

A GENERAL THEORY OF ACTION LANGUAGES

Alexander Letichevsky* and David Gilbert**

We present a general theory of action-based languages as a paradigm for the description of those computational systems which include elements of concurrency and networking, and extend this approach to describe distributed systems and also to describe the interaction of a system with an environment.

As part of this approach we introduce the Action Language as a common model for the class of non-deterministic concurrent programming languages and define its intensional and interaction semantics in terms of continuous transformation of environment behavior. This semantics is specialized for programs with stores, and extended to describe distributed computations.

Keywords: interaction, semantics, behavior, environments, distribution.

1. INTRODUCTION

We present a general theory of action-based languages as a paradigm for the description of those computational systems which include elements of concurrency and networking, and extend this approach to describe distributed systems and also to describe the interaction of a system with an environment. Our claim is that we are able to characterize most existing computational and interactive systems with our approach, and to relate the concepts of computation and interaction. We hope that our approach will facilitate the design and construction of new computational and interactive systems in the future.

Our basic notion is that of an *action* which transforms the state of a world; actions are performed by agents¹ whose behavior is changed as a result. We distinguish between an agent and its state and thus speak of an agent in a given state; special types of agents are programs (which have a syntactical representation) and environments (which usually are not syntactically represented, and into which programs can be inserted). Behaviors are agents in a given state considered up to bisimilarity, or possibly to a weaker equivalence. Each agent may be represented as a transition system labeled by actions from a corresponding action domain and whose action algebra describes combination, nondeterministic, and sequential composition. Thus we distinguish between *primitive actions* and *compound actions*, the latter being formed from combination of other actions.

Interaction between agents is of two types. The first is expressed by the parallel composition of agents over the same action domains and is characterized by the combination of actions or interleaving. The second is expressed by the insertion of an agent into some environment and results in the transformation of the environment into a new environment. Some informal examples of environments are:

- a computer, or interpreter for some programming language (which does not perform global analysis and only considers actions performable at some moment of time),
- a server on a computer network, or a software system which manipulates queries considered as actions of programs, where some actions can be performed immediately and others are suspended,
- an interactive interface connecting a program with a user, where the user may interrupt the execution of the program and perform his own action.

Interactive computing is a well-established technique applied to many problem domains, for example, in the construction of controllers, operating systems, programming environments, expert systems, etc. However, this

¹The term "agent" is used as a notion which formalizes real objects such as programs, environments, users, clients, servers, and agents as in the meaning of "software agents" [6].

Fig. 1. Relations of an algebra of actions.

paradigm has not been regarded as fundamental until the relatively recent advent of widely available communications facilities which abstract from physical locations and networks, coupled with a very high rate of accessibility to computers. Peter Wegner has documented and explored the paradigm shift from algorithms to interaction in his recent CACM articles [30, 31]. Our view is of computation *and* interaction as two somewhat orthogonal concepts as opposed to the view of computation *as* interaction characterized by Milner in [24].

We believe that descriptions of interactive systems should be made using formalisms based on very generalized (abstract) languages, and that a sound semantics needs to be given for them. This paper presents our first attempt in this direction. We base our approach on that of a general abstract Action Language (AL) as a common model for the class of nondeterministic concurrent programming languages [19] (ncpl) and consider them as interactive programming languages by giving a compositional semantics for them. The set of continuous transformations of the behavior algebra is used as a semantic domain for this purpose. This approach is in some sense a generalization of the idea of discrete transformer introduced by V. Glushkov in [10] and considered as a model of computation (see also [11]). As a further extension, we give a distribution semantics for those ncpl languages which have the notion of store components.

Nondeterministic concurrent programming languages (ncpl) are languages which employ as primitive constructs nondeterministic choice, parallel and sequential composition. The best known are the languages based on CCS [21] and the π -calculus [22] of R. Milner, CSP [16] of C. A. R. Hoare, and process algebra [5] which were designed to study communication and interaction in concurrent processes. Another class are the concurrent constraint programming languages [7, 9, 26, 27], which appeared during the last decade and are very popular nowadays, and combine the properties of computation (over relations) and interaction in a very high level and abstract manner. All of these languages use all three characteristic constructs of ncpl. Nondeterministic choice is an important feature of declarative programming and also of specification languages, although it may be present implicitly. For example, the choice of rewriting rules and redexes in algebraic specifications as well as the choice of clauses in logic programs considered as specifications of subject domains, are nondeterministic. Parallel composition may also be present implicitly as the possibility of simultaneously computing the values of subexpressions of algebraic expressions or simultaneously solving constraints.

An important advantage of our approach is that it can easily be specialized to describe specific features of languages belonging to the ncpl class. For example, the following are some special features of the cc family: a store, variables, and synchronization mechanisms. Another advantage lies in the use of our model to design tools such as interpreters, simulators, and workbenches for ncpl languages.

2. THE ACTION LANGUAGE

The general abstract Action Language (AL) is a common model for the class of ncpl languages. The abstract syntax of the Action Language is as follows, where the syntax of Act and ProcedureCall are the parameters of each particular language of the class.

$$\text{Prog} ::= \text{Act} \mid \text{ProcCall} \mid (\text{Prog} + \text{Prog}) \mid (\text{Prog} \parallel \text{Prog}) \mid (\text{Prog}; \text{Prog})$$

2.1. Actions

The meaning of actions is defined by some algebra of actions A (action algebra) and if it does not result in any contradictions then action expressions (considered up to their equivalence) will be identified with the actions themselves. The language is called a language over A if all action expressions are interpreted in the algebra A .

The main operation of the algebra of actions is a binary ac-operation (associative and commutative) denoted as \times and called the combination of actions. There is also the empty action δ which is the neutral element for combination and the zero element 0 (the impossible action). Therefore the algebra of actions is a commutative monoid. It may include also some other operations, as for instance in [23]. Among the different operations we are interested in are nondeterministic choice and sequential composition of actions. The main properties of these operations are illustrated in Fig. 1 (nondeterministic choice of a and b is $a + b$, sequential composition is ab).

An action is called *deterministic* if it cannot be represented as a nondeterministic choice of two different nonzero actions. A deterministic action is called *primitive* if it is δ or 0 , or it cannot be split into a combination of actions different to δ and 0 . Nondeterministic or nonprimitive actions are called *compound* ones. The algebra of actions is called *primitive* if

1. It is generated by primitive actions;
2. The representation of a nonzero action as a (finite) sum of nonzero deterministic actions is unique up to the commutativity and idempotence relations for sum.

Theorem 1. *Each action algebra is a homomorphic image of a primitive action algebra.*

A free action algebra defined by the equations of Fig. 1 is a primitive one and any action algebra is a homomorphic image of some free action algebra.

In the sequel we shall consider only primitive action algebras without explicit reference to this fact.

