurred, matching the physical behavior of sea-level evolution over time. By embedding the integrated Gaussian process (IGP) model in an Errors-In-Variables (EIV) framework (which takes account of time uncertainty), we can estimate rates with quantified uncertainty. We use the same priors for the parameters ϕ as described in Cahill et al. (2015).

4 Case study: New Jersey Common Era sea level

On the Atlantic coast of southern New Jersey (Fig. 1), salt marshes form in quiet-water, depositional settings and display a zonation of plants into distinct vertical zones corresponding to ecologically important tide levels. Elevations be-

low mean tide level (MTL) are not vegetated and the inorganic sediment is comprised of silt and fine sand, often with shell material. Low salt-marsh environments between MTL and mean high water (MHW) are vegetated by *Spartina alterniflora* (tall form), which is a C₄ plant. Sediment in this zone is organic gray silt and clay. High salt-marsh environments exist between MHW and highest astronomical tide (HAT). This zone is typically a wide, flat meadow vegetated by *Spartina patens* and *Distichlis spicata* (C₄ species). The sediment deposited in this zone is brown peat with abundant plant remains. The transition between high salt-marsh and the freshwater upland is vegetated by C₃ plants such as *Phragmites australis*, *Iva frutescens*, *Schoenoplectus americanus*, and *Typha angustifolia*. This community exists at tidal elevations above mean higher high water (MHHW), including freshwater environments above the reach of tidal influence, and occurs with black, amorphous, organic sediment.

4.1 Modern training set

The transfer function approach is under-pinned by surveys that quantify the modern, observable relationship between foraminifera and tidal elevation. Modern (surface) samples are collected from depositional environments analogous to those represented in the fossil material under investigation (Horton and Edwards, 2005). At individual sites sampling should span the full range of tidal elevations from shallow sub-tidal settings through to supra-tidal zones. Kemp et al. (2013a) compiled a modern training set from 12 salt-marshes in southern New Jersey (Fig. 1). At stations along each transect, surface (0–1 cm) sediment samples were collected to count foraminifera. The tidal elevation of each sample was measured in the field. Since the great diurnal tidal range (mean lower low water to MHHW) varies among sites in the study region, tidal elevation is expressed as a standardized water level index (SWLI; e.g., Horton et al., 1999), where a value of 0 corresponds to MLLW and 100 is MHHW. We used the modern training set of Kemp et al. (2013a) without modification.

The 12 sites were selected to span a wide range of physiographic settings including brackish marshes located up to 25 km from the coast with a strong fluvial influence. The sites share a common climate and oceanographic regime and therefore constitute a regional-scale training set. The spatial scope of modern training sets has frequently been discussed and it is widely accepted that regional-scale training sets capture natural variability in the distribution of foraminifera and provide a large suite of samples from which to draw modern analogs (e.g., Horton and Edwards, 2005). The principal advantage of local-scale training sets is that they produce more precise reconstructions, but at the expense of offering only a narrow range of modern analogs (e.g., Horton and Edwards, 2005). Kemp et al. (2013b) described and discussed the effect of using regional- and local-scale modern training sets to reconstruct RSL in New Jersey and concluded that it

Figure 1. Location of study sites in southern New Jersey, USA. The distribution of modern foraminifera was described at 12 different salt marshes including five in Great Egg Harbor (not located with symbols in the figure). Bulk surface sediment $\delta^{13}\text{C}$ values were measured at three sites and cores for sea-level reconstruction (filled circles) were collected at Leeds Point and at Cape May Courthouse.

was necessary to use the regional data to provide sufficient modern analogs for interpreting assemblages of foraminifera preserved in sediment cores. This led Kemp et al. (2013a) to use the regional-scale training set when they produced Common Era RSL reconstructions from two locations in southern New Jersey and their analysis showed that the closest modern analogs for core samples were drawn from 11 of the 12 sites in the modern training set. Since it is not our aim to investigate the relative utility of local- and regional-scale modern training sets, we use the same data as Kemp et al. (2013a) to ensure that the new B-TF can be compared directly with existing results. However, an important difference is that the B-TF uses raw counts of foraminifera as the input, while the WA-TF model uses relative abundances expressed as percentages.

4.1.1 Modern counts of foraminifera

The modern data set comprised 172 paired observations of 18 foraminiferal species (including many zeros) and tidal elevation. The foraminifera count sizes ranged from 8 to 307 dead individuals. The highest occurrence of foraminifera (HOF; Wright et al., 2011) in the modern data set is at 141.5 SWLI. Higher samples were devoid of foraminifera and interpreted as being located above marine influence. This modern training set demonstrates that foraminifera (like plants) form distinct assemblages that correspond to elevation in the tidal

frame (e.g., Scott and Medioli, 1978), but with a secondary influence of salinity (e.g., de Rijk, 1995). Kemp et al. (2013b) provide a qualitative discussion of the influence that salinity has on the assemblages of modern foraminifera employed in our case study. Throughout southern New Jersey, low-marsh environments are occupied by *Miliammina fusca* and *Ammonia* spp. (Fig. 2). High salt-marsh environments are characterized by a number of foraminiferal assemblages including groups dominated by *Trochammina inflata*, *Arenoparella mexicana*, and *Tiphrotrocha comprimata*. High salt-marshes at sites with strong fluvial influence and correspondingly low (brackish) salinity are occupied by *Ammonia* spp. (Fig. 2). At some sites, elevations above MHHW are characterized by a group of foraminifera in which *Haplophragmoides manilaensis* is the dominant species. The pattern (uniform low marsh and diverse high marsh) and composition of these assemblages is similar to those identified elsewhere on the US Atlantic coast (e.g., Murray, 1991; Gehrels, 1994; Kemp et al., 2009a; Wright et al., 2011; Edwards et al., 2004).

4.1.2 Modern bulk-sediment $\delta^{13}\text{C}$ measurements

In the mid-Atlantic and northeastern USA, the low salt-marsh and high salt-marsh zones are dominated by C_4 species such as *Spartina alterniflora*, *Spartina patens*, and *Distichlis spicata*, while the transitional marsh and surrounding upland zones are dominated by C_3 species. In New Jersey the boundary between C_3 and C_4 plant communities corresponds to MHHW and $\delta^{13}\text{C}$ measured in bulk sediment can be used to reconstruct RSL by determining whether a sample formed above or below the MHHW tidal datum. Based on a data set of surface (0–1 cm) bulk-sediment $\delta^{13}\text{C}$ measurements from three sites in southern New Jersey (Fig. 1) and presence or absence of foraminifera, Kemp et al. (2013a) recognized three types of sediment that were likely to be encountered in cores of organic coastal sediment. To ensure comparability we use their interpretation here without modification:

1. Samples with $\delta^{13}\text{C}$ values more depleted than -22.0‰ and with foraminifera present formed at tidal elevations from 100–150 SWLI. The lower limit of this range corresponds to MHHW and the upper limit is conservatively set to extend slightly beyond the observed highest occurrence of foraminifera (141.5 SWLI) in the modern data set.
2. Samples with $\delta^{13}\text{C}$ values less depleted than -18.9‰ formed at tidal elevations from 0–100 SWLI since C_4 plants are dominant only below MHHW. This interpretation is the same if foraminifera are present or absent.
3. Samples with intermediate $\delta^{13}\text{C}$ values between -18.9 and -22.0‰ provide no additional information and if foraminifera are present these samples are interpreted

as having formed at 0–150 SWLI (MLLW to slightly above HOF).

