Knowledge Bases (KBs) are widely used as one of the fundamental components in Semantic Web applications as they provide facts and relationships that can be automatically understood by machines. Curated knowledge bases usually use Resource Description Framework (RDF) as the data representation model. In order to query the RDF-presented knowledge in curated KBs, Web interfaces are built via SPARQL Endpoints. Currently, querying SPARQL Endpoints has the problems like network instability and latency, which affect the query efficiency. To address these issues, we propose a client-side caching framework, SPARQL Endpoint Caching Framework (SECF), aiming at accelerating the overall querying speed over SPARQL Endpoints. SECF identifies the potential issued queries by leveraging the querying patterns learned from clients' historical queries and prefetches/caches these queries. In particular, we develop a distance function based on graph edit distance to measure the similarity of SPARQL queries. We propose a feature modelling method to transform SPARQL queries to vector representation that are fed into machine learning algorithms. A time-aware smoothing-based method, Modified Simple Exponential Smoothing (MSES), is developed for cache replacement. Extensive experiments performed on real world queries showcase the effectiveness of our approach, which outperforms the state-of-the-art work in terms of the overall querying speed.

1 INTRODUCTION

Knowledge Bases (KBs) are computer systems that hold knowledge or facts in structured or unstructured way. They are widely used as one of the fundamental components in Semantic Web applications as they provide facts and relationships that can be automatically understood by machines (e.g., computer programs). Knowledge bases can be generally categorized into *curated KBs* and *open KBs*. Curated KBs are built from collaboratively and manually collected Web corpus (i.e., Wikipedia¹) and represent knowledge in the structured form. On the other hand, open KBs are constructed by assertions that are automatically extracted from Web pages. The lack of well-structured schema of open KBs makes querying open KBs very different from querying curated KBs. Only simple queries without joins or constraints can be answered by open KBs [3, 28]. Our work focuses on querying curated KBs because curated KBs are more widely adopted and support complex queries. We will use KBs and curated KBs interchangeably hereafter.

Figure 1 illustrates a generic architecture for querying curated KBs. In the knowledge bases layer (bottom), curated KBs (e.g., DBpedia²) usually use Resource Description Framework (RDF) as the data representation model because RDF has been accepted as the standard model by W3C³. RDF encodes a relationship (or fact) with a tri-ary tuple (i.e., triple): (*subject, predicate, object*), (*s, p, o*) for short. Moreover, RDF allows the sharing and reuse of data across boundaries [10]. In order to allow users perform querying over knowledge bases, a service is built upon each knowledge base. The service is called SPARQL (SPARQL Protocol and RDF Query Language) Endpoint and is realised by the HTTP bindings provided by KBs. SPARQL includes two parts: a standard query language for RDF and the protocol, which uses Web Services Description Language (WSDL) to describe a means for conveying SPARQL queries to an SPARQL query processing service and returning the query results. SPARQL Endpoint also realises the potential of federated SPARQL through SERVICE keyword introduced in SPARQL 1.1 specification, whereby several SPARQL Endpoints are combined allowing complex queries to be run across a number of KBs. To the clients (i.e., query issuers), a SPARQL Endpoint acts as a machine-friendly interface towards each knowledge base.

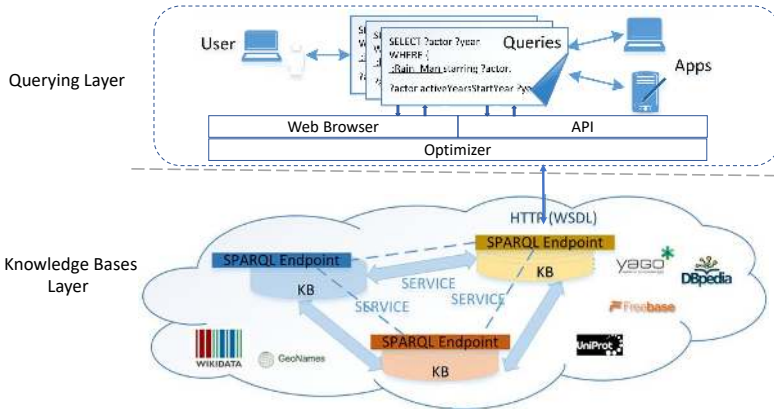

Fig. 1. Querying Curated Knowledge Bases

In the querying layer (top), a natural language question is transformed into a structured query which is executed against a KB and the answers are returned. Currently, querying SPARQL Endpoints has the problems like network instability and latency, which affect the query efficiency. Dumping the data and setting up local SPRAQL Endpoint is a solution, but data in a local Endpoint is not up-to-date and hosting an Endpoint requires expensive infrastructural support. Many research efforts have been dedicated to circumvent this problem [16, 17, 25–27] and caching is one of the popular directions [23]. While most research efforts focus on providing a server-side caching mechanism, being embedded in triple stores, client-side caching has not been fully explored [17]. Server-side caching is usually embedded in the background databases. Sometimes they are part of the query optimizer. Server-side cache is well developed but it is not customized to catch the different querying patterns from clients. Moreover, the design and development of server-side cache highly depend on the knowledge of background databases/servers. Therefore, it is not easy to develop a generic approach. On the other hand, client-side caching is a technique from Web applications, where the background databases/servers are black boxes to the Web users. Using client-side caching avoids making repeated requests to the servers and can quickly get answers. In addition, it is possible to collect client’s querying behaviours. In this article, clients refer to the users who perform the querying on SPARQL Endpoints. A user can be a human or a machine.

Our approach, SPARQL Endpoint Caching Framework (SECF), adopts the client-side caching idea and is domain-independent. In other words, our approach does not require the knowledge on what kind of data and how they stored in the knowledge base. SECF caches the (query, result) pairs for current processing query and its similar queries. This is motivated by the observation that end users who consume RDF-modelled knowledge typically use programmatic query clients, e.g., software or services to retrieve information from SPARQL Endpoints [16]. These queries usually have repetitive query patterns and only differ in specific elements of a triple pattern (a triple pattern is similar to a triple, except that at least one element namely subject, predicate or object, is a variable). Moreover, they are usually issued subsequently. To illustrate, Figure 2 gives two example queries that are structurally similar. Query 1 retrieves start year (i.e., the year their acting careers started) from the actors of the movie *Rain Man* and the year should be later than 1980. Query 2 requests similar information but for a different movie (*Eyes Wide Shut*). The differences between these two queries are the movie names (the underlined terms) and the year in the Filter expression. By considering these observations, we propose to prefetch and cache the query results of similar queries in advance. Since the subsequent queries have high possibility to be the similar queries that are cached, the results will be returned immediately (if cached) rather than being retrieved from SPARQL Endpoints. Therefore, the average query response time will be reduced.