In real languages the combination of actions is usually either parallel (simultaneous) performance of information-independent computations, or interaction (for example, send and receive operations for the exchange of data between two processes). Combinations expressing multiparty communications which are performed in parallel with communication and interaction are also possible. The complexity of actions and their compositions depends on the point of view and level of abstractness desired.

The sequential composition of two actions is a nontrivial (different from 0) action if these actions are interpreted as functions or relations and in this case the new action is equivalent to the sequential performance of two actions. Nondeterministic composition of actions is used for technical reasons and, as will be shown later, usually can be eliminated at the level of program transformations.

The simplest examples of action algebras are Hoare action algebra ($a \times a = a, a \times b = 0$ if $a \neq b$) and Milner action algebra ($a \times \bar{a} = \tau, a \times b = 0$ if $b \neq \bar{a}$). Relations on some set of states or transformations defined by assignments on a set of memory states are also examples of action algebras. Others include Milne's Circal calculus [20], the algebra of Hennessy [15], LOTOS [17, 29], and its extensions (e.g., LOTCAL [8]).

2.2. Procedure calls

The syntax of procedure calls is another parameter of action language and each program is associated with a set of procedure definitions and also an algorithm which *unfolds* any procedure call to a program. We do not consider the details of procedure definitions, parameter passing, etc. in order not to restrict generalizations. As an example the utilization of rewriting technique for the definition of unfolding algorithm is quite useful.

$$\begin{aligned}
u + v &= v + u \\
(u + v) + w &= u + (v + w) \\
u + u &= u \\
u + 0 &= 0 + u = u \\
(a + b)u &= au + bu \\
0u &= 0
\end{aligned}$$

Fig. 2. Relations of an algebra of behaviors.

$$\begin{aligned}
\perp &\sqsubseteq u \\
u \sqsubseteq v &\Rightarrow u + w \sqsubseteq v + w \\
u \sqsubseteq v &\Rightarrow au \sqsubseteq av
\end{aligned}$$

Fig. 3. Approximation for behaviors.

Thus a program may be considered as an infinite object which can be obtained by means of infinite (in the case of nontrivial recursive definitions) unfolding of procedure calls. Formally this infinite program may be considered as the limit of a directed set of finite programs using an approximation relation with a bottom element added to the set of all programs. If the unfolding algorithm is partially defined, then the resulting program may contain occurrences of the bottom element. The unfolding process will be formally defined later.

3. SEMANTICS

Semantics is a function defined on the expressions of a language and which maps the program expressions of a language to their meaning in some semantic domain. Different semantic functions reflect different levels of abstractions and different properties of a program. We are interested in two kinds of semantics: computational and interaction ones; we also want our semantical functions to be compositional, which means that the meaning of a composition of programs is a corresponding composition of their meanings.

A semantic domain is usually equipped with some topology which provides the possibility of constructing infinite objects using passage to the limits. Classical examples of such domains are Scott functional domains [14]; see also [3]. In this paper we shall use domains which are continuous algebras [12, 13] or algebras with approximation [18]. The latter is a poset with partial order called an approximation relation, a minimal element \perp , and operations which are continuous w.r.t. the approximation relation. We shall also assume that in each algebra with approximation which we consider there is given a subalgebra of finite elements which contains the bottom element \perp and that all other elements are the limits of ordered sets of finite elements. In [18] it has been shown how an arbitrary algebra with approximation can be completed by such limits.

We speak about *computational semantics* of a program if it has been designed to compute some function or relation. In this case the meaning of a program is that function or relation itself. This corresponds to the traditional denotational semantics of programs. However, the execution of any program takes place in some environment which interacts with the program, performing the sequences of actions defined by this program or allowing these sequences to be performed. If the environment only supports the computational properties of a program it is passive and does not change the operational meaning of a program. This interaction is described by the traditional operational semantics of programs [25]. However, the environment may be more active, and change the predefined behavior of a program within wide limits. For example, it may contain some other programs designed independently and intended to interact and communicate with the given program at its run time. Therefore the interaction semantics must include an environment as the main parameter. The classical theories of communication (CCS, CSP, π -calculus) are based on the notions of transition systems and bisimulation, and consider interaction within the scope of the parallel composition of agents. The influence of the environment is sometimes expressed as an explicit language operation such as restriction in CCS or hiding in CSP.

Our approach in describing the interaction semantics of the Action Language is also based on the notion of bisimilarity, but the environment is considered as a semantic notion and is not explicitly included in the program.

$$\begin{aligned}
(u + v)w &= uw + vw \\
u(v + w) &= uv + uw \\
(au)(bv) &= (a \times b)(u|v) + a(u|bv) + b(au|v) \\
\Delta|u &= u|\Delta = u \\
0|u &= u|0 = 0 \\
\perp|u &= u|\perp = \perp \\
\\
(u + v)w &= uw + vw \\
(au)v &= a(uv) \\
\Delta u &= u\Delta = u \\
0u &= 0 \\
\perp u &= \perp
\end{aligned}$$

Fig. 4. The definition of parallel and sequential composition of behaviors.

The meaning of an interactive program is defined as a transformation of an environment which corresponds to inserting the program into its environment. When this action is performed the environment changes and this change is considered as the main property of a program which is to be described by its meaning.

In order to realize this approach first we formalize the notion of *behavior* in terms of algebras with approximation. Each behavior is an element of some behavior algebra over an algebra of actions. This behavior defines some transition system (with a given initial state); two behaviors are equal iff the initial states of corresponding transition systems are bisimilarly equivalent. Therefore behaviors are the invariants of transition systems considered up to the bisimilarity relation. Then each program is assigned its behavior which is defined independently of its environment. The behavior of a program is called its *intensional meaning*. The construction of the intensional meaning of a program is built in two steps. The first step is to convert the syntactic algebra of the AL to a continuous syntactic algebra by eliminating procedure calls. This conversion is realized by homomorphism which identifies equivalent procedure calls (having the same infinite unfoldings). Then the continuous syntactic algebra is homomorphically mapped to the behavior algebra by means of continuous homomorphism which provides programs of the AL by behavioral meaning.

After introducing the intensional semantics of programs the notion of an *environment* is presented. The environment is defined as a four-tuple which includes as a component a subset of some behavior algebra (the algebra of environment behaviors) over the action algebra different from the action algebras of the languages which are accepted by this environment. This subset is closed over transitions. Then the algebra of continuous transformations of environment behaviors is introduced and the continuous homomorphism of intensional semantics algebra of the AL to the algebra of transformations is defined providing each program with its interaction meaning. The homomorphism is determined by a residual function which sets the relationships between the actions of a program and those of an environment.