4.2 Proxy data

Cores of salt-marsh sediment were recovered from two sites in southern New Jersey (Cape May Courthouse and Leeds Point; Fig. 1) and sliced into 1 cm thick samples. Three types of data were generated for each sediment core that we use as originally presented by Kemp et al. (2013a).

4.2.1 Fossil counts of foraminifera

In the Cape May Courthouse core *Jadammina macrescens* and *Trochammina inflata* were the dominant species from 1.72 to 1.29 m (Fig. 3a, upper panel). Foraminifera were absent at 1.25 to 1.12 m. Between 1.10 and 0.33 m *Jadammina macrescens* was the dominant species, while samples in the interval from 0.31 to 0.05 m included *Trochammina inflata*, *Tiphrotrocha comprimata* and *Jadammina macrescens*. Two samples near the top of the core with total counts of 194 (at 0.03 m) and 174 (at 0.05 m) included 34 and 37 *Miliammina fusca* respectively. Counts of foraminifera throughout the core ranged from 16 to 194 per sample with an average of 98. In the lower part of the Leeds Point core (2.85 to 3.95 m), *Jadammina macrescens* was the most common species and occurred with *Tiphrotrocha comprimata* and *Trochammina inflata* (Fig. 3a, lower panel). Within this section, at ~ 3.00 m there was an unusual occurrence of 24 *Miliammina petila* (out of a total of 101) and from 2.82 to 2.95 m 30% of the counted individuals were *Miliammina fusca*. From 2.82 to 1.85 m *Trochammina inflata* was the dominant species. The uppermost section of the Leeds Point core (1.73 to 1.20 m) was comprised of a near mono-specific assemblage of *Jadammina macrescens*. Counts of foraminifera in this core ranged from 4 to 127 per sample with an average of 70.

The assemblages of foraminifera preserved in each core were compared to those in the modern training set. If the dissimilarity between a core sample and its closest modern analog (measured using the Bray–Curtis metric) exceeded the 20th percentile of dissimilarity among all possible pairings of modern samples then the core sample was deemed to lack a suitable modern analog and was excluded from further analysis by Kemp et al. (2013a). We did not reconstruct PME for these samples because they may lack ecological plausibility (e.g., Jackson and Williams, 2004). On Fig. 3, these samples therefore lack a PME reconstruction (panels b, c, and e).

4.2.2 Fossil bulk-sediment $\delta^{13}\text{C}$ measurements

In the Cape May Courthouse core all samples were less depleted than -18.9‰ and were interpreted as having formed below MHHW in a salt-marsh dominated by C_4 plants (Fig. 3d, upper panel). In the lowermost part of the Leeds

Figure 2. Data set of modern foraminifera described from a total of 172 surface sediment samples from 12 different sites. The data are presented as relative abundances. Only the abundance of the eight most common species are shown. Modified from Kemp et al. (2013a). Red dashed lines and pink shading indicate the species optima and tolerances estimated by the weighted averaging transfer function. Tidal datums are indicated by blue dashed lines. HOF is highest occurrence of foraminifera, MHHW the mean higher high water, and MTL the mean tide level.

Point core (below 3.35 m), the presence of foraminifera and bulk sediment $\delta^{13}\text{C}$ values more depleted than -22.0‰ indicate that the sediment accumulated above MHHW in an environment dominated by C_3 plants, but below HOF (Fig. 3d, lower panel). Between 3.31 and 2.86 m bulk-sediment $\delta^{13}\text{C}$ values were variable and interpreted to record the transition from highest salt-marsh to high salt-marsh environments. Above 2.86 m, all samples were less depleted than -18.9‰ and were interpreted as having formed below MHHW in a salt-marsh dominated by C_4 plants.

4.2.3 Age–depth profile estimated by Bchron

Age–depth models for the Cape May Courthouse and Leeds Point cores were previously developed by Kemp et al. (2013a) using Bchron and are used here in the chronol-

ogy module without modification (Fig. 3f). The Cape May Courthouse core was dated by recognition of pollution markers, the appearance of *Ambrosia* pollen as a land-clearance marker, and radiocarbon dating of in situ and identifiable plant macrofossils. These data were combined into a single age–depth model that estimated the age of every 1 cm thick sediment sample in the core with an average uncertainty of ~ 30 years for the period since ~ 700 CE (Fig. 3f, upper panel). Anthropogenic modification of the Leeds Point site limited dating and RSL reconstruction to the interval from ~ 500 BC to ~ 1750 CE. The core was dated using only radiocarbon measurements performed on in situ and identifiable plant macrofossils. These data were combined into a single age–depth model that estimated the age of every 1 cm thick sediment sample in the core with an average uncertainty of ~ 50 years (Fig. 3f, lower panel).