The problem then turns into how to find similar queries that are potential subsequent queries. To this end, SECF utilizes machine learning techniques to learn from the historical queries and captures

```

Query 1
SELECT ?actor ?year WHERE {
  :Rain_Man dbpedia-owl:starring ?actor .
  ?actor dbpedia-owl:activeYearsStartYear ?year .
}
FILTER(?year>1980)

Query 2:
SELECT ?actor ?year WHERE {
  :Eyes_Wide_Shut dbpedia-owl:starring ?actor .
  ?actor dbpedia-owl:activeYearsStartYear ?year .
}
FILTER(?year > 1960)

```

Fig. 2. Example of Similar Queries. The queries only differ in the movie name and year.

the querying characteristics of the users. The key challenge centres on how to transform queries into vector representation that can be used by learning algorithms. We propose *Template-based feature modelling* to transform a SPARQL query into a vector using the distances between this query and a set of “template queries”. Each distance is considered as a feature value in this vector. This modelling approach drastically reduces the computation time compared to the state-of-the-art clustering-based feature modelling presented in [7]. SECF then modifies the k -Nearest Neighbour (k -NN) [1] model to learn from the feature vectors of training queries and to suggest similar queries of a new issued query Q . The suggestion process runs in the background thread. The training set will be updated periodically to reflect the changes. Thus, the training process will accordingly perform in a periodical manner. After identifying similar queries, SECF prefetches the results of these similar queries and caches the (query, result) pairs.

As the cache space is limited, less useful data should be removed from the cache. A cache replacement algorithm is introduced for this purpose. However, techniques for relational databases are page-based (e.g., LRU- k [20]), which cannot be directly applied into our client-side caching framework because our caching is record based. Moreover, our client-side application is not based on relational database management system (RDBMS). In this article, we use a *time-aware frequency* based algorithm, which leverages the idea of a novel approach recently proposed for caching in main memory databases in *Online Transaction Processing (OLTP)* systems [15]. More specifically, we propose and develop Modified Simple Exponential Smoothing (MSES) to evaluate the hit frequencies of cached queries and remove the ones with the lowest frequencies from the cache.

The contributions of this work are three folds. Firstly, we address the problem of providing a learning-based approach for accelerating query answering process for SPARQL Endpoints and design a caching framework. The framework can be deployed as a Web browser plugin, but ultimately we envisage it being embedded within SPARQL Endpoints that act as clients to other SPARQL Endpoints. Secondly, SECF suggests similar queries by leveraging machine learning techniques. The distance measurement for SPARQL queries considers both Basic Graph Patterns (BGPs) and the most used SPARQL operators. SECF also provides a time-aware smoothing-based cache replacement algorithm. Thirdly, we perform extensive experiments on real world queries to showcase the effectiveness of SECF.

The remainder of this paper is structured as follows. We give some background knowledge and overview the related work in Section 2. Then we introduce SECF and the technical details in Section 3. The experimental results are reported in Section 4. We give some discussions in Section 5 and finally conclude this article in Section 6.

2 BACKGROUND

In this section, we briefly introduce the SPARQL query language and then we overview the related work.

2.1 SPARQL Preliminary

The official syntax of SPARQL1.1 considers operators OPTIONAL, UNION, FILTER, SELECT and concatenation via a dot symbol (.) to group patterns. VALUES and BIND are to define sets of variable bindings. We use B, I, L, V for denoting the (infinite) sets of blank nodes, IRIs, literals, and variables. A SPARQL graph pattern expression is defined recursively as follows [22]:

- (i) A valid triple pattern $T \in (IVB) \times (IV) \times (IVLB)$ is a graph pattern,
- (ii) If P_1 and P_2 are graph patterns, then expressions $(P_1 \text{ AND } P_2)$, $(P_1 \text{ UNION } P_2)$ and $(P_1 \text{ OPTIONAL } P_2)$ are graph patterns,

- (iii) If P is a graph pattern and R is a SPARQL built-in condition, then the expression $(P \text{ FILTER } R)$ is a graph pattern.

A BGP is a graph pattern represented by the conjunction of multiple triple patterns. A SPARQL query can be decomposed into BGPs for certain operators and the result that can be regarded as a hierarchical tree. The decomposition is defined as follows:

Definition 2.1. (SPARQL Query Decomposition) Let $Q = (S_Q, P_Q)$ be the query where S_Q is the SELECT expression and $P_Q = P_1 \oplus \dots \oplus P_n$ is the query pattern with $\oplus \in \{\text{AND, UNION, OPTIONAL, FILTER, BIND, VALUES, MINUS}\}$. When pattern feature $\oplus \in \{\text{AND, UNION, OPTIONAL, MINUS}\}$, graph pattern $P_i, i \in [1, n]$ can be recursively decomposed to sub-level graph patterns until the graph pattern is a BGP which can be further decomposed to triple patterns as $P_{bgp,i} = T_1 \oplus \dots \oplus T_k$, where $\oplus = \text{AND}$. When pattern feature $\oplus \in \{\text{FILTER, BIND, VALUES}\}$, graph pattern P_i cannot be decomposed to BGPs and is represented as expressions.

2.2 Related Work

Our work mainly addresses caching problems in two research areas, namely *Query Caching* and *Query Suggestion*. We review the recent representative works of these two areas in this section.

Query caching has the rationale that it keeps the historical data for the usage of new queries. If new queries use the same data, results can be returned immediately, reducing the overall query response time. Query caching was originally developed in database communities and in recent years, has been extended to triple stores that manage SPARQL queries. Martin et al. [17] first proposed caching for SPARQL queries, in which both the complete triple query result and the application object are cached. However, this approach only considers repeated identical queries, while our work takes both identical and similar queries into consideration. The latter ones have high potential to be requested. Yang and Wu [27] developed an approach that caches intermediate result of basic graph patterns in SPARQL queries. For a new query, the approach checks if the result of any BGP or join of BGPs of this query is cached. The hit results are joined with the other parts of the query to form the final query result. This approach is designed to be embedded in a triple store and works with the query processing mechanism in the triple store. Very recently, Papailiou et al. [21] introduced canonical labelling to identify isomorphic subgraphs in SPARQL query patterns, which are cached for subsequent querying. This solution implements a caching layer on top of the distributed partitions and dynamically updates the contents of the cache. Verborgh et al. [26] proposed a Linked Data Fragments (LDF) approach, aiming at improving data availability. It can also be regarded as a caching technique because it caches fragments of queryable data from servers that can be accessed by clients. Each client is able to process SPARQL queries on replicated fragments cached from servers.