3.1. Behaviors

A behavior over an action algebra A is considered as an element of an *algebra of behaviors* over A (sometimes called a behavior algebra). This algebra is an algebra with approximation (poset with a minimal element and continuous operations²). It has two operations, the first being denoted by $+$ and is the internal binary aci-operation (idempotent ac-operation). This operation corresponds to nondeterministic choice. The second operation is prefixing au , a being an action, u being a behavior. The minimal element of a behavior algebra is denoted \perp . The empty behavior Δ performs no actions and usually denotes the termination of a process. The impossible behavior 0 is denoted by the same symbol as the impossible action and is the neutral element for nondeterministic choice.

Generating relations of any algebra of behaviors are shown in Fig. 2. The symbols a, b are actions, and u, v, w are behaviors. All other relations are consequences of them.

The approximation relation of the algebra of behaviors over A is the minimal partial order which satisfies the relations presented in Fig. 3.

²A function $f : D \rightarrow D$ on a poset D is called continuous if it is monotone and for each directed set $\{x_i | i \in I\}$ if this set is convergent, i.e., has the least upper bound $\bigsqcup_{i \in I} x_i$, then the set $\{f(x_i) | i \in I\}$ is also convergent and $f(\bigsqcup_{i \in I} x_i) = \bigsqcup_{i \in I} f(x_i)$. An operation is continuous if it is continuous as a function of each of its arguments.

$$\begin{aligned}
& \perp \subseteq P \\
& P \subseteq Q \Rightarrow P \parallel R \subseteq Q \parallel R \\
& P \subseteq Q \Rightarrow P + R \subseteq Q + R \\
& P \subseteq Q \Rightarrow PR \subseteq QR
\end{aligned}$$

Fig. 5. Approximation for programs.

$$\begin{aligned}
p^{(0)} &= \perp \\
p^{(n+1)} &= (\text{unfold}(p))\sigma_n \\
\sigma_n(p) &= p^{(n)}
\end{aligned}$$

Fig. 6. Unfolding procedure calls.

The elements of the minimal sub-algebra $F_{\text{fin}}(A)$ of the algebra of behaviors over A that is a sub-algebra generated by the empty behavior, the impossible behavior and the bottom element are called *finite behaviors*. All other behaviors are assumed to be the limits (least upper bounds) of the countable directed sets of finite elements. The algebra of behaviors which includes all such limits is denoted $F(A)$. It is defined uniquely up to the continuous isomorphism and all behavior algebras considered in the paper are assumed to be subalgebras of this algebra.

From the primitivity of an action algebra it follows that each behavior u can be represented in the form

$$u = \sum_{i \in I} a_i u_i + \varepsilon \quad (1)$$

where a_i are nonzero deterministic actions, u_i are behaviors, I is a finite (for finite elements) or infinite (but countable) set of indices, $\varepsilon = \Delta, \perp, \Delta + \perp, 0$ (*termination constants*).

Theorem 2. *If all summands in representation (1) are different, then this representation is unique up to the associativity and commutativity of nondeterministic choice.*

For a finite behavior u the statement of this theorem is true because the set of behaviors of a type av with a deterministic such as $u = av + v'$ does not depend on the representation of u as an expression of the behavior algebra considered up to the commutativity and associativity of nondeterministic choice. The same is true for the termination constants. For infinite behaviors the theorem follows from the uniqueness of the representation of u as an infinite sum

$$u = \sum_{a \in A_0 \wedge P(av)} av + \varepsilon$$

where A_0 is the set of deterministic actions, ε is the termination constant, and the predicate P is defined as follows:

$$P(z) \Leftrightarrow \exists x \in F_{\text{fin}}(A). x + \perp \subseteq u \wedge z = \coprod_{x \subseteq y \in F_{\text{fin}}(A), y + \perp \subseteq u} y$$

Parallel and sequential compositions are introduced as derived operations using the recursive definitions presented in Fig. 4 where u, v, w are behaviors, and a and b are deterministic actions. Parallel composition is denoted by \parallel and sequencing by $;$ (however, we will sometimes omit this latter operator as in Fig. 4).

These definitions uniquely determine sequential and parallel composition on finite elements and may be uniquely extended to all others by continuity if the corresponding limits are in the algebra of behaviors³ under consideration.

³The behavior algebra plays the same role in the theory of interactive programs as the Kleene algebra does in the theory of automata. In fact the only difference from the Kleene algebra is the absence of right distributivity (if nondeterministic choice and sequential composition are considered as the only operations of the algebra of behaviors) and the Kleene algebra may be obtained as the homomorphic image of the corresponding algebra of behaviors.

$$\begin{aligned}
\llbracket P + Q \rrbracket &= \llbracket P \rrbracket + \llbracket Q \rrbracket \\
\llbracket P \parallel Q \rrbracket &= \llbracket P \rrbracket \parallel \llbracket Q \rrbracket \\
\llbracket P; Q \rrbracket &= (\llbracket P \rrbracket; \llbracket Q \rrbracket) \\
\llbracket a \rrbracket &= a\Delta
\end{aligned}$$

((P + Q) \parallel R) &\rightarrow P \parallel R + Q \parallel R \\
(a; P) \parallel (b; Q) &\rightarrow ((a \times b); (P \parallel Q)) + (a; (P \parallel (b; Q))) + (b; ((a; P) \parallel Q)) \\
P \xrightarrow{a} (a; Q) + R &\Rightarrow P \xrightarrow{a} Q \\
a, b &\text{ are actions}
\end{aligned}$$

Fig. 8. Reductions and labeled transitions of programs.

Theorem 3. *Sequential composition is associative; parallel composition is associative and commutative.*

The theorem is proved first for finite behaviors and then extended to the infinite ones. The proofs for finite behaviors use induction on the length of a behavior which is defined so that $\text{length}(\varepsilon) = 0$ for the termination constant ε , $\text{length}(au) = \text{length}(u) + 1$, and $\text{length}(u+v) = \max(\text{length}(u), \text{length}(v))$. The following (expansion) theorem gives the explicit form of parallel composition. In this theorem $E(u)$ is a termination constant for a behavior u , and u and v are finite behaviors.

Theorem 4. *Let $u = \sum a_i u_i + E(u)$, $v = \sum a_j v_j + E(v)$. Then*

$$u \parallel v = \sum (a_i \times b_j)(u_i \parallel v_j) + \sum a_i (u_i \parallel b_j v_j) + \sum b_j (a_i u_i \parallel v_j) + E(u) \parallel v + u \parallel E(v)$$

Proof is by induction on the sum of the lengths of u and v . From this theorem the associativity of parallel composition is proved by direct computation (other properties of compositions are trivial). To simplify the computations it is useful to distinguish between final and nonfinal behaviors. A behavior u is called *final* if it is equal to 0 or $E(u) \neq 0$ and *nonfinal* otherwise. The associativity law is first proved for nonfinal behaviors, then for parallel composition of three behaviors at least one of which is a termination constant, and then for a general case.