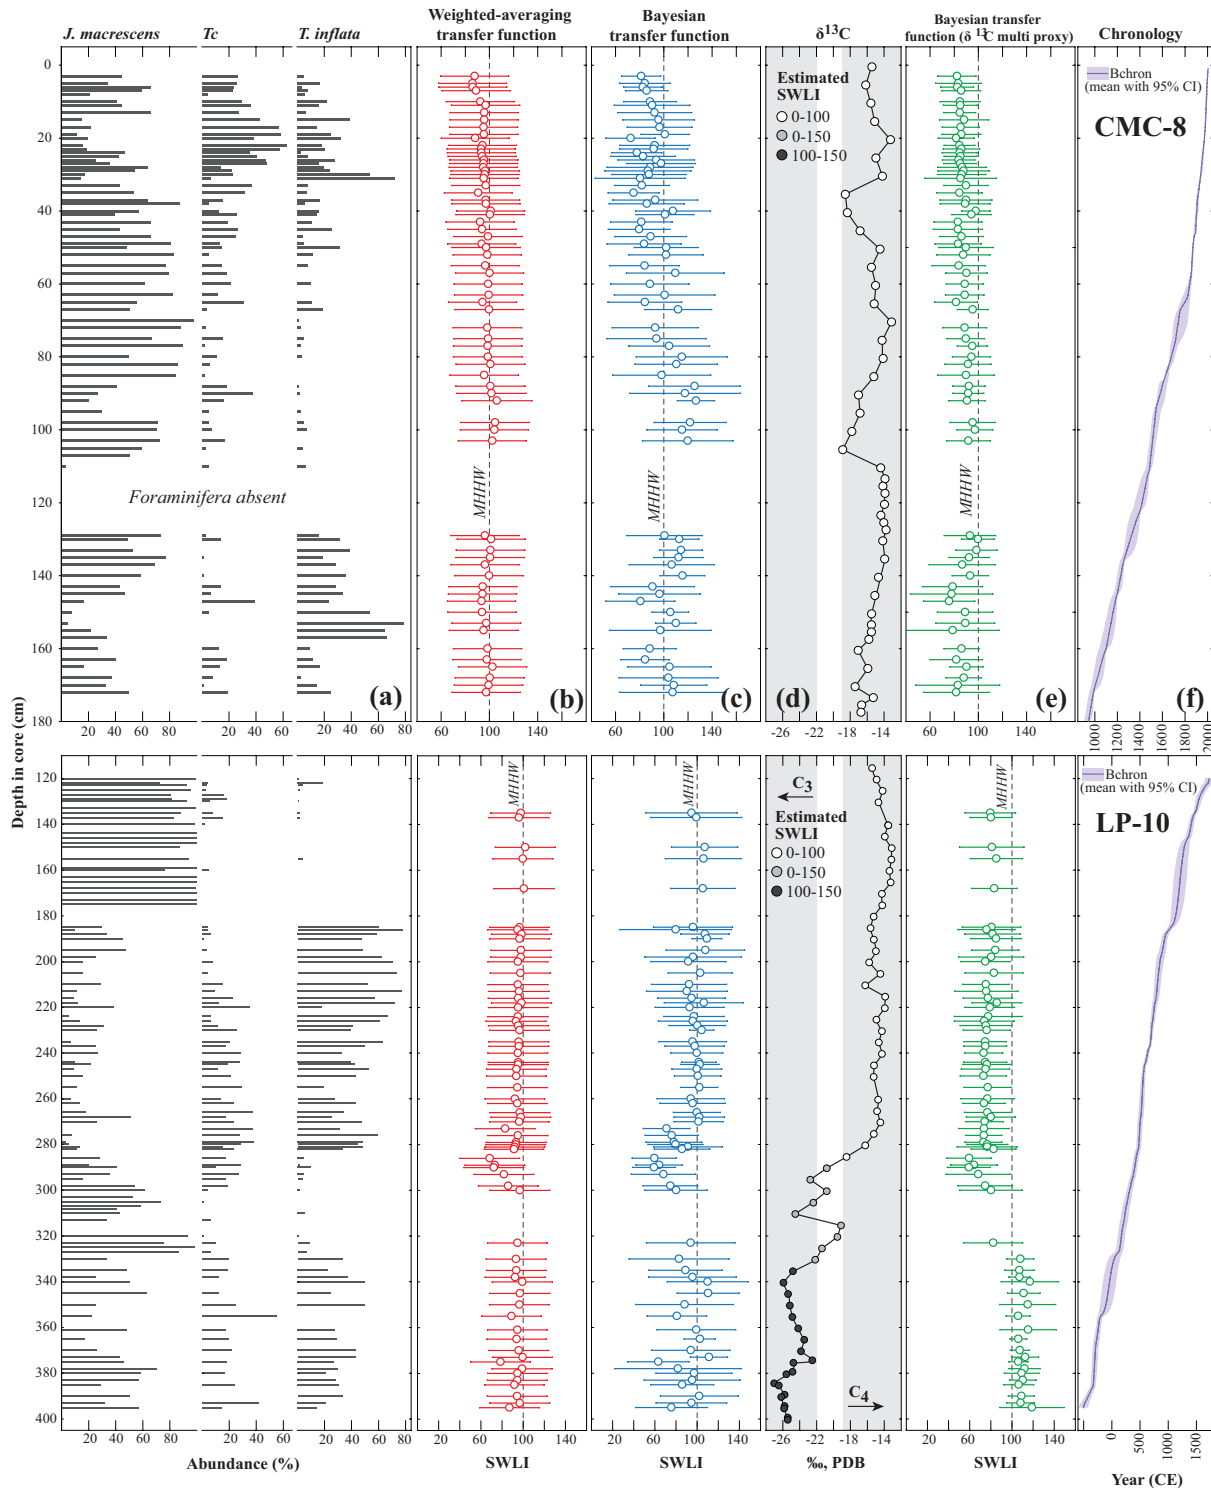

Figure 3. The abundance of the three most common species (*Tc* = *Tiphotrocha comprimata*) of foraminifera found in cores from Cape May Courthouse (CMC-8) and Leeds Point (LP-10) are represented by the horizontal gray bars (a). Paleo-marsh elevation, in standardized water level index (SWLI) units, was reconstructed using the weighted average transfer function (b), the Bayesian transfer function (c) and the multi-proxy Bayesian transfer function (e). Mid-points of the reconstruction are shown as white circles with the bars representing $\pm 2\sigma$ uncertainty. Vertical dashed lines show the elevation of the mean higher high water (MHHW) tidal datum. Stable carbon isotope concentrations ($\delta^{13}C$) for bulk sediment are parts per thousand (‰) relative to the Vienna Pee Dee Belemnite (VPDB) standard (d). Bchron provided the chronology for both cores (f). Note that some samples with counts of foraminifera lack a corresponding PME reconstruction because they lack a suitable modern analog using the criteria applied by Kemp et al. (2013).

4.3 Instrumental data

A tide gauge is an instrument that automatically measures the sea surface height with reference to a control point on the land many times during a day. These measurements are averaged to obtain annual values to minimize the effects of weather and tidal variability. In New Jersey (Fig. 1), tide-gauge data are available since 1911 CE when the Atlantic City tide gauge was installed. The Sandy Hook, Cape May and Lewes (Delaware) tide gauges began measurements in 1932 CE, 1966 CE and 1919 CE respectively. A single regional record was compiled by averaging annual data from these four local tide gauges. RSL is zero between 2000 and 2010 CE, roughly equivalent to the age of a surface sample in the core (by definition RSL = 0 m when the core was collected). The resulting record minimizes spatial variability and the influence of decadal-scale RSL variability (Douglas, 1991).

5 Results

The Cape May Courthouse and Leeds Point RSL reconstructions were developed separately to one another and were then merged into a single, regional-scale data set for analysis using the EIV-IGP model to capture the continuous and dynamic evolution of RSL change while taking account of the quantified uncertainty in both sea-level and age reconstructions.