Query suggestion is usually adopted in search engines to better understand users' information needs with the ultimate goal to improve the recall of querying. Researchers recently introduce query suggestion to improve the SPARQL querying. Lehmann et al. [14] proposed to leverage a supervised learning framework to suggest SPARQL queries based on examples previously selected by users. This approach narrows the range of possible answers asked by users and requires no knowledge of the underlying schema or the SPARQL query language. Hasan [7] used a suggestion model to predict the performance of newly issued SPARQL queries. The model is trained with previously issued queries and corresponding query performance, e.g., query time. For new queries, their performances can then be predicted from the trained model. The key contribution is that the SPARQL queries are modelled as feature vectors. However, their feature modelling method is very time-consuming. Query relaxation is closely related to query suggestion and extends the original

query to obtain more information by removing some constraints (e.g., “ages of the students in a class” returns more data than “ages of the female students in a class” by removing the constraint “female”). In recent years, query expansion techniques have been used by several research efforts on SPARQL queries. Elbassuoni et al. [2] proposed multiple types of relaxation methods to improve the recall of entity-relationship search. Lorey et al. [16] clustered similar SPARQL queries to different templates in order to detect recurring patterns in queries. These templates can be used to expand queries for query processing. Fokou et al. [4] investigated query relaxation over RDF data and focused on identifying parts of SPARQL query that are responsible for the failure of the query. A recent work proposed by Zhang et al. [29] expands a query in order to obtain accessed triples when executing the query. Caching these accessed triples will help facilitating subsequent queries that might need to access them. The work expands a query Q according to the triple patterns of Q . A new query is generated by picking and modifying one of the triple patterns of Q and keeping the other parts in Q .

3 THE SPARQL ENDPOINT CACHING FRAMEWORK

3.1 Overview

Figure 3 illustrates the working processes of SECF. We use different color of numbering to depict the different processes in this framework. The blue numbers are about fetching query results directly from SPARQL Endpoint. The green ones show the process that the results are returned from the cache. The orange numbers are for the suggestion process while the yellow numbers are for caching suggested queries into the cache. When a new query is issued, SECF first checks if query recording is enabled (①). If yes, a background process will log all queries (⑥). The logged queries are used for the suggestion process, including training and suggestion (⑦). Then it checks if an identical query (either cached as an issued query or a suggested query) has been cached (②). If not, SECF fetches (③) and returns (④) the results directly from the SPARQL Endpoint. These results are cached in the cache module (⑤). If the results are in the cache (⑧), they are returned immediately via the cache model (⑨ and ⑩). When query suggestion is enabled, during run-time, suggested queries are generated for the current query in the suggestion module. The results of these suggested queries will be retrieved (⑪) from the SPARQL Endpoint in advance and cached (⑫), together with the queries in the form of (query, result) pairs (q_i, r_i). The aim of prefetching and caching similar queries in advance is to enhance the hit rate of cache (i.e., how much percentage

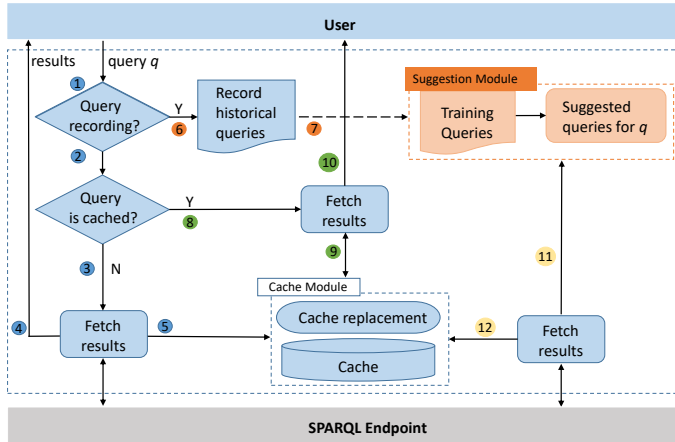

Fig. 3. SPARQL Endpoint Caching Framework

of queries can be answered immediately from cached results). A cache replacement algorithm is executed when the cache is full or the number of cache queries is reached. It runs in a separate thread so that it does not affect the query answering process.

The overall query speed depends on the hit rate of the cache. As it is observed that most subsequent queries are similar to previous issued queries in [16], the prefetch/cache process will increase the number of queries that are hit. If we cache the similar queries, which are potential subsequent queries, higher hit rate can be achieved. To identify and cache similar queries, we propose a learning based approach that consists of following three main steps:

- Step 1: *Feature modelling*. We propose to model SPARQL query to feature vectors that can be fed into multiple learning algorithms. However, transforming a SPARQL query into vector representation is a challenging problem. We first introduce the distance measurement between SPARQL queries in Section 3.2 and then discuss our feature modelling approach based on this distance in Section 3.3.
- Step 2: *Training and suggestion*. After obtaining the feature vectors of SPARQL queries, we train a suggestion model using historical queries as the training set. A trained model is the output. When a new query Q arrives, we first transform Q to a feature vector using techniques from Step 1. Then we feed the vector into the trained suggestion model for similar queries recommendation. We introduce our approach in Section 3.4.
- Step 3: *Cache and replacement*. We prefetch the results of similar queries. As the cache is with limited size, less useful queries (and their results) should be removed from the cache. We introduce our cache and replacement algorithm in Section 3.5.

3.2 Query Distance Calculation

To find similar queries, we compute the distance between two given SPARQL queries by calculating the distance between patterns of the two queries:

$$d(P_Q, P'_Q) = d(P_{bgp}, P'_{bgp}) + d(P_{filter}, P'_{filter}) + d(P_{bind}, P'_{bind}) + d(P_{value}, P'_{value}) \quad (1)$$

Where P_Q contains $P_{bgp}, P_{filter}, P_{bind}, P_{value}$ and P'_Q contains $P'_{bgp}, P'_{filter}, P'_{bind}, P'_{value}$. $d(P_Q, P'_Q) = 0$ denotes the two queries are structurally the same.

3.2.1 BGP Distance. We propose to use Graph Edit Distance (GED) [24] to measure the distance between BGPs because a BGP can be represented as a graph. In the graph, *subject* and *object* are nodes linked by *predicate* as the edge. GED between two graphs is the minimum amount of edit operations (i.e., deletion, insertion and substitutions of nodes and edges) needed to transform one graph to the other. However, different BGPs share the same graph, which contains two nodes and

Fig. 4. Mapping Triple Patterns to Graphs. Eight types of triple patterns are mapped to eight structurally different graphs. Black nodes are conjunction nodes for clarity. s is for *subject*, p is for *predicate*, o is for *object*. The question mark indicates that the corresponding component is a variable.

Fig. 5. Graph Modelling for BGPs in Query 1.

one edge. Therefore, the distance between each pair of BGPs is zero. In order to distinguish each BGP graph, we formulate the problem of modelling BGPs to distinct graphs as follows:

PROBLEM 3.1. (BGP Graph Modelling) Given $P_{bgp_i} = \{tp_1, tp_2, \dots, tp_n\}$ denote a BGP of a SPARQL query, $tp_k, k \in (1, n)$ is a triple pattern rooted at P_{bgp_i} . $ged(g_o, g_d)$ represents the graph edit distance between graph g_o and graph g_d . BGP graph modelling is the task that models each tp_k to a graph g_{tp_k} satisfying $ged(g_{tp_k}, g_{tp_l}) > 0$ when $k \neq l$.