3.2. Behaviors and transition systems

We present the well-known notions of a transition system and (partial) bisimulation, adapted to our collection of termination constants.

Definition 1. *A transition system over the set of actions A is a set S of states with a transition relation $s \xrightarrow{a} s'$, $s, s' \in S$, $a \in A$ and two subsets S_Δ and S_\perp called correspondingly sets of terminal and divergent states.*

$$\begin{array}{c}
p \rightarrow \text{unfold}(p) \\
\frac{P \xrightarrow{a} Q, Q \xrightarrow{a} R}{P \xrightarrow{a} R} \\
a \xrightarrow{a} \Delta \\
\frac{P \xrightarrow{a} Q, S \neq \perp, 0}{P + R \xrightarrow{a} Q, PR \xrightarrow{a} QR, P\|S \xrightarrow{a} Q\|S} \\
\frac{P \xrightarrow{a} Q, P' \xrightarrow{a'} Q', a \times a' \neq 0}{P\|P' \xrightarrow{a \times a'} Q\|Q'}
\end{array}$$

Fig. 9. Transition system representing strong intensional semantics of Action Language.

$$\begin{aligned}
(\varphi + \psi)(u) &= \varphi(u) + \psi(u), \\
(a\varphi)(u + v) &= (a\varphi)(u) + (a\varphi)(v) \\
(a\varphi)(cu) &= \begin{cases} \sum_{c' \in \text{res}(c, a)} c' \varphi(u) & \text{if } \text{res}(c, a) \neq \emptyset \\ c(a\varphi)(u) & \text{otherwise} \end{cases} \\
& \quad a \neq 0 \\
(a\varphi)(\Delta) &= \Delta \\
(a\varphi)(0) &= 0 \\
(a\varphi)(\perp) &= \perp
\end{aligned}$$

Fig. 10. The definition of nondeterministic choice and prefixing in the algebra of behavior transformations.

Definition 2. A binary relation $R \subseteq S \times S$ is called a *partial bisimulation* if for all s and t such that sRt and for all $a \in A$

- $s \in S_\Delta \Rightarrow t \in S_\Delta$
- $s \xrightarrow{a} s' \Rightarrow \exists t'. t \xrightarrow{a} t' \wedge s'Rt'$
- $s \notin S_\perp \Rightarrow (t \notin S_\perp \wedge t \xrightarrow{a} t' \Rightarrow \exists s'. s \xrightarrow{a} s' \wedge s'Rt')$

A state s of a transition system S is called a *bisimilar approximation* of s' denoted as $s \sqsubseteq_B s'$ if there exists a partial bisimulation R such that sRs' . Symmetric closure of partial bisimulation is a *bisimulation equivalence* denoted $s \sim_B s'$.

To each state s of a transition system there is a corresponding behavior u_s which is a component of a minimal solution of a system of equations

$$u_s = \sum_{s \xrightarrow{a} s'} a u_{s'} + \varepsilon_s$$

Theorem 5. $s \sqsubseteq_B s' \Leftrightarrow u_s \sqsubseteq u_{s'}$ and $s \sim_B s' \Leftrightarrow u_s = u_{s'}$

These are standard domain theoretic constructions. Detailed proofs of similar statements based on Plotkin power domains can be found in [1].

The *transition closure* $\text{Tr}(u)$ of behavior u is the minimal set of behaviors which includes u and for any $v \in \text{Tr}(u)$ if $v = aw$ for some action a then $w \in \text{Tr}(u)$. If $\text{Tr}(u) = \{u_i | i \in I\}$ then u may be represented as a component of the minimal solution of a system of equations in an algebra of behaviors (equational representation):

$$\frac{P \xrightarrow{a} Q, u \xrightarrow{c} v, c \xrightarrow{a} d, \text{ complete}(d), d \neq 0}{(P, u) \xrightarrow{d} (Q, v)}$$

$$\frac{P \xrightarrow{a} Q, u \xrightarrow{c} v, \text{ complete}(c)}{(P, u) \xrightarrow{c} (aQ, v)}$$

Fig. 11. Transition representation of a computation semantics.

$$\frac{P \xrightarrow{a} Q, u \xrightarrow{c} v, c \xrightarrow{a} d, d \neq 0}{(P, u) \xrightarrow{d} (Q, v)}$$

$$\frac{P \xrightarrow{a} Q, u \xrightarrow{c} v, \text{res}(c, a) = \emptyset}{(P, u) \xrightarrow{c} (aQ, v)}$$

Fig. 12. Interaction semantics of AL, transition representation.

$$u_i = \sum_{(i,j,k) \in M_i} a_{ijk} u_j + \varepsilon_i, \quad i \in I, M_i \subseteq I^2 \times K \quad (2)$$

The notion of a transition closure can be naturally extended to sets of behaviors. The set U is called *transition closed* if it coincides with its transition closure. A transition closed set U can be considered as a set of states of a transition system with transitions defined by the following rule:

$$v \xrightarrow{a} v' \Leftrightarrow v = av' + v''$$

The state u is terminal if $E(u) = \Delta + \varepsilon$ and divergent if $E = \perp + \varepsilon$. In all such representations we assume that a is a deterministic action.

3.3. Examples

Let us consider some special cases of behaviors which cover the majority of classical examples and are useful for applications.

3.3.1. Finite (rational) behaviors. We obtain finite state transition systems by taking the sets I and M_i in the equational representation (2) as finite. This corresponds to the “linear case,” the behaviors u_i constituting the minimal solution of a system of linear equations. Bisimilarity is algorithmically recognizable, and many theoretical and practical problems such as proving and recognizing properties, model checking, and so on may be solved completely [4].

3.3.2. Algebraic behaviors. Equational representation:

$$u = F_i(u_1, \dots, u_n), \quad i = 1, \dots, n$$

Here $F_i(u_1, \dots, u_n)$ are expressions of some behavior algebra, which use not only prefixing and nondeterministic choice but also parallel and sequential compositions. This is the simplest way to introduce constructive transition systems with infinite sets of states and this corresponds to the “nonlinear case.” The continuity of parallel and sequential compositions provides the minimal solution. An interesting special case occurs when parallel composition is not used, and corresponds to “context-free behaviors” [28].

3.3.3. Parameterized algebraic behaviors. Equational representation:

$$u_i(x_1, \dots, x_m) = F_i(v_1, \dots, v_k), \quad i = 1, \dots, n$$

$$v_j = u_{i_j}(f_1(x_1, \dots, x_m), \dots, f_m(x_1, \dots, x_m)), \quad i_j \in [1 : n]$$

$$\frac{P \xrightarrow{a} Q, (s, u) \xrightarrow{c} (t, v), c \xrightarrow{a} d \quad d \neq 0}{(P, s, u) \xrightarrow{d} (Q, t, v)}$$

$$\frac{P \xrightarrow{a} Q, (s, u) \xrightarrow{c} (t, v), \text{res}(c, a) = \emptyset}{(P, s, u) \xrightarrow{c} (aQ, t, v)}$$

Fig. 13. Transitions for programs over store.