5.1 The Bayesian transfer function

5.1.1 Species-response curves

The B-TF estimated a response curve (mean with a 95 % credible interval) for each species of foraminifera (expressed as raw counts) to tidal elevation (expressed as SWLI) from the modern training set of 172 samples (Fig. 4). The response curves are estimated from a multinomial distribution (in which species compositions are considered as a whole) parameterized by a probability vector \mathbf{p} , which is the probability of a species being present at a given tidal elevation. The multinomial model (described in detail in Sect. 3.1) utilizes the combined species information from these observed responses to estimate PME. The species prediction intervals (dashed red lines in Fig. 4) will aid in providing uncertainty for the PME estimates.

Broadly, we identify two forms of species-response curve in southern New Jersey. First, a skewed, unimodal form describes the distribution of *Haplophragmoides manilaensis* with a maximum probability of occurrence of ~ 0.2 at 123 SWLI compared to a WA-TF species optimum of 99 SWLI. *Jadammina macrescens* and *Trochammina inflata* also have a skewed, unimodal form with the highest probability of occurrences found in high salt-marsh environments at 124 SWLI ($p \sim 0.3$) and 110 SWLI ($p \sim 0.4$) respectively.

The optima for these species were placed at lower elevations by the WA-TF (92 SWLI for both species). Both *Ammonia* spp. (highest probability of occurrence of ~ 0.3 at 22 SWLI) and *Miliammina fusca* (highest probability of occurrence ~ 0.5 at 31 SWLI) have skewed unimodal distributions with maximum probability of occurrence in low salt-marsh environments. The WA-TF estimated species optima of 58 and 78 SWLI respectively for these two species. *Ammoastuta inepta* also has a skewed, unimodal form (maximum probability of occurrence of ~ 0.2 at 140 SWLI). This species generally has a low probability of being present because its distribution in southern New Jersey is restricted to sites with brackish salinity such as those located up-river in Great Egg Harbor (Fig. 1). Relatively few samples from these environments are included in the modern training set and therefore in the data set as a whole it is a rare, but ecologically important, species. Second, a unimodal Gaussian-like form describes the distributions of *Arenoparrella mexicana* (maximum probability of occurrence of ~ 0.07 between 60 and 70 SWLI) and *Tiphotrecha comprimata* (maximum probability of occurrence of ~ 0.3 at 78 SWLI). For these species the WA-TF indicated optima of 86 and 89 SWLI respectively.

5.1.2 Cross-validation of the modern data

Performance of the new B-TF and existing WA-TF was judged using 10-fold cross-validation (Fig. 5). The uncertainty bounds ($\pm 2\sigma$; shown as vertical lines on Fig. 5) for predicted elevations contained the true elevation for 90 % of samples using the B-TF, compared to 92 % for the WA-TF. The average of the 2σ prediction uncertainties is slightly larger for the WA-TF (28 SWLI) than for the B-TF (21 SWLI). This suggests that while the WA-TF is more successful than the B-TF at capturing the true elevation within the prediction uncertainty bounds, part of the reason for this may be because the intervals are larger. Prediction performance is often penalized for large intervals (e.g., Gneiting and Raftery, 2007).

The pattern of residuals in the WA-TF displayed a structure in which the elevation of low salt-marsh samples is over-predicted (negative residuals) and the elevation of high salt-marsh samples is under-predicted (positive residuals; Fig. 5). For example, the WA-TF showed an average residual of -16.6 between ~ 10 and ~ 70 SWLI and an average residual of 22.5 between ~ 120 and ~ 140 SWLI. This structure is absent in the B-TF, suggesting that it is better suited to reconstructing values close to the extremes of the sampled elevational gradient than the WA-TF. In contrast, the WA-TF performs better at elevations between 80 to 100 SWLI because the distribution of samples in the modern training set is focused at ~ 90 SWLI, and, by the very nature of the WA-TF, estimates of elevation will be drawn towards this average value.