To address the above problem, we propose to map all the eight types of triple patterns to eight structurally different graphs, as shown in Figure 4. The black circles denote conjunction nodes for clarity. They are not coloured in graph modelling. As we only consider the structures of queries, whether the connecting node represents a join or union is not distinguished. Therefore, the different meanings of connecting nodes are not considered in this work. Using these mappings, we model the triple patterns of BGPs in Query 1 in Figure 2, to a graph, which is depicted in Figure 5.

There are various ways to map triple patterns to graphs. However, in our work, the way that we choose for the mapping does not affect the final cache result very much. So we only focus on mapping distinct triple patterns to distinct graphs. The reason is that in our work, similar queries that can lead to a cache hit are mostly the ones that are structurally the same with the current processing query. Specifically, the k -NN model first returns the structurally the same queries as similar queries, then returns the ones that are structurally the same but with different filter and bindings, and finally returns structurally similar queries. As the queries are mostly issued by programmatic clients and are generated with query templates (as described in Section 1), most returned queries are the ones using the same template, i.e., are structurally the same. Thus the structurally similar queries will not affect the caching results much as they are with small numbers. So the distances between different triple patterns that are considered in measuring structurally similar queries give limited impact on caching performance. Therefore, the difference of various mapping ways is not considered here.

3.2.2 Other Distances. We calculate $d(P_{filter}, P'_{filter})$, $d(P_{bind}, P'_{bind})$ and $d(P_{value}, P'_{value})$ only when $d(P_{bgp}, P'_{bgp}) = 0$. We define distance between two FILTER expressions as half of their *levenshtein* distance when the variables in these two expressions are identical, otherwise the distance is a fixed value 1. Thus the distance is in the range of $[0, 0.5]$ or equals to 1.

$$d(P_{filter,i}, P'_{filter,i}) = \begin{cases} \frac{levenshtein(E(i), E'(i))}{2 \max(\text{length}(E(i)), \text{length}(E'(i)))}, & \text{if } V(i) = V'(i) \\ 1, & \text{else} \end{cases} \quad (2)$$

where $E(i)$ and $E'(i)$ represent the FILTER expression for $P_{filter,i}$ and $P'_{filter,i}$. $V(i)$ and $V'(i)$ are variables in these two FILTER patterns respectively. When there are multiple Filter expressions

that can be compared, the total difference is defined as:

$$d(P_{filter}, P'_{filter}) = \sum_{i=1}^m d(P_{filter,i}, P'_{filter,i}) \quad (3)$$

Filter expressions in Query 1 and Query 2 are similar as the distance is 0.05 using Equation (3). So $d(P_{Q1}, P'_{Q2}) = 0.05$ (Equation (1)). We also have similar functions for BIND and VALUE patterns.

3.3 Feature Modelling

Using the distance function Equation (1), it is intuitive to suggest similar queries to a given query Q by calculating the distances between Q and each historical query, then rank the distances in descending order and find the top k similar ones. However, the calculation of distances between Q and each historical query is time-consuming when the number of historical queries is large. Moreover, it cannot leverage the machine learning algorithms to facilitate the suggestion process because machine learning algorithms require the vector representation of objects [6]. Therefore, we choose to construct feature vectors for SPARQL queries that leverages the distances and can facilitate the similar queries suggestion. It is worth mentioning that the work in [7] proposes an approach to transform SPARQL query to vector representation. For comparison, we firstly introduce the approach in [7], which we refer to as *cluster-based feature modelling* (Section 3.3.1) and then discuss our approach, the *template-based feature modelling* (Section 3.3.2).

3.3.1 Cluster-based feature modelling. In cluster-based feature modelling, distances between each pair of queries in the training set are calculated using only BGP distance. Then *k-medoids* algorithm [11] is utilized to cluster the training queries by using distance scores that are calculated. The center queries of each cluster are selected and the distance scores between each center query and a query Q is obtained to form a feature vector of Q , where each score is regarded as an attribute of the feature of Q . Thus the number of clusters equals to the number of dimensions (i.e., the number of feature attributes) of the feature vector of Q .

3.3.2 Template-based feature modelling. The cluster-based feature modelling requires distance calculation between all training queries. Moreover, the clustering process adds additional time consumption. To reduce the feature modelling time, we propose to replace the center queries used in cluster-based feature modelling with representative queries that are generated by benchmark templates. Specifically, we generate queries from 18 out of 25 valid templates in the DBPSB benchmark [18] (we excluded queries which do not return any results: Query 1, 2, 3, 10, 16, 21 and 23). We refer to these queries as *template queries*. By recording the distance scores between a query Q with the 18 template queries, we obtain an 18-dimension feature vector for Q . The computation is then drastically reduced from $O(n^2)$ in cluster-based feature modelling to $O(n)$, where n is the number of queries. Therefore, our approach is feasible to apply to large size of training sets.

Moreover, we adopt three dimension reduction algorithms, namely Canonical Correlation Analysis (CCA) [8], Principal Component Analysis (PCA) [9] and Non-negative Matrix Factorization (NMF) [13] on the feature vectors. In machine learning, dimension reduction is the process of reducing the number of random variables to describe a large set of data while still describing the data with sufficient accuracy. It helps reducing the learning time on the feature vectors. CCA calculates the coefficient among all features and chooses the most uncorrelated features. PCA aims to find a linear transformation to project the original data to a lower-dimensional space which is as informative as possible to capture as much of the variance of the original data in an unsupervised manner. NMF finds approximate decomposition of original data matrix and thus reduces the dimension by storing the two decomposed lower dimensional matrices.

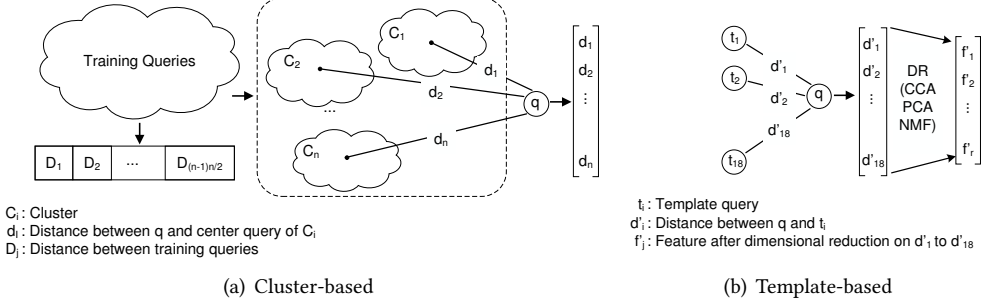

Fig. 6. Feature Modelling. The cluster-based modelling (a) is based on the distances among each pair of all the training queries. Clustering is done using these distances. d_i is the distance between query Q and the center query of the cluster C_i , and it represents a feature of Q . The template-based modelling (b) uses template queries. The distance between Q and template query t_i represents a feature of Q . After dimensional reduction (DR), the features are extracted to f'_1 to f'_r where $r < 18$.