Here x_1, \dots, x_m are variables (formal parameters), and $f_j(x_1, \dots, x_m)$ are expressions of some algebra where the variables are assigned values (data algebra). $F_i(v_1, \dots, v_k)$ are again behavior algebra expressions. Each equation is in fact a set of equations indexed by value tuples from data algebra (compare with value passing in CCS). This is another more powerful way to introduce the infinite state behaviors.

3.3.4. Behaviors over state spaces. Action $a \in A$ is interpreted as a partial transformation $f_a \subseteq S \rightarrow S$ of a state space. It may be, for instance, conventional memory states or stores in concurrent constraint programming [27] (conjunctions of primitive constraints). The equality of transformations performed by actions must be a congruence w.r.t. combination: $f_a = f_b \Rightarrow f_{a \times c} = f_{b \times c}$. Now a behavior over a state space S may be defined in the equational form in the following way:

$$u_i(s) = \sum_{(i,j,k) \in M_i, s \in \text{Dom}(a_{ijk})} a_{ijk} u_j(sa_{ijk}) + \varepsilon_i, \quad i = 1, \dots, n$$

Here $\text{Dom}(a)$ is the domain of f_a , $sa = f_a(s)$. Usually if the behavior of a program and information environment is considered, it is split into the behavior of a program

$$u_i = \sum_{(i,j,k) \in M_i} a_{ijk} u_j + \varepsilon_i, \quad i = 1, \dots, n$$

and the behavior of a whole system which is defined by the following rule:

$$\frac{u_i \xrightarrow{a} u_j, \quad s \in \text{Dom}(a)}{u_i(s) \xrightarrow{a} u_j(sa)}$$

3.4. Syntactic algebras

The main syntactic compositions of programs define the algebra of syntactic expressions which is called the syntactic algebra of a language. In the case of the Action Language there are three main compositions (nondeterministic choice, parallel and sequential composition). Actions and procedure calls are the generators of the syntactic algebra. We may construct the syntactic algebra with approximation and delete procedure calls in the following way.

Extend the syntax of programs by adding the undefined program \perp to the definition of Prog . Define the approximation relation \sqsubseteq on the set Prog as the minimal partial order satisfying the rules in Fig. 5.

Let Fprog be the set of all programs without procedure calls. For each $p \in \text{ProcCall}$ and each integer $n = 0, 1, \dots$ define the n step unfolding $p^{(n)}$ of p and the substitution $\sigma_n : \text{ProcCall} \rightarrow \text{Fprog}$ by the definition in Fig. 6.

For each program P define its complete unfolding $\text{Unfold}(P)$ as the least upper bound of the set $\{P\sigma_n\}_{n=0,1,\dots}$. Completing the algebra Fprog by these limits we obtain the continuous algebra Prog^* . This algebra is a homomorphic image of Prog with homomorphism Unfold which obviously identifies the procedure calls with the same complete unfoldings. In the rest of this paper we shall identify the program with its complete unfolding and consider it as a member of a continuous syntactic algebra.

3.5. Intensional semantics

The intensional meaning of a program in AL is its behavior defined independently of any external environment. If the language is a language over A , the meaning of its program is an element of a behavior algebra $F(A)$. This

$$\begin{aligned}
\text{res}(\text{prog} : a, a) &= \{a\} \text{ for all } a \in A \\
\text{res}(\text{prog} : a, b) &= \emptyset, \text{ if } b \neq a \\
\text{res}(\text{env} : a, b) &= \emptyset \text{ for all } b \in A \\
\text{res}(\text{inter} : a, b \times c, b) &= \{(\text{inter} : a \times b, c)\} \\
\text{res}(\text{inter} : a, d, b) &= \emptyset \text{ if there is no } x \text{ such that } d = b \times x
\end{aligned}$$

$$\begin{aligned}
(s, u) &\xrightarrow{(\text{prog}:a)} (t, v) \Rightarrow s \xrightarrow{a} t \\
(s, u) &\xrightarrow{(\text{env}:a)} (t, v) \Rightarrow s \xrightarrow{a} t \\
(s, u) &\xrightarrow{(\text{inter}:a,b)} (t, v) \Rightarrow s \xrightarrow{a \times b} t
\end{aligned}$$

Fig. 14. Residual and transition functions of the environment with common store.

$$\begin{aligned}
\text{Loc}(X, P) + Q &\rightarrow \text{Loc}(Y, P\sigma + Q) \\
\text{Loc}(X, P) \parallel Q &\rightarrow \text{Loc}(Y, P\sigma \parallel Q) \\
(\text{Loc}(X, P); Q) &\rightarrow \text{Loc}(Y, (P\sigma; Q)) \\
\text{Loc}(X, \text{Loc}(Y, P)) &\rightarrow \text{Loc}(X \cup Z, P\sigma) \\
P \rightarrow Q &\Rightarrow \text{Loc}(X, P) \rightarrow \text{Loc}(X, Q)
\end{aligned}$$

Fig. 15. Reductions of local program components.

algebra will also be called an intensional algebra of the language. The formal definitions are presented in Fig. 7.

P and Q in this figure are programs, and a is an action. The same operation symbols on the left- and right-hand sides of the equations denote the operations in different algebras. The left-hand side operations are the operations of the syntactic algebra, and the right-hand side operations are the operations of the intensional algebra of the language. The mapping $[\cdot]$ is obviously a continuous homomorphism, so the intensional semantics is compositional.

The intensional meaning of a program can also be presented as a labeled transition system defined up to the bisimilarity relation where labels are actions. First we define the equivalence relation on a set of programs as an equivalence generated by the identities of the algebra of behaviors (Fig. 2), associativity of sequential composition, associativity and commutativity of parallel composition, and relations among termination constants and other compositions (Fig. 4). Now the reduction relation \rightarrow is defined on a set of programs and the transition system is defined by only one inference rule in Fig. 8. The relation \xrightarrow{a} is the transitive closure of the reduction relation defined on programs and \xrightarrow{a} denotes a labeled transition on programs.

Note that our definition of parallel composition is weaker than that usually defined in the process algebra using the so-called left merge operator [5]. The system corresponding to this stronger definition is presented in Fig. 9. Nondeterministic choice and parallel composition are considered here as commutative operations.

3.6. Interaction semantics

The interaction or extensional semantics of AL over an action algebra A is defined for a given environment (E, A, C, res) . Here E is a transition closed subset of behavior algebra $F(C)$ over an algebra of action C called the behavior algebra of an environment, and

$$\text{res} : C \times A \rightarrow 2^C$$

is called a *residual function*. The set E is also called a set of behavior states of an environment, and its symbol is sometimes used as a symbol of the environment instead of a four-tuple.