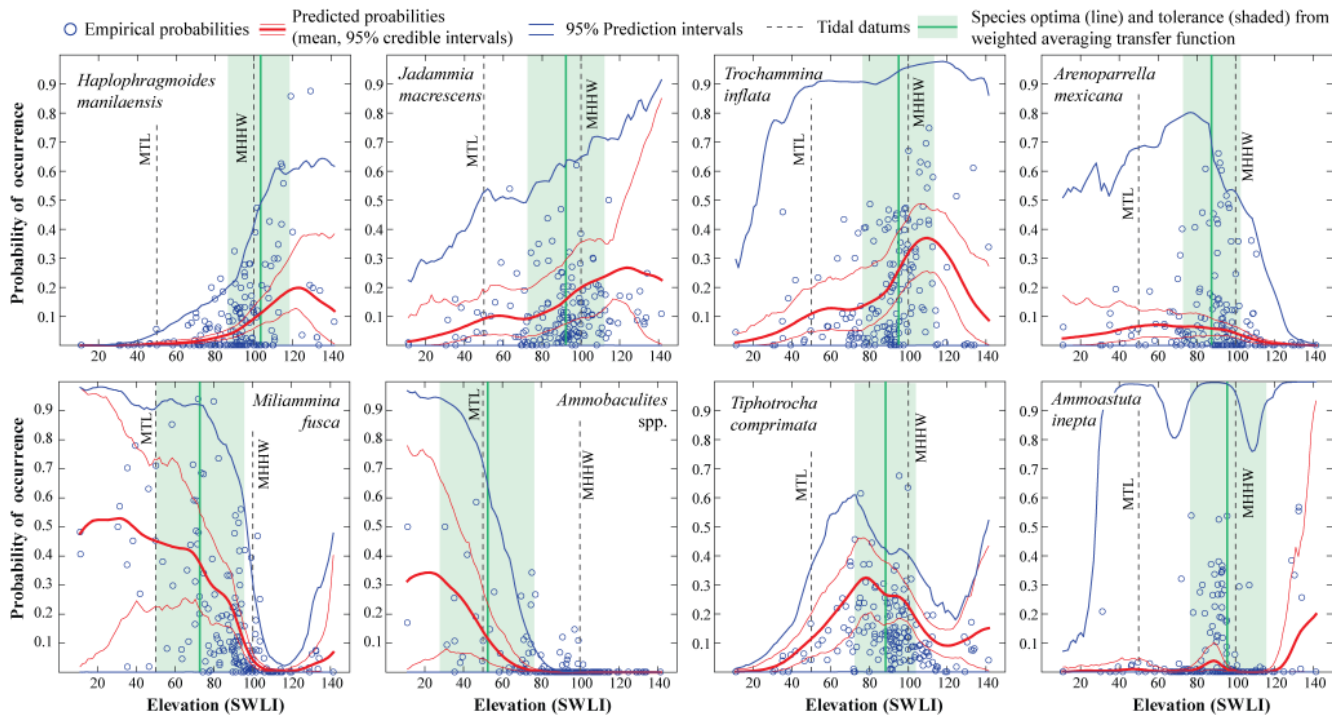

Figure 4. The response of foraminifera species to elevation estimated from the modern training set of raw counts using the Bayesian transfer function. The blue circles represent the probabilities of species occurrence as determined from the count data (empirical probabilities). The response probabilities of occurrence estimated by the Bayesian transfer function model are shown with a mean (heavy red line), a credible interval for the mean (light red line), and a prediction interval (blue line). The green vertical lines and shading represent the species optima and tolerances determined from the weighted average transfer function. Tidal datums are indicated by vertical dashed black lines. MTL is mean tide level and MHHW the mean higher high water. SWLI indicates the standardized water level index.

5.1.3 Reconstructions of paleommarsh elevation

We reconstructed PME in the Cape May Courthouse and Leeds Point cores using the WA-TF and B-TF models. At Cape May Courthouse, the B-TF estimated an average PME close to MHHW (SWLI = 100) of 96.2 SWLI, with a standard deviation 14.1 SWLI (Fig. 3c, upper panel). The WA-TF also estimated an average PME close to MHHW of 96.7 SWLI, with a standard deviation of 4.1 SWLI (Fig. 3b, upper panel). The 2σ uncertainties for the B-TF reconstructions ranged from 15.1 to 45.7 and are more variable than those from the WA-TF (28.1 to 29.0 SWLI). At Leeds Point, the B-TF estimated an average PME close to MHHW of 92.8 SWLI, with a standard deviation 12.8 SWLI (Fig. 3c, lower panel). The WA-TF estimated PME close to MHHW for all samples except for the 3.00–2.80 m interval where *Miliammina fusca* was present and PME reconstructions were correspondingly lower (Fig. 3b, lower panel). The 2σ uncertainties for the B-TF reconstructions ranged from 11.5 to 59.8 SWLI and were more variable than those from the WA-TF (28.0 to 28.5 SWLI). Comparison of the two models shows that the B-TF typically reconstructed PME with greater variability among samples than the WA-TF model. Within their uncertainties the PME reconstructions for the

B-TF and WA-TF overlap for all samples in both sediment cores.

5.1.4 Multi-proxy reconstruction

On salt-marshes in the mid-Atlantic and northeast coast of the USA measurements of $\delta^{13}\text{C}$ in bulk-organic sediment are useful sea-level proxies because they readily distinguish between sediment that accumulated above MHHW in an environment dominated by C_3 plants and sediment that accumulated below MHHW in an environment dominated by C_4 plants. This additional paleoenvironmental information was combined with the B-TF to generate a multi-proxy reconstruction of PME. The inclusion of the $\delta^{13}\text{C}$ proxy did not treat MHHW as a hard bound for PME, rather, if a sample is dominated by C_3 plants then the probability of PME being above MHHW increases. Likewise, if a sample is dominated by C_4 plants then the probability of PME being below MHHW increases.

At Cape May Courthouse, using the downcore $\delta^{13}\text{C}$ values as a secondary proxy, the B-TF estimated an average PME of 87.5 SWLI (a reduction of 9 SWLI compared to the original B-TF). The 2σ PME uncertainties were reduced by 32 % on average and by up to ~ 60 % for some samples (Fig. 3e,

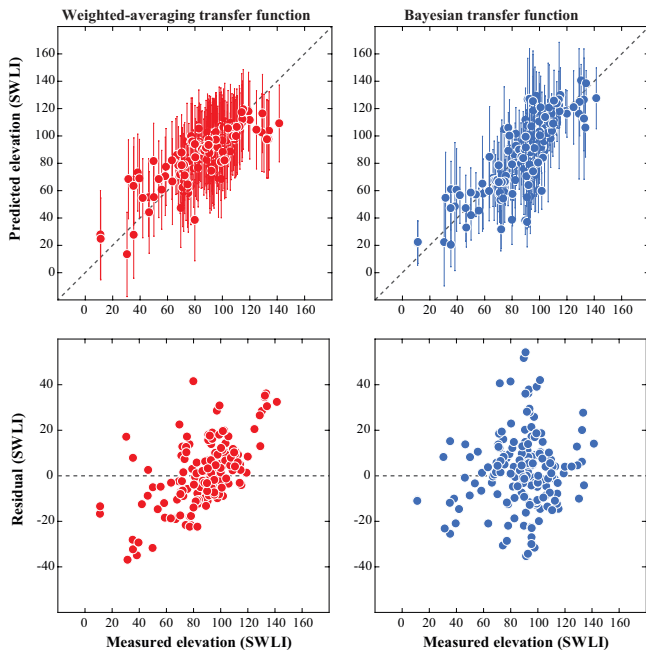

Figure 5. Cross-validation of the modern training set for the weighted averaging transfer function (red) and the Bayesian transfer function (blue). Upper panels are measured vs. predicted elevations in standardized water-level index (SWLI) units, with lines representing $\pm 2\sigma$ uncertainty for prediction. Lower panels show the (observed–predicted) residuals.

upper panel). For the Leeds Point core, the inclusion of the secondary $\delta^{13}\text{C}$ proxy resulted in an average PME reconstruction of 86.1 SWLI (a reduction of 7 SWLI compared to the original B-TF). The 2σ PME uncertainties decreased by $\sim 25\%$ on average (Fig. 3e, lower panel). However, for samples where $\delta^{13}\text{C}$ values and the presence of foraminifera indicate deposition in the transitional marsh (above MHHW, but below HOF) the uncertainty was reduced by an average of $\sim 50\%$ and by up to $\sim 70\%$ for some samples because the constraint on PME changed from 0–150 to 100–150 SWLI. These results demonstrate that incorporating a second line of proxy evidence in the B-TF framework is an efficient and formalized way to reduce uncertainty in RSL reconstructions in some (but not all) sedimentary environments.