Figure 6 illustrates the process and difference of cluster-based feature modelling and template-based feature modelling. In Figure 6(a), the modelling is based on all training queries. $\{D_{i=1}^{(n-1)n/2}\}$ record distances between each training queries. $\{C_{i=1}^n\}$ denote clusters. $\{d_{i=1}^n\}$ are distances between query Q and center queries of clusters. In Figure 6(b), t_1 to t_{18} are template queries. d'_1 to d'_{18} are distances between query Q and 18 template queries. f'_1 to f'_r are features that are obtained after applying dimensional reduction algorithm (i.e., CCA, PCA or NMF), where $r < 18$.

3.4 Suggesting and Prefetching Similar Queries

After the feature vectors are obtained (Step 1 in Section 3.1), we train a suggestion model with the feature vectors of training queries and suggest similar queries to a new query (Step 2). We adopt k -Nearest Neighbours (k -NN) [1] as prediction model because it is one of the two common types of similarity searches [12]. k -NN is a non-parametric classification and regression algorithm that predicts the performance of new data point based on its k -nearest training data points:

$$p_{new} = \frac{1}{k} \sum_{i=1}^k (p_i), \quad (4)$$

where p_{new} is the predicted value of the new data and p_i is the performance of the i -th nearest training data. If the new data is not in the training set, k -NN finds the point which is the closest to the new point according to its features.

k -NN is often successful in the cases where the decision boundary is irregular, which applies to SPARQL queries [7]. It is originally a supervised learning algorithm which requires labels (or classes). A k -d tree is built for the training data (points) with labels. For a new point, its k nearest neighbours in the tree are searched and its label (or class) is decided by the labels of these neighbours. In our work, we do not have labels and the task is not to classify the data points (a point refers to a query in this work) but to find the data points that are close to a given point. We therefore modify k -NN algorithm to only build the k -d tree according to the Euclidean distance between feature vectors of SPARQL queries and we omit the label part. The k -NN thus turns into an unsupervised learning algorithm. Then we use trained k -NN model to suggest the nearest (i.e., the most similar) queries for a new query. Given the similar queries for a query Q , we prefetch the results of these queries directly from SPARQL Endpoints and put the (q_i, r_i) pairs into the cache during the caching process.

3.5 Caching and Replacement

As the cache has limit space, the less useful data should be removed from the cache to give space to more useful data. In traditional page-based cache in databases, the less useful data is less frequently accessed which will be removed to give space to more frequently accessed data. When the data required by a new query is in the cache, the result is returned immediately. Each time the data in cache is accessed, it is called a *cache hit*. Therefore, the problem of cache replacement is the problem of identifying the more frequently accessed data.

SECF, the proposed client-side caching framework, does not require the knowledge of underlying system of SPARQL Endpoint. Thus we cannot directly apply the cache replacement algorithms used in page-based databases. We propose to use a *time-aware frequency* based algorithm, which leverages the idea of a novel approach recently proposed for caching in main memory databases in *Online Transaction Processing (OLTP)* systems [15]. Specifically, we cache the (query, result) pairs and consider the hit frequencies of them when performing cache replacement. The recently most hit queries in the cache are *hot* queries which are more useful queries. Hot queries will be kept in the cache, whereas queries in the cache that do not belong to hot queries are considered less useful, which will be removed from the cache.

Before we introduce the proposed cache replacement algorithm, we introduce how to measure the hit frequencies of queries in Section 3.5.1. Then we apply the proposed frequency measurement in developing two cache replacement strategies in Section 3.5.2.

3.5.1 Modified Simple Exponential Smoothing (MSES). We adapt the algorithm used for identifying hot triples in our previous work [29]. Here we introduce this algorithm and how we adapt it to identify hot queries.

The *Exponential Smoothing (ES)* is a technique to produce a smoothed data presentation, or to make forecasts for time series data, i.e., a sequence of observations [5]. It can be applied to any discrete set of repeated measurement and is currently widely used in smoothing or forecasting economic data in the financial markets. Equation (5) shows the simplest form of exponential smoothing. This equation is also regarded as *Simple Exponential Smoothing (SES)*.

$$X_t = \alpha * x_t + (1 - \alpha) * X_{t-1}, \quad (5)$$

where X_t stands for smoothed observation of time t , x_t is the actual observation value at time t , and α is a smoothing constant with $\alpha \in (0, 1)$. From this equation, it is easy to observe that SES assigns exponentially decreasing weights as the observation becomes older, which meets the requirement of selecting the most frequently and recently issued queries. The reason behind our choice of SES is its simplicity and effectiveness [15].

In SECF, we exploit SES to estimate hit frequencies of queries. In this case, x_t represents whether the query is hit at time t , thus it is either 1 for a cache hit; or 0 otherwise. Therefore, we can modify Equation (5) to *Modified Simple Exponential Smoothing (MSES)*:

$$E_t = \alpha + E_{t_{prev}} * (1 - \alpha)^{t_{prev}-t} \quad (6)$$

where t_{prev} represents the time when the query is last hit and $E_{t_{prev}}$ denotes the previous frequency estimation for the query at t_{prev} . E_t denotes the new frequency estimation for the query at t [15].

The accuracy of MSES can be measured by its standard error. We gave the derivation and the standard error of Equation (6) and provided a theoretical proof that MSES achieves better hit rates than the most used cache replacement algorithm LRU-2 in [29].

3.5.2 Cache Replacement Algorithms. We perform cache replacement based on the estimation score calculated by MSES. Each time a new query is executed, we examine the frequency of cache hit of this query using MSES. If it is in the cache, we update the estimation of frequency for it.

Fig. 7. Cache and Two Types of Records for Two Replacement Strategies. q_i denotes a query; r_i denotes the results of q_i ; e_i is the estimation of records calculated by Equation 6; t_{prev_i} is the last time q_i was hit in the cache; t_{pprev_i} is the second last time q_i was hit in the cache; H is the number of hot queries can be cached; n is the total number of historical queries; m is the number of historical queries recorded in the partial records.

Otherwise, we just record the new estimation. In order to realise the replacement, we use one hash map to store contents in the cache and the other hash map for recording information of historical queries. Figure 7 depicts the two hash maps. Cache stores the query and its results, denoted as (q_i, r_i) , where q_i is the key and r_i is the value. In the full-records, q_i is the key and r_i, e_i, t_{prev_i} is the value. In the partial records, one more information, the second last hit time of q_i is recorded and it is denoted as t_{pprev_i} . When the cache is not full, (q_i, r_i) are cached. Accordingly, related information is stored in the records. When the cache is full, replacement is required.

To decide which records can be kept in the cache, we develop two cache replacement strategies, namely the *Full-records replacement* and the *Improved replacement*. The difference of these two strategies is whether to keep the full records of the historical queries or not.