The interaction meaning $[[P]]_E$ of a program P is the continuous transformation of $F(C)$ restricted to the set E . This transformation is defined by means of a residual function res .

Definition 3. If $\text{res}(c, a) \neq \emptyset$ then action a is said to be conformant with the environment action c , and any action $d \in \text{res}(c, a)$ is called a residual of c generated by a .

$$\begin{aligned}\text{Loc}(X, \text{Loc}(Y, P), s) &= \text{Loc}(X \cup Z, P, (s\sigma)) \\ (P, s) &= \text{Loc}(\emptyset, P, s)\end{aligned}$$

Fig. 16. Equivalence of local store components.

$$\frac{P \xrightarrow{a} Q, s \xrightarrow{a} t}{\text{Loc}(X, P, s) \xrightarrow{h(X, a, s, t)} \text{Loc}(X, Q, t)}$$

$$\frac{s\sigma \xrightarrow{a} t}{\text{Loc}(X, P, s) \xrightarrow{a} \text{Loc}(Y, P\sigma, t)}$$

Fig. 17. Transition system for programs with local store.

Definition 4. An action of the environment is said to be *complete* if it has no conformant actions, otherwise it is *incomplete*.

Instead of considering a function, one may consider a ternary relation $\text{res} \subseteq C \times A \times C$. This relation defines a label transitions system on the set C with transitions

$$d \in \text{res}(c, a) \Leftrightarrow c \xrightarrow{a} d$$

The function res induces the equivalence relation on A :

$$a \sim b \Leftrightarrow \forall c \in A \quad \text{res}(c, a) = \text{res}(c, b)$$

The important restrictions on res are the following:

1. The relation $a \sim b$ is a congruence w.r.t. combination, that is, for all $c \in A$ $a \sim b \Rightarrow a \times c \sim b \times c$;
2. $\text{res}(c, 0) = \text{res}(0, a) = \emptyset$;
3. $a \neq 0 \Rightarrow \exists c \in C (\text{res}(c, a) \neq \emptyset \wedge \text{res}(c, a) \neq \{c\})$.

An environment and an action algebra A are said to be *compatible* if they satisfy the restrictions above.

The domain for the interaction semantics is the algebra $T_{\text{res}}(A, C, E)$ of continuous behavior transformations of the type $\varphi : E \rightarrow F(C)$. This algebra has the same type as an intensional algebra, that is, nondeterministic choice and prefixing by actions from A are defined for behavior transformations, but this algebra may possess more relations among behaviors. It is also an algebra with approximation built up in the following way. First generate a finite element algebra using the following as generators (basic transformations):

- (i) the identity transformation I , such that $I(u) = u$,
- (ii) the zero transformation φ_0 , such that $\varphi_0(u) = 0$,
- (iii) the bottom transformation φ_{\perp} , such that $\varphi_{\perp}(u) = \perp$ for all $u \in E$.

Then complete this algebra by all necessary limits. Nondeterministic choice and prefixing in this algebra are defined in Fig. 10. Action a in this definition is supposed deterministic, and the definition of prefixing is recursive and must be understood as the minimal fixed point.

The (informal) meaning of this definition is the following. The interaction between a program and an environment at the current moment of time consists of choosing a conformant pair of actions $a \in A$ and $c \in C$ from all possible ways defined by the nondeterminism of their current states. From the point of view of game semantics [2] a program and an environment are partners in a game and this choice is a choice of moves. We do not fix the order of moves “splitting the atom of interaction” and leave it for applications. Both cases are possible.

If an environment moves first then the choice of an action c defines the set of actions of a program which are conformant with the action of an environment and which a program may choose as an answer. The residual action c' of an environment is selected as a result of an interaction of a program and an environment. If this residual is

complete it means that no other programs may interact with the new environment and the given program at this moment of time. Moreover, if some of these programs are ready to interact, this interaction will be postponed and may only be performed in the future. Otherwise a program may interact at the current moment with other programs according to the rules of the game defined by the conformance relation.

This is of course only one interpretation of the interaction semantics introduced here. Other interpretations may include many programs and many environments to describe more complex multiparty hierarchical interaction.

Now the meaning $\llbracket P \rrbracket_E$ of a program P in the environment E is defined by the equation

$$\llbracket P \rrbracket_E = \text{trans}[P]$$

The function trans is the continuous homomorphism of the intensional semantic algebra $F(A)$ to the algebra of behavior transformations defined by the equations $\text{trans}(\Delta) = I$, $\text{trans}(0) = \varphi_0$, $\text{trans}(\perp) = \varphi_\perp$. This provides the compositionality of the extensional semantics w.r.t prefixing and nondeterministic choice.

3.7. Compositionality of parallel and sequential compositions

To prove compositionality, parallel and sequential composition must be defined in the algebra of behavior transformations so that $\text{trans}(\varphi \parallel \psi) = \text{trans}(\varphi) \parallel \text{trans}(\psi)$, $\text{trans}(\varphi\psi) = (\text{trans}(\varphi))(\text{trans}(\psi))$.

Both compositions are defined by the same equations as for behaviors (i.e., Fig. 4 with Δ changed to I , 0 changed to φ_0 , \perp to φ_\perp , and behavior transformations considered instead of behaviors).

Now the problem is to prove the uniqueness of this definition. For this purpose we introduce the normal form for finite behavior transformations. Each finite behavior transformation can be presented in the form $\sum_{i \in I} a_i \varphi_i + \varepsilon$, where $a_i \neq 0$ and $\varepsilon = I, \varphi_0, \varphi_\perp$, or $I + \varphi_\perp$. Then we can apply the relation $a\varphi + b\varphi = (a + b)\varphi$ and all φ_i will be different. Such a representation is called the normal form of a transformation. The main theorem is on the uniqueness of this normal form.

Theorem 6. *If the set of states of an environment which is compatible with an algebra A is a subalgebra of the environment algebra $F(C)$, then the normal form of behavior transformations is unique up to the equivalence of prefixes and the order of summands.*

To prove the theorem first we prove that for $a \neq 0$, $a\varphi = b\psi \Leftrightarrow a \sim b$, and $\varphi \doteq \psi$. Denote $\text{Res}(c, a) = \sum_{c' \in \text{res}(c, a)} c'$ and let $\text{res}(c, a) \neq \emptyset$ (such c exists because of compatibility). Then $(a\varphi)(cu) = \text{Res}(c, a)\varphi(u) = \text{Res}(c, b)\psi(u)$, (note that $\text{res}(c, b) \neq \emptyset$ because the equality must be true for $u = \Delta$). The arbitrariness of $u \in E$ implies the required result.