5.2 Comparison among reconstructions

We applied the EIV-IGP model to the RSL reconstructions produced from the WA-TF, B-TF and multi-proxy B-TF to describe RSL trends along the coast of southern New Jersey since ~ 500 BCE (Fig. 6). The WA-TF and B-TF models show ~ 3.9 m of RSL rise compared to ~ 4.1 m of RSL rise for the multi-proxy B-TF model. The multi-proxy B-TF reconstructed lower RSL at the beginning of the record compared to the B-TF and the WA-TF, because of the additional constraint placed on the lowermost section of the

Leeds Point core by $\delta^{13}\text{C}$ values that indicate deposition at 100–150 SWLI. All of the reconstructions show three phases of RSL behavior (Fig. 6). The period from ~ 500 BCE to ~ 500 CE is characterized by a continuous increase in the rate of RSL rise. The second stage (~ 500 to ~ 1400 CE) shows a decline in rates of RSL rise. After 1400 CE there is a continuous acceleration in the rate of RSL rise until reaching historic rates, which are unprecedented for at least 2500 years. All reconstructions show an expanding uncertainty for the most recent rates. This is an edge effect that occurs as a result of using a Gaussian process model on the rates. These rates are estimated based upon their relationship (through an integration step) to the observations. As we approach the edge of the data, there are fewer constraints from the observations. This means that there are multiple rate trajectories that are consistent with recent data and so the uncertainty in the rate process increases.

There are some differences among the three reconstructions. For example, the B-TF shows the highest modern rate of rise at 4.1 mm yr^{-1} (95 % C.I. $3.27\text{--}4.92 \text{ mm yr}^{-1}$) in 2000 CE compared to 3.16 mm yr^{-1} (95 % C.I. $2.68\text{--}3.65 \text{ mm yr}^{-1}$) and 3.11 mm yr^{-1} (95 % C.I. $2.45\text{--}3.77 \text{ mm yr}^{-1}$) for the multi-proxy B-TF and the WA-TF respectively. The B-TF consistently estimated RSL lower than the multi-proxy B-TF and the WA-TF between ~ 1400 to ~ 1700 , resulting in the observed difference in the rates into the 21st century. When compared to the observed tide-gauge data for the last ~ 100 years from New Jersey (Fig. 7), the quality of the estimated RSL mid-point reconstructions can be assessed using mean squared error (MSE). For the multi-proxy B-TF the MSE was 0.003 m^2 , compared to 0.014 m^2 for the B-TF and the WA-TF, indicating that the multi-proxy B-TF mid-points are better estimates of the RSL changes measured by tide gauges in the study region than those from the B-TF and WA-TF.

6 Discussion

The B-TF provides an alternative to the (non-Bayesian) regression-based transfer functions commonly used for reconstructing RSL (e.g., Horton et al., 1999; Gehrels, 2000; Barlow et al., 2014) and in conjunction with the previously developed chronology and process modules enables RSL to be reconstructed in an entirely Bayesian framework. A key difference between the B-TF and existing transfer functions (e.g., the WA-TF) is the modeled relationship between species of foraminifera and tidal elevation. The number and type of species-response curves estimated by the B-TF model stands in contrast to the WA-TF, which assumes a unimodal Gaussian form for all species. The optima and tolerance estimated for each species by the WA-TF show overlap with the B-TF species-response curves, particularly those that have a Gaussian form such as *Tiphotrocha comprimata*. However, this form is only appropriate for two of the eight dominant