Full-records replacement. In the full-records replacement, the algorithm keeps the estimation records for all processed queries. Specifically, it processes all the historical queries. When encountering a hit to a query at time t , the algorithm updates this query's hit frequency estimation using Equation (6). When the scan on records is completed, the algorithm ranks each query by its estimated frequency and returns the H queries with the highest estimates as the hot set. These top- H queries are kept in the cache, while lower ranked queries will be removed from the cache. However, this algorithm requires storing the whole estimation records which produces large overhead. Furthermore, it consumes a significant amount of time when calculating and comparing the estimation values. To solve these issues, we consider improving the algorithm in two ways. One possible solution is that we just keep a record after skipping certain ones. This is a naive sampling approach. We vary the sampling rate but it turns out that the performance of this sampling approach is not desirable (see Section 4.3). The other possible approach is that we maintain partial records by only keeping those within a specified range of time.

Improved replacement. In the improved replacement, we only keep estimation records from a certain point of time to the current time to reduce the space overhead of the records. If we only keep very short records, the new cached query may fail to find its last estimation. In that case, the new estimated frequency of this query may be very small and it will be incorrectly removed from the cache. If we keep very long records, the space overhead is an issue as we discussed in full-records cache replacement. So we propose a solution that additionally keeps the second last hit time of a query in the records. Then we measure the maximum time gap between the last hit time and the second last hit time for each query in the records. After that, we use current time to minus this maximum time gap and get a previous time, which is the time that we start to keep the records. All the records before this time will be deleted.

Table 1. Selected patterns from SELECT queries. FILTER occupies large proportion in SELECT queries

	FILTER	VALUE	BIND
DBpedia3.9	83.97%	0.81%	0.06%
LinkedGeoData	50.72%	0.005%	0.0006%

Table 2. Analysis of clients associated with queries and clusters

	AvgQ/Client	AvgClusters/Client	AvgQ/Cluster
DBpedia3.9	23.31	2.27	10.26
DBpedia3.9-100	447.49	3.23	138.54
LinkedGeo	612.51	5.16	118.70
LinkedGeo-100	16,441.84	67.90	245.40

4 EVALUATION

We evaluate our proposed framework in this section. We first describe the setup of our evaluation environment (Section 4.1). Then we provide a detailed analysis of the real-world queries used in the evaluation (Section 4.2). Finally, we report the experimental results, including the performance comparison of cache replacement algorithms, feature modelling approaches and the performance comparison to the state-of-the-art work (Section 4.3 to 4.5).

4.1 Setup

Datasets. We analysed the query logs from DBpedia’s SPARQL Endpoint⁴ (DBpedia3.9) and Linked Geo Data’s Endpoint⁵ (LinkedGeoData) provided by USEWOD 2014 challenge. We extract queries by decoding, identifying SPARQL queries from query strings and removing incomplete queries and queries with syntax errors according to SPARQL1.1 specification. We focused on SELECT queries in the experiments and retrieved 198,235 valid queries from DBpedia3.9 and 1,790,047 valid queries from LinkedGeoData. Among these queries, 83.97% DBpedia3.9 queries and 50.72% LinkedGeoData queries have FILTER operator (Table 1).

Implementation and System. We obtained BGPs by parsing the SPARQL queries using Apache Jena-2.11.2. We implemented GED using a suboptimal solution integrated in the Graph Matching Toolkit⁶. The modified k -NN and LRU-2 were implemented in Java. Specifically, we adopted Weka library⁷ to build the k -d tree for k -NN. We set up our own SPARQL Endpoint by installing local Virtuoso server and loading datasets into the Virtuoso. The server has the configuration of 64-bit Ubuntu 14.4 with 16GB RAM and 2.40GHz Intel Xeon E5-2630L v2 CPU. Our code runs on a PC with 64-bit Windows 7, 8GB RAM and 2.40GHZ Intel i7-3630QM CPU.

4.2 Analysis of Real-world SPARQL Queries

4.2.1 Analysis of Average Queries. We used the distance measurement described in Section 3.2 to cluster the queries. Table 2 shows that the average queries for a client in DBpedia3.9 log files is 23.31, and the average clusters a client’s queries belong to is 2.27. The average queries in each cluster is 10.26. For LinkedGeoData queries, the average queries per client is 612.51 and each client’s queries belong to 5.16 clusters in average. The average queries in each cluster is 118.70. Our analysis shows that each client performed several queries which have shared clusters, indicating clients issued similar queries.

⁵<http://linkedgeodata.org/sparql>

⁶<http://www.fhnw.ch/wirtschaft/iwi/gmt>

⁷<https://weka.wikispaces.com/>

Fig. 8. Analysis of Average Matched Time. Similar queries are usually issued within a short period of time.

We also selected 100 clients with the most queries issued and found that the average number of queries for these top clients in DBpedia3.9 is 447.49 and the average clusters for one client is 3.23. The average queries per cluster increases to 118.70. The numbers for the top 100 clients who issued most queries in LinkedGeoData are higher, as average queries per client is 16,441.84, and average number of clusters per client is 67.90. In average, 245.40 queries belong to one cluster. These findings indicate that clients performed a large number of queries which have similar structures. The average number of queries for one cluster shows that queries have high similarity.

4.2.2 Analysis of Subsequent Queries. To estimate how likely it is that queries are similar to previous queries and therefore could benefit from the prefetched results, we evaluated the time difference between one query and the next matched query (i.e., the next query belonging to the same cluster) for each client. DBpedia3.9 log files have a total of 8,500 distinct client IDs and LinkedGeoData has 2,921 distinct client IDs. We assigned distinct IDs starting from 1 for clients of both datasets. Figure 8 shows the average time gap between two matches for both datasets. Blue crosses indicate the average time gap (to next matched query) for each client ID. From Figure 8(a), we can see most of the time gap are close to zero, positioning blue cross on the X-axis, which means that the client issues similar-structured queries subsequently. A small number of blue crosses are away from the X-axis, which means that these clients seldom issue similar-structured queries. Similar observations are found in Figure 8(b). It demonstrates the fact that most clients issue similar queries subsequently. Moreover, on average, the similar queries are issued by the same client with previous queries within a very close time period. This further confirms that our approach can benefit the clients' subsequent queries in terms of querying answering speed.

4.3 Performance of Cache Replacement Algorithm

We firstly evaluated our cache replacement algorithm MSES, because it would be used in the following experiments. To evaluate the performance of MSES, we implemented various algorithms including the full-record MSES, improved MSES, the sampling MSES, and LRU-2. LRU-2 is a commonly used page replacement algorithm which we implemented based on record rather than page. All of LinkedGeoData valid queries obtained were processed in this experiment because the size of this query set is much larger than DBpedia3.9 query set. Thus we can observe the difference between Improved MSES and MSES algorithms.

Fig. 9. Cache Replacement Performance (LinkedGeoData). Different values of α have different impact on the hit rates (a). Different cache replacement algorithms affect the hit rates largely (b). The improved MSES reduces the space overhead largely compared to the MSES (c).

Impact of α . As the *Exponential Smoothing* has only one parameter α , the choice for α would affect the hit rate performance. However, as per our experiments on different values for α , the hit rates differ only slightly and a value of 0.05 shows better performance, as shown in Figure 9(a).