Similar reasoning can be applied to the sum of guarded transformations and for the transformations of the type $\varphi + \varepsilon$, which then completes the proof.

The compositionality of parallel and sequential composition is proved using this theorem together with the congruence property of \sim . We must prove the independence of the definition of parallel and sequential composition from the representation of transformation in normal (now canonical) form. It can be done first for finite behaviors and then extended to their limits.

3.8. Computational semantics

In the definition of interaction semantics, arbitrary combinations of choices of actions for program and environment are possible. This reflects the situation in which a given program may interact with arbitrary other programs which were inserted to the environment before the choices under consideration had to be made. But in reality there may be some restrictions or commitments which the choices made by a program and an environment must satisfy. Specifically, if the program has been developed as a computational one, that is, for computation of some function or relation, then only interaction with the environment, not with other programs, must be considered for the definition of its computational meaning.

The aim of this section is to define the computational meaning of a program in an abstract and possibly general form. For this purpose the notion of completeness of environment action will be used. Namely, if the action of a program forces the transition $u \xrightarrow{d} v$ and d is complete, then a transition $u \rightarrow v$ can be considered as a transition

which is the result of the interaction of an action and an environment only, otherwise some other actions produced by other programs could participate in generating this transition.

So the computational meaning can be defined as a relation $\text{comp}[[P]]_E \subseteq E \times E$. By definition $(u, v) \in \text{comp}[[P]]_E$ iff there exists a sequence of transitions

$$(P, u) = (P_1, u_1) \xrightarrow{d_1} \dots \xrightarrow{d_{m-1}} (P_m, u_m) = (\Delta, u)$$

such that all d_i , $i = 1, \dots, m-1$ are complete. Computational semantics can be expressed also in the form of a transition system. This presentation is given in Fig. 11.

An important property of a computation semantics is the following.

Theorem 7. *Computation semantics is compositional w.r.t. sequential composition.*

The computation meaning of a sequential composition of programs is the sequential composition of their meanings considered as relations over environment behaviors.

The operational representation of computation semantics (Fig. 11) also allows us to distinguish between different forms of termination, which is important for studying the computational properties of a program.

If the state of a computation system is (Q, u) then if $P = \Delta$ this is a successful termination of a computation process. If $Q \neq \Delta$ and there are no moves from (Q, u) , the termination is unsuccessful. We can also distinguish between a case in which there exists such an action c of an environment that $u \xrightarrow{c} v$ (deadlock) or there is no such action (fail).

4. ENVIRONMENTS

If φ is the transformation defined by a given program over an environment E , then all behaviors $\varphi(u)$, $u \in E$, may be represented as states of a transition system defined on a set of pairs (P, u) , where P is a state of a program. This is illustrated by the rules in Fig. 12 where the first rule describes a move of a program in a state P and the second rule describes the situation where a program is suspended (with the already selected action a). We also identify states of a type (Δ, u) with u , so a system continues its performance after a program has finished. The terminal state of a system is therefore Δ (not (Δ, u)) and there are three types of divergent states: (\perp, u) , (P, \perp) , and \perp .

Let us consider some useful examples of environments. Each example considers an environment (E, A, C, res) and define this environment by the properties of its components. Sometimes we refer to an environment instead of its behavior having in mind an environment in a given initial or intermediate state which defines this behavior.

Example 1. Let $A \cup \{e\} \subseteq C$ and the residual function satisfy the equations $\text{res}(e, a) = \{a\}$, $\text{res}(a, b) = \emptyset$, $a, b \in A$. Let

$$u = eu$$

be a behavior of the environment ($u \in E$), P be a program, and φ_P the interaction meaning of this program. Then

$$\varphi_P(u) = (P; u)$$

and if φ_Q is the interaction meaning of another program Q , then

$$\varphi_Q(\varphi_P(u)) = (P; Q; u)$$

Example 2. Generalization to multi-threaded computing. For an arbitrary action algebra let us define $a^n = a \dots a$ and $[a]^n = a \times \dots \times a$, n times; note that $a^0 = [a]^0 = \delta$. Assume the following properties of the residual function (for this example):

$$\text{res}([e]^n, a) = \{[e]^{n-1} \times a\}, \quad n > 0$$

$$\text{res}([e]^n \times a, b) = \{[e]^{n-1} \times a \times b\}, \quad n > 0$$

Now if the state of an environment is

$$u = \sum_{n=0}^{\infty} [e]^n u$$

then several programs are permitted to be inserted to it and interact using combinations of actions. The environment

$$u = \sum_{n=0}^{\infty} [e]^n u + \sum_{a \in A} au$$

not only permits several programs to be inserted, but can itself interrupt the execution of a program and perform its own action, changing the intensional meaning of a program.

5. ACTION LANGUAGES OVER STORES

Usually (especially for computational programs) some actions of a program are interpreted as functions or relations over some state space, and the algebra of actions of a program generated by these actions is the algebra of relations. The states can be memory states if there are names and values, or some abstract structures describing all the possible values which names (or variables) may take in a given state as in the constraint programming paradigm. We shall use the general term *store* to denote the state space and sometimes say “store” instead of “state of a store.” If the actions of a language are interpreted on some store the language is called a *language over stores*.

If a program P comprises the parallel composition of some other programs, then the store is a common store for these programs and therefore it must be considered as a part of an environment into which P will be inserted before execution.

After inserting a program into this environment, a new environment will be obtained whose behavior can be described by a transition system with states (P, s, u) . In this triple, P represents a state of a program, s is a state of a store, and u is a state of the control part of an environment. Of course the environment must be compatible with the algebra of actions of a program. As before we suppose that $(\Delta, s, u) = (s, u)$. The transition system which produces this behavior can be defined by the rules in Fig. 13.

5.1. Synchronous and asynchronous communication

The above presentation of interaction semantics of programs over stores is very general and hence cannot serve to provide a good understanding of what happens in reality when the program interacts with its environment. Especially it does not describe synchronous and asynchronous communication as well as the computational connections between the actions of a program and an environment. So let us consider a more specific case in which a store is used as a common memory for exchanging the information between a program and an environment. Let the action space of the environment include the following three types of actions:

1. (prog : a), $a \in A$, computational program actions;
2. (env : a), $a \in A$, computational environment actions;
3. (inter : a, b), $a, b \in A$, interactions.

Let actions of A be interpreted as relations on a store and computational actions as relations on the environment states. The desired properties of a residual function and relations between the actions of an environment and a program are presented in Fig. 14.

The special cases when computational actions “add something to a store” or “remove something” can be considered as asynchronous communication. Interactions are obviously synchronous ones.