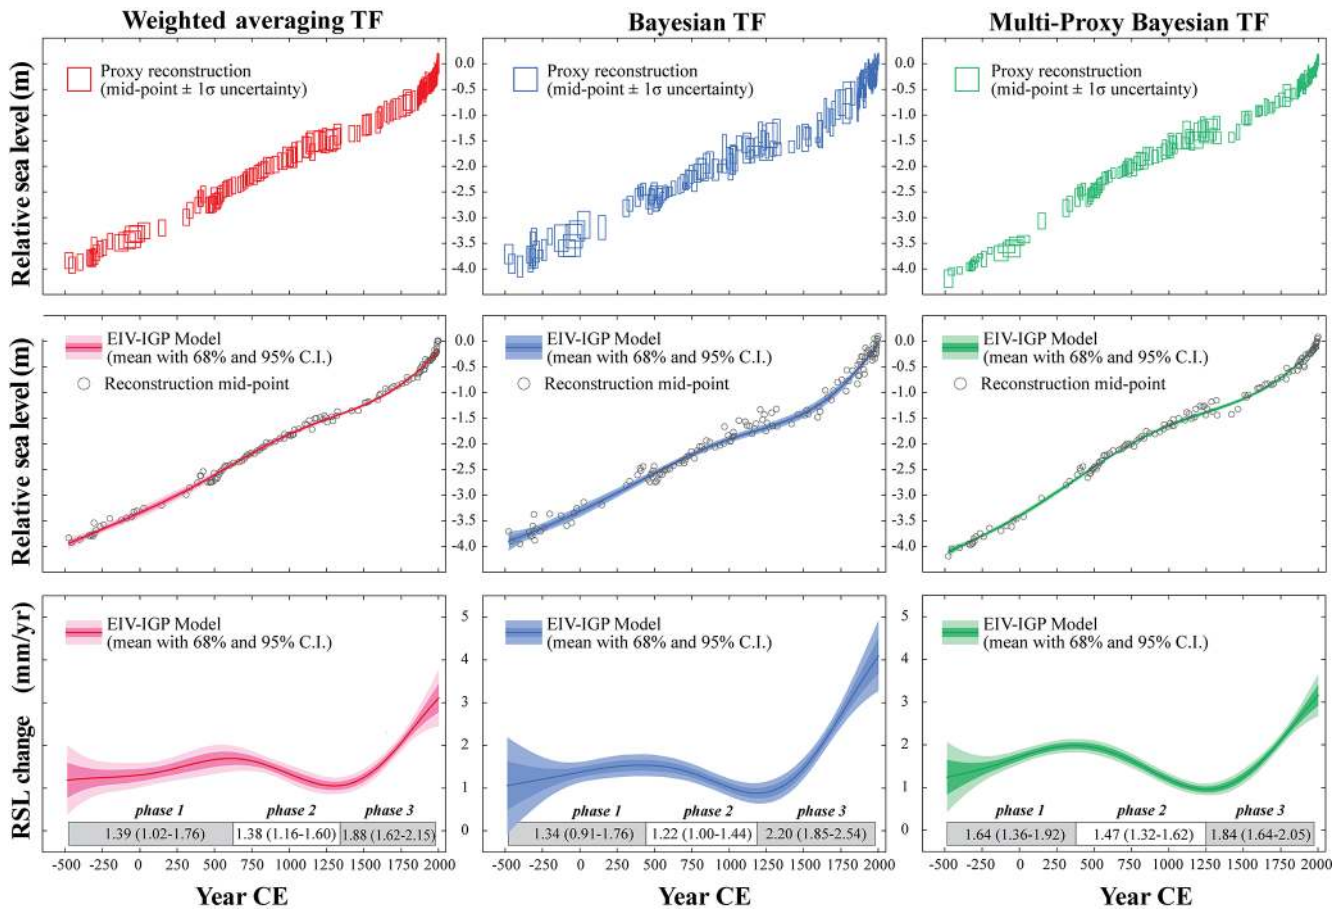

Figure 6. The EIV-IGP model results for reconstructions produced using the Bayesian transfer function (B-TF), the weighted averaging transfer function (WA-TF) and the multi-proxy Bayesian transfer function. The upper panel shows individual data points (represented by rectangular boxes that illustrate the 95 % confidence region) and include age and relative sea-level uncertainties. The middle panels show the posterior fit of the Errors-In-Variables integrated Gaussian process model to the relative sea-level reconstructions. Solid line represents the mean fit with the 68 and 95 % confidence intervals (C.I.) denoted by shading. The lower panels are the rates of relative sea-level (RSL) change. Shading denotes 68 and 95 % confidence intervals (C.I.) for the posterior mean of the rate process. The average rate for each phase of the reconstruction is given (in mm yr⁻¹) with a 95 % confidence interval.

species in the southern New Jersey training set. The flexible, species-specific response curves provided by the B-TF are more appropriate given that models based on the assumption of a single response do not adequately explain the ecological behavior of the dominant species in New Jersey, other assemblages of salt-marsh foraminifera (e.g., Edwards and Horton, 2006), or species from other biological groups used in RSL reconstructions such as diatoms (e.g., Zong and Horton, 1999; Gehrels, 2000). However, our results suggest that the flexibility in the B-TF can, in some instances, make it more susceptible to unusual observations. For example, the *Miliammina fusca* response curve in the B-TF shows a slight increase in probability of occurrence above ~ 120 SWLI (Fig. 4), because of three unusual samples located above 130 SWLI in which this species occurs (Fig. 2). This distribution may represent the advantage of a regional-scale training set in capturing natural variability

caused by ecological complexity and/or the influence of secondary environmental variables. Equally these samples could be an anomalous occurrence (e.g., tests washed in by a storm) that ought to be screened prior to analysis. Since Kemp et al. (2013a) retained these samples, we also elected to use them in developing the new B-TF.

The implication of the flexibility of the B-TF is illustrated in the cross validation results. The WA-TF displayed edge effects (a tendency to bias PME predictions towards the mean of the training data), which is a common artifact of using weighted-average-based methods (e.g., ter Braak and Juggins, 1993; Birks, 1995). Our B-TF does not suffer from this prediction bias and outperformed the WA-TF in the upper and lower extremes of tidal elevation. The consequences of such an improvement are significant where true PMEs lie close to the ends of the sampled environmental gradient. For example, on subduction zone coastlines such as the Pacific

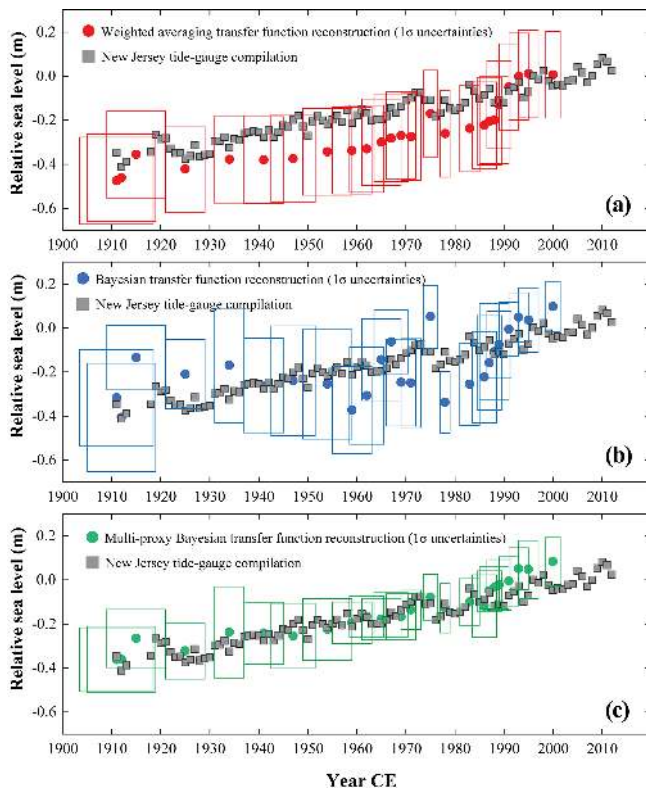

Figure 7. Comparison of the weighted average transfer function (a), the Bayesian transfer function (b) and the multi-proxy Bayesian transfer function (c) relative sea-level reconstruction with tide gauge data observed in the New Jersey region. The boxes represent $\pm 1\sigma$ uncertainty region for the reconstruction.

northwest coast of North America, cyclical tectonic activity contributes to reconstructed RSL trends (e.g., Nelson et al., 1996). During a slow (100 to 1000s of years) inter-seismic phase, accumulation of strain results in uplift of the coast (RSL fall). Conversely, the strain is released during an instantaneous co-seismic phase in which the coastline subsides (RSL rise). These processes cause significant and very rapid shifts in depositional environment that can span the full elevational range of coastal environments from sub-tidal settings to supra-tidal, freshwater uplands. In these settings, samples that are analogous to those at the ends of the sampled environmental gradient are frequently encountered in core material. In contrast, the sediment sequences targeted for reconstructing Common Era RSL on passive margins (e.g., New Jersey) are commonly comprised of unbroken sequences of high salt-marsh peat that are less susceptible to edge effects.

Further motivation for the development of the B-TF lies in the quantification of PME uncertainty. Non-Bayesian transfer function methods (e.g., the WA-TF model) assume that model parameters are fixed and known. Therefore, they do not incorporate uncertainty into the estimation of the PME reconstruction itself, rather, the uncertainty is produced sep-

arately either before or after PME was estimated. This uncertainty is the root mean square error from two sources (S1 and S2; Birks et al., 1990; Juggins and Birks, 2012). The S1 contribution is sample specific and is the standard deviation of bootstrapped PME reconstructions. The S2 contribution is the difference between observed and predicted tidal elevations established by cross-validation of the modern training set (Fig. 5). The PME uncertainties reconstructed by the WA-TF model show very little variability among samples (2σ ranges from 28.0 to 29.0 SWLI). This pattern arises because the contribution from the sample-specific (S1) uncertainty is very small compared to the model uncertainty (S2) which is common to all samples. As a result, the PME reconstructions for all core samples have very similar uncertainties, despite biological variability in species composition.