Impact of Cache Replacement Algorithms. Figure 9(b) shows the hit rates achieved by the four algorithms we implemented. It should be noted that in the experiment, the caching size was set to 20% of the total historical queries and α was set to 0.05 for MSES and its variants. We chose 20% as the caching size because it is neither too large (e.g., > 50%) to narrow the performance differences among algorithms, nor too small (e.g., < 10%) leading to inaccurate performance evaluation due to insufficient processed data. From the figure, we can see that MSES and Improved MSES have the same hit rate until they have processed about 1.5 million RDF triples, after which MSES has a higher hit rate than Improved MSES. This is because MSES maintains the estimations for all processed records while the Improved MSES only keeps part of the estimations. The changing point denotes that from which, the Improved MSES maintains partial volume of estimation records. From the figure, we can also see that Sampling MSES does not perform well. This figure only shows the hit rate of sampling MSES with the sampling rate of 50%, which is expected to have a high hit rate. The LRU-2 algorithm has the lowest hit rate of all the algorithms. The hit rates of all algorithms start from 0 and reach their first peak at certain points, then fluctuate. The direction to the first peak shows the warm-up stage and the rest of the lines are the warmed stage. This illustrates that we exploit an incremental approach, which includes a warm-up stage to calculate the hit rate.

Space Usage for Records. Figure 9(c) gives the measurement of space usage by recording the estimations. As discussed before, MSES performs better than the Improved MSES. However, it consumes more storage space to maintain the estimation records for all processed triples. It also takes longer time to check the cache. Figure 9(c) shows the maximum space consumption for each algorithm. Note that we used all valid LinkedGeoData queries in this experiment. The columns are classified into four groups which represent the percentage of hot queries to all processed queries. In each group, the left column represents the maximum space used by MSES, including the hot queries and the estimation records. The middle column represents the space usage of the Improved MSES that also includes the hot queries and the estimation records. The right column represents the size of the hot queries. From this figure, we can see that the Improved MSES consumes less space.

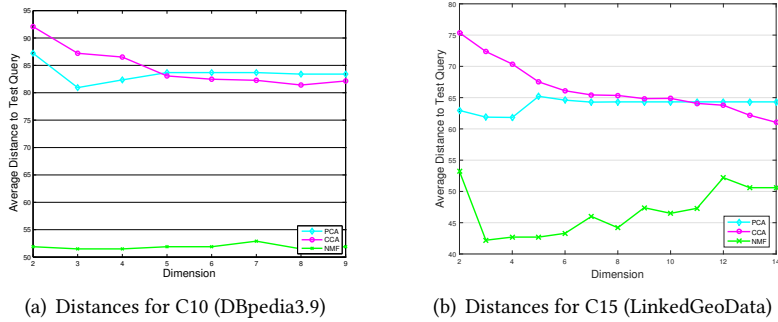

Fig. 10. Performance Comparison among Using CCA, PCA and NMF to Reduce Dimension (Cluster-based)

4.4 Comparison of Feature Modelling Approaches

In the experiments of this section, we compared our feature modelling approach (i.e., template-based feature modelling) with the state-of-the-art approach (i.e., cluster-based feature modelling), and evaluated the performance under the scenarios of applying and without applying suggestion/prefetching. We applied the dimensional reduction algorithms on both template-based feature modelling and cluster-based feature modelling methods.

Because the time consumption of cluster-based approach is tremendous, we did not use all valid queries as the training set. We randomly chose 21,600 training queries and 5,400 testing queries from the two query sets separately. The cache replacement algorithm used in all testing cases is Improved MSES and $\alpha = 0.05$. Because the larger size of cache, the higher hit rate it would achieve, we only show experimental results when the number of queries in cache is set to 1,000.

4.4.1 Performance of Cluster-Based Feature Modelling. In order to compare to template-based feature modelling approach, we applied dimensional reduction algorithms on cluster-based feature modelling approach. We generated new feature files with different lower dimensions for DBpedia3.9 and LinkedGeoData queries using CCA, PCA and NMF discussed in Section 3.3.2. The files are from Dimension 1 (D1) to D9 for DBpedia3.9 with 10 clusters (C10) and D1 to D14 for LinkedGeoData with 15 clusters (C15). We then trained k -NN model with these files respectively and got k suggested queries for a randomly chosen query Q . We computed the average distance between suggested queries with Q and computed the distances obtained when using CCA, PCA and NMF. The lower the average distance is, the better the suggestion is. As large amount of the queries from these two SPARQL Endpoints are similarly-structured or repeated (see Section 4.2), we set a large number of queries to suggest to avoid the distance to be zero. Thus we chose $k=500$ in k -NN in this experiment. As shown in Figure 10, NMF always performs the best for both DBpedia3.9 and LinkedGeoData queries. It gets optimal result when the number of dimensions is 3. PCA performs better than CCA when dimension is low and worse than CCA when dimension becomes high. For DBpedia3.9 queries, the intersection is $D=5$, while for LinkedGeoData, the intersection is $D=11$. We used NMF for our dimension reduction in the comparisons thereafter.

4.4.2 Performance of Template-Based Feature Modelling. In template-based feature modelling, we also leveraged dimensional reduction algorithms. The performance of different algorithms is shown in Figure 11. It is shown that NMF still outperforms other algorithms in extracting the most representative features.

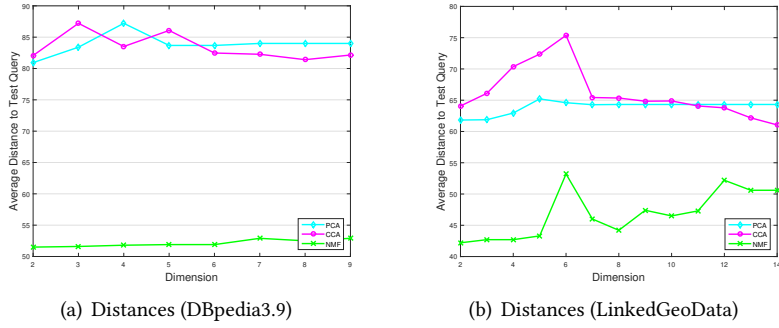

Fig. 11. Performance Comparison among Using CCA, PCA and NMF to Reduce Dimension (Template-based)

Table 3. Time comparison on feature modelling approaches

	Datasets	Cluster-based modelling (sec.)	Template-based Modelling (sec.)
Training Time	DBPedia3.9	33,446	1,109
	LinkedGeoData	23,405	758
Average Query Time	DBPedia3.9	355	251
	LinkedGeoData	234	158

Table 3 gives the impact of two feature modelling algorithms on time consumption. The training time is recorded for 21,600 training queries. Cluster-based approach requires 33,446 seconds, which is more than 9 hours for DBPedia3.9 queries, and 23,405 seconds (i.e., more than 6 hours) for LinkedGeoData queries. Template-based approach largely reduces the time to 1,109 seconds and 758 seconds, respectively. In terms of the average query time, our template-based approach also outperforms the cluster-based approach.