5.2. Local store

In real programs only a part of a store may be used as a shared item; other parts are localized in a program and the external part of an environment cannot access them. To express this partitioning on the semantic level the notion of variables or names must be introduced on the language level and then used in the definition of the extensional (interactive) semantics of programs. Action expressions of a language and procedure calls are called

$$\begin{aligned}\text{Loc}(X.\text{Loc}(Y, \Delta, s) \| C, t) &= \text{Loc}(X \cup Z, C, (s\sigma) \times t) \\ \text{Loc}(X.\text{Loc}(Y, C, s), t) &= \text{Loc}(X \cup Z, C\sigma, (s\sigma) \times t) \\ \text{Loc}(X, 0, s) &= 0\end{aligned}$$

Fig. 18. Equivalence of components.

$$\text{Loc}(X, P)Q \rightarrow \text{Loc}(Y, (P\sigma)Q, \perp)$$

Fig. 19. Reductions for components.

primitive programs. Actions of an environment are represented by means of syntactic expressions of an extended AL and also are considered as primitive programs.

Let V be a set of variables, and assume that for each primitive program q , a set of variables $\text{Var}(q) \subseteq V$ on which it depends is given. If primitive programs contain operators with bound variables such as, for instance, lambda abstraction, only free occurrences must be considered, and they also contain all free variables which can appear under the unfolding of this procedure call. We also need the renaming substitutions $\sigma = [X/Y]$ where X and Y are ordered sets of the same numbers of variables (if the order is not given it must be chosen in an arbitrary way). These substitutions are defined on primitive programs and extended to arbitrary ones by renaming of all occurrences of primitive programs.

The notion of program is extended by adding the notion of *local program components* with the syntactical form $\text{Loc}(X, P)$, where X is a finite set of variables and P is a program. Local program components are considered up to renaming. This means that if $\sigma = [Y/X]$ is a substitution which changes symbols from X to symbols from Y different from all symbols which occur free in P ($Y \cap V(P) = \emptyset$), then $\text{Loc}(X, P)$ is equivalent to $\text{Loc}(Y, P\sigma)$. This assumption extends the equivalence of programs. We also define the reduction relation for local program components by Fig. 15 which extends the reductions in Fig. 8.

We define an interaction semantics for programs with a local store, and the control part of an environment given by the equation

$$u = eu + \sum_{a \in A} au$$

For this case the state of the control part of an environment must not be considered in the definition of the interactive semantics of AL and the state of a transition system for interactive semantics is a *local store component* $\text{Loc}(X, P, s)$. We assume that the set of free variables and renaming are also defined for store states. Local store components are considered up to the equivalence relation defined in Fig. 16. The renaming σ renames all variables $y \in Y$ to those which are different from X .

The transition system for the interactive semantics is presented in Fig. 17. Renaming σ protects the local variables of a program when the transition is defined by an environment. Hiding operator h also hides the local information of a program action from other programs which can be inserted into the transformed environment as well as from an environment itself.

5.3. Channels

Communication between a program and an environment in AL with a local store (as well as between programs inserted into an environment) can be realized via common (global) memory or as a synchronous interaction (rendezvous, handshaking, etc.). Channels may be represented by variables in the common memory which have values assigned to them or changed by actions. The use of these actions can be restricted by an environment according to the information which the program gives to its environment or introduced by special compositions equivalent to the declaration of properties of variables.

$$\begin{array}{c}
\frac{C \xrightarrow{a} C', C \xrightarrow{a} C''}{C \xrightarrow{a} C''} \\
\\
\frac{C \xrightarrow{a} C'}{C \parallel C'' \xrightarrow{a} C' \parallel C''} \\
\\
\frac{C \xrightarrow{a} C', D \xrightarrow{b} D', a \times b \neq 0}{C \parallel D \xrightarrow{a \times b} C' \parallel D'} \\
\\
\frac{C \xrightarrow{a} C', s \xrightarrow{a} t}{\text{Loc}(X, C, s) \xrightarrow{h(X, a, s, t)} \text{Loc}(X, C', t)} \\
\\
\frac{s\sigma \xrightarrow{a} t}{\text{Loc}(X, C, s) \xrightarrow{a} \text{Loc}(Y, C\sigma, t)}
\end{array}$$

6. DISTRIBUTED ACTION LANGUAGES

Distributed computation is a very important area of modern computer science and its applications. The main characteristic of this area is the use of local sites for distributing memory and programs. These local sites may be separate processors in the network or the components of a multiprocessor system as well as persistent software components (software agents) which perform concurrent computation sharing the time of a central processor (multi-threading) or other resources.

The AL with local store could be used for distributed programming, but its interactive semantics defined in the previous section has some disadvantages which limit this use. The main disadvantage of the semantics for programs with a local store is that it loses the structure of a program state defined by nesting program components and partitioning a global store on local spaces for parallel composition. In reality this information could be used for the organization of a distributed implementation of a given program. Moreover, if the programmer is aware of the strategy for the distributed implementation, he could use this information for the development of efficient distributed programs using the localization operator as a tool for expressing his algorithmic ideas for the distribution of data and actions.

Another use of a local component structure could be a more adequate description of components of real systems as programs which simulate their activity or create communities of software components.

To eliminate the disadvantage mentioned above, a new distributed interaction semantics is introduced for the AL with local store. We call this new language the distributed action language (DAL). The main semantic notion of the DAL is the notion of a distributed action component (dac) which is used to describe the state of computation with distributed programs and stores (local stores). The definition is the following:

1. A program is a (simple) dac;
2. Parallel composition of dacs $C \parallel D$ is a (parallel) dac;
3. If C is a dac and s is a store, then $\text{Loc}(X, C, s)$ is a (local) dac.

The equivalence of dacs includes the equivalence of programs, renaming, and extra equivalences introduced by Fig. 18.

Instead of reductions of local components in Fig. 15 we introduce only one reduction rule on action components (Fig. 19) where σ is a protective renaming.

Transitions of dacs which define the distributed interaction semantics are introduced in Fig. 20.

The transition rules for dacs cover some of the transition rules of programs as a special case of a dacs. Therefore these rules can be reduced to those presented in Fig. 21.

7. CONCLUSIONS

We have presented a general theory of action-based languages as a paradigm for the description of those computational systems which include elements of concurrency and networking, and extended this approach to describe distributed systems and also to describe the interaction of a system with an environment. As part of this approach we have introduced the Action Language as a common model for the class of nondeterministic concurrent programming languages and defined its intensional and interaction semantics in terms of continuous transformation of environment behavior. This semantics has been specialized for programs with stores, and extended to describe distributed computations.

In the future we intend to specialize our theory in order to obtain a working semantics for reasoning about and designing programs in different paradigms, including concurrent constraint languages. We have started on this work, and the ideas presented in this paper are being used as the basis for the design of a workbench for action languages.

We plan to study the semantics of distributed languages. Our present approach to semantics does not describe the structure of distributed programs, and we will investigate the possibility of preserving this structure using equivalent transformations of distributed components.