Alternatively, Bayesian methods explicitly model the uncertainty associated with individual reconstructions. Uncertainty for PME (and other unknown parameters) is included in the probability model through prior distributions. Assuming distributions for unknown parameters (in contrast to non-Bayesian approaches that use point estimates) allows the parameter uncertainty from the calibration step to be formally propagated into the reconstruction step. Therefore, estimates of PME produced by the B-TF take fuller account of the uncertainties related to the model and its parameters than non-Bayesian approaches. Consequently, the uncertainties estimated by the B-TF (excluding a secondary proxy) show more pronounced variability among core samples (2σ uncertainties range between 15.1 to 45.7 SWLI) than the WA-TF model. This variability arises from the observed response distribution of each species to tidal elevation (estimated from the modern data; Fig. 4). For each individual species there is variability in both the uncertainty of the mean response curves and in the prediction intervals (i.e., uncertainty is greater in some parts of the elevational gradient than at others).

The variability of reconstructed PME from the B-TF may reflect a more ecologically plausible reconstruction than the WA-TF model. For example, the key, high salt-marsh species *Jadammina macrescens* and *Trochammina inflata* vary in relative abundance from 0 (absent) to 100 % and approximately 80 %, respectively (Fig. 3). Despite this variability there was a pronounced lack of variability in reconstructed PME using the WA-TF model (average of ~ 95 SWLI with a standard deviation of 5.5). In contrast, PME reconstructions from the B-TF are also estimated at an average of ~ 95 SWLI, but with a larger standard deviation of 13.1. Intuitively the higher degree of PME variability reconstructed by the B-TF model is a better reflection of the species composition changes observed in the two sediment cores than the near-stationary PME values reconstructed by the WA-TF.

The majority of quantitative RSL reconstructions employ a single proxy (e.g., Kemp et al., 2011). A number of other proxies are available to support RSL reconstructions primarily produced from salt-marsh foraminifera. Additional bio-

logical proxies could include different groups of organisms with a relationship to tidal elevation such as diatoms (e.g., Zong and Horton, 1999; Shennan et al., 1994) or testate amoebae (e.g., Charman et al., 2010; Roe et al., 2002). These organisms can be incorporated as presence/absence data or as species counts from a modern training set of paired observations of species abundance and tidal elevation. A number of lithological proxies (e.g., Nelson, 2015) are also available, which can be qualitative (such as field- and lab-based descriptions of sediment as high marsh or low marsh) or quantitative (such as measurements of organic content; e.g., Plater et al., 2015) and may provide thresholds in a similar fashion to sediment geochemistry in New Jersey. Although secondary proxies are often available to provide additional and independent constraints, a barrier to their use is the lack of an accessible and formal framework for combining multiple proxies with appropriate consideration of uncertainty. A strength of our B-TF is its ability to accommodate these secondary proxy sources. In the example from New Jersey we primarily used a biological proxy (assemblages of foraminifera), but amended the model to include information from a geochemical proxy (bulk sediment $\delta^{13}\text{C}$). On average this approach reduced the uncertainty for PME reconstructions by $\sim 28\%$. The reduction in uncertainty consequently provides more precise estimates of RSL and the rate of RSL change through time. This is highlighted in the reconstruction of sea level between ~ 500 BCE and 500 CE where the uncertainty for rate estimates was reduced by 25% for the multi-proxy B-TF compared to the WA-TF and the B-TF. These results highlight the specific utility of bulk sediment $\delta^{13}\text{C}$ measurements as a sea-level indicator along the mid- and northeast Atlantic coast the USA and the general utility of employing a multi-proxy approach to reconstructing RSL where the goal is to produce reconstructions with the best possible precision. A practical and intuitive means to illustrate the improved performance of the multi-proxy B-TF over the WA-TF model is to compare RSL reconstructions with long-term measurements made by nearby tide gauges (e.g., Kemp et al., 2009b, 2013b; Barlow et al., 2014; Long et al., 2014; Leorri et al., 2008). We compare the reconstruction provided by the WA-TF, B-TF and multi-proxy BTF with regional tide-gauge measurements from New Jersey (Fig. 7). The tide-gauges measured about 30 cm of RSL change over the period 1911 to 2012 CE. For each transfer function method, the tide-gauge observations fall within the 95% reconstruction uncertainty bounds, with the multi-proxy B-TF providing notably improved mid-point estimates as indicated by the calculated MSEs.

7 Conclusions

To accurately reconstruct the continuous and dynamic evolution of relative sea-level change, we developed a Bayesian hierarchical model comprised of three formally interconnected

modules. (1) A B-TF for the calibration of foraminifera into tidal elevation, which is flexible enough to formally accommodate additional proxies such as bulk sediment $\delta^{13}\text{C}$. (2) An existing chronology developed from a Bchron age-depth model. (3) An existing EIV-IGP model for estimating rates of sea-level change. Previous reconstructions treated these three components as independent and employed existing approaches that were developed in a variety of numerical frameworks.

Our new B-TF provides an alternative to existing transfer functions. The relationship between species of salt-marsh foraminifera and tidal elevation was described using a regional-scale modern training set ($n = 172$) comprised of paired observations of species abundance and elevation, from 12 salt-marshes in southern New Jersey, USA. Results from the B-TF show that six of the eight most dominant foraminifera do not conform to the unimodal, Gaussian response curve prescribed by the WA-TF and other existing transfer functions.

We applied the transfer functions to cores of salt-marsh sediment that were recovered from two sites in southern New Jersey. The flexible approach utilized in the B-TF results in more variability in reconstructed PME and associated uncertainty among samples than the WA-TF model. This variability is consistent with observed changes in foraminiferal population in core samples and we propose that the B-TF produces a more complete evaluation of uncertainty than the WA-TF model.

The B-TF allows results from additional, independent sea-level proxies to be formally incorporated alongside the primary biological proxy to produce a multi-proxy reconstruction. In New Jersey, we used bulk sediment $\delta^{13}\text{C}$ values to determine if a core sample formed above or below the MHHW tidal datum. The addition of a second proxy reduced reconstruction uncertainty by an average of 28 and up to $\sim 70\%$ for samples that formed in some salt-marsh sub-environments (the transition from high salt marsh to upland specifically).

We assessed the ability of the multi-proxy B-TF, B-TF and the WA-TF to reconstruct RSL through comparison with observed tide-gauge data from New Jersey. Results showed that the 2σ uncertainty bounds for all reconstructions capture the observations from the tide gauge. However, the multi-proxy B-TF provides improved estimates ($\text{MSE} = 0.003 \text{ m}^2$) for the reconstructed RSL mid-points compared to the B-TF and the WA-TF ($\text{MSE} = 0.014 \text{ m}^2$). This practical test suggests that the multi-proxy B-TF is the best approach for generating accurate and precise RSL reconstructions using salt-marsh sediment on the mid- and northeast Atlantic coast of the USA