4.5 Performance Comparison with the State-Of-The-Art Work

We also compared our work with the Adaptive SPARQL Query Cache (ASQC) introduced in [17], as it is the first and complete work to cache SPARQL query in a client-side manner.

4.5.1 System Performance Comparison. In this experiment, we compared the average hit rate, average query time and space usage between our work SECF and ASQC. We also gave performance when no cache was used. To compare our approach with ASQC, we modified the code of ASQC⁸ to access our datasets. We performed the experiment on DBpedia3.9 dataset. We used Cluster-Based Feature Modelling and Improved MSES with $\alpha=0.05$. Table 4 presents the results. The first three columns of Table 4 show the performance comparison. Compared to the hit rate of ASQC (72.63%), SECF (78.59%) increases the performance by 5.96%. ASQC takes 264 ms in average for one query and SECF takes 247 ms. So SECF reduces the query time by 6.44%. When no cache is applied, the average query time increases to 625 ms. We did not include prefetching time as it is in a separate thread. The improvements showcase the effectiveness of our learning based approach and provide a research direction for improving SPARQL query performance using machine learning techniques. Space consumption evaluates how much memory the cache uses. In SECF, the total usage (before slash) for caching 1,000 queries includes cached queries and answers as well as the estimation records for cache replacement (after slash). We used the same implementation for ASQC in order to compare. The results indicate that the most space is consumed by cached (query, result) pairs.

⁸<http://wiki.aksw.org/Projects/QueryCache>

Table 4. Performance comparison

	ASQC	SECF	No Cache
<i>Hit</i>	72.63%	78.59%	NA
<i>AvgTime</i>	264ms	247ms	625ms
<i>Space</i>	7.15MB	7.15MB/0.45KB	NA
<i>AvgFreeMem</i>	217.87MB	206.35MB	224.30MB
<i>AvgIO</i>	11.49	21.43	7.72
<i>AvgCPU</i>	9.37ms	10.60ms	10.09ms

4.5.2 Server Overhead Comparison. In order to evaluate the impact of cache on the Endpoint server, we monitored the memory and CPU usage as well as I/O on the server. We captured the usage every 20 seconds until the querying ends. The last three columns of Table 4 show the server performance of ASQC, SECF and no cache applied. AvgFreeMem refers to the average free memory usage, AvgIO refers to the average I/O usage and AvgCPU is for the average CPU time, including system CPU and user CPU time. We only present the result on querying DBpedia3.9 dataset due to limited space. From the result, we found out that SECF and ASQC cause higher computation overhead (I/O and CPU) and memory usage on server compared to querying without cache and ASQC performs slightly better than SECF with more free memory (217.87MB vs 206.35MB), less I/O (11.49 vs 21.43) and less CPU time (9.37ms vs 10.60ms). It is because that SECF requires prefetching results for similar queries from server which leads to additional overhead.

5 DISCUSSION

In this section, we discuss some issues from our experience in this work and identify future research directions.

Partial Caching vs Query Caching. Some works focus on caching part of queries (i.e., subgraph) [21, 27] and identifying the hit subgraph (i.e., containment checking) [25]. These methods not only cache the exactly matched queries, but also the queries which share the same subgraph with the cached ones. Using such subgraph caching broadens the cached items and improves the cache hit rate. However, parsing and identifying query subgraphs is a very time-consuming task that counteracts the speed improvement achieved by caching. In some occasions it cannot accelerate the querying speed. In our current work, we have not considered partial caching of queries. Investigating efficient solutions by integrating partial queries into our framework will be part of our future work.

Dynamic Learning. In the training process, the larger the size of the training queries, the better performance we can get. The reason is that more query variety can be captured and the model will be less sensitive to unforeseen queries. However, in practice, unseen queries can be issued very frequently and quickly. In this case, no matter how large the current training set is, it is inefficient to cover as much as possible query varieties. There are two solutions for this issue. One solution is to periodically train on historical queries. We adopt this idea in our work. Similar to the suggestion process which is in a background thread, the periodical training, especially the building of the k -NN model, also runs in the background. Therefore, although it is time-consuming to train large query sets, periodical training will not affect the querying process. One benefit to use periodical training is that we can leverage the well developed learning algorithms. Moreover, our approach has already achieved great improvements in reducing the training time (Section 4.4). The other solution is incremental learning (or referred to online learning), which holds a new input batch in addition to

the existing learning model to reflect recently executed queries. We leave the investigation of these techniques as our future work.

Space Overhead. From evaluation (Section 4.5.2), we observe that the memory space used by SECF is mostly consumed by cached (query, result) pairs. This is because SECF caches the pairs in text directly. The size of the cached texts can be reduced by leveraging encoding techniques. Many existing triple stores (i.e., systems that holds RDF data) [19, 31] encode the RDF triples to numerical values in order to reduce the space overhead. By developing their own indexing algorithms, the access and retrieval of the triples become efficient. We could adapt the ideas to encode SPARQL queries or part of queries, e.g., BGPs and develop tailored indexing algorithms. We also can adapt compression techniques for data stream (e.g., [30]) to compress (query, result) pairs in our work. We will investigate these techniques in the future.

Sever Overhead. We observe from the comparison to the state-of-the-art work, ASQC, that SECF introduces slightly larger overhead to server side (Section 4.5.2). This is due to the fact that the prefetching process continuously requests data directly from the SPARQL Endpoint server. One possible improvement for this issue is to find the common results of multiple similar queries, so that less data requests will be issued. Containment checking can be considered to solve this problem [25], however, it is time-consuming. A supplementary solution is to add estimation of the results of these queries and prune the ones that would return empty results. In this way, less queries are issued directly to the server side.

6 CONCLUSION

In this article, we introduce a client-side caching framework, SECF, to improve the overall querying performance on the SPARQL Endpoints that are built upon curated knowledge bases. SECF utilises machine learning techniques to learn clients' query patterns and suggests similar queries, whose results are prefetched and cached in order to reduce the overall querying time. Our proposed template-based feature modelling method greatly outperforms the state-of-the-art method, cluster-based feature modelling method in terms of training and suggestion time. The suggestion process achieves the improvement on the overall cache hit rate and is further improved by introducing dimensional reduction algorithms, especially NMF. The proposed cache replacement algorithm, MSES, outperforms the most used cache replacement algorithm LRU-2 in terms of hit rate. Improved MSES further reduces the space overhead by considering a part of estimation records without losing cache hit rate. Compared to the state-of-the-art client-side caching framework ASQC, SECF outperforms ASQC in terms of the average query time, but attracts some overhead on the server. Based on our experience from this work, we also identify a number of interesting research dimensions to further improve our approach: i) we will investigate more efficient solutions by integrating partial queries into our framework; ii) we will examine if incremental learning would be beneficial to our framework; iii) we will also adapt compression techniques for data stream to compress (query, result) pairs in our work.
