A new non-isolated low-power inductorless piezoelectric DC-DC converter

B. Pollet, G. Despesse, and F. Costa, *Member, IEEE*

Abstract—A new non-isolated low-power inductorless piezoelectric resonant converter is presented. The piezoelectric material is used as an energy storage element like an inductance in a classical Buck-Boost power electronic converter. As opposed to most existing piezoelectric converters, the proposed topology enables to dynamically adjust the output power and ratio keeping a high efficiency for a large range of output powers and for a large range of conversion ratios taking advantage of piezoelectric high quality factor and achieving zero voltage switching. A theoretical analysis of the step-up converter using an energetic approach is introduced and enables a fast and reliable pre-design of the piezoelectric component. This analysis is in perfect agreement with the simulation model performed on Matlab/Simulink. For a given piezoelectric resonator both analytical and simulation models provide very high efficiencies for different output powers. The converter is tested experimentally with a 10 V input voltage using the piezoelectric radial resonance mode. An efficiency higher than 98% for a 160 mW power conversion was achieved, decreasing slowly to 78% at 1.4 W. For a large range of voltage gains, the efficiency remains higher than 90% up to an output power of 750 mW. The experimental results are in perfect agreement with the theoretical analysis until 500 mW.

I. INTRODUCTION

WITH the significant progress of the manufacturing processes in the last decades, piezoelectric materials have become increasingly performing and widely used [1]. Indeed, piezoelectric direct and reverse effects are present in numerous and various applications like sonar systems, energy harvesting, ultrasound scanner for health care, and power electronics converters [2]–[5]. In power electronics, piezoelectric elements enable to have a high power density, a thin and planar geometry, low EMI radiations, an excellent efficiency; moreover, they can be integrated on silicon more easily than popular wire wound magnetic components. That is why piezoelectric converters are very relevant for compact and planar low power conversions (from mW to dozens of W), and are therefore particularly well adapted in energy harvesting, medical applications and autonomous devices.

Most of piezoelectric converters work with a piezoelectric transformer (PT) associated with a half bridge topology [6]. They are quite well adapted for low power with high output voltage ratio applications. The parallel capacitance of the primary electrodes of the PT constitutes an inherent difficulty to achieve zero voltage switching (ZVS) and therefore to reduce the switching losses and to optimize the efficiency. To fix it, the most common approach involves adding an inductance in order to generate a series resonant LC circuit in order to achieve ZVS conditions [7]. The corresponding converter is represented in Fig. 1-a. ZVS mode can also be obtained by adding a parallel inductor with a series capacitor [8]. Another solution without any additional magnetic device was proposed in [9]. The idea is to benefit from the natural inductive behavior of the resonating piezoelectric material at specific frequencies to charge or discharge the parallel input capacitance for ZVS. However, it implies specific conditions to operate like a sufficient current and a short "dead time" that limits the operating range. Different analyses were carried out to predict the ZVS areas [10]–[13]. Some converters use a single piezoelectric element (without PT) in which the material plays a role of energy storage [14], [15]. Fig.1-b illustrates an inductor-less DC-DC resonant converter operating with ZVS conditions. It works like an improved resonant type switched capacitor circuit [16].

Fig. 1-a. Half bridge piezoelectric converter with an added inductance L_{in}

Fig. 1-b. Improved switch capacitor inductor less piezoelectric step up converter

For all the previously mentioned piezoelectric converters, excellent efficiency higher than 90% were reported with output powers able to reach dozens of Watts (with several hundred Volts of input voltage). The switches are controlled with a fixed duty cycle at a frequency close to the piezoelectric resonance one. The output voltage/current is regulated by driving the frequency. However, there is a strong connection between output voltage/current and frequency. Therefore, for a given load and given output voltage, only a narrow range of frequencies corresponding to a small range of input voltages will allow the voltage regulation. For instance, in Fig.7 of [15], for a 10W step down conversion, the range of reported transfer gains is between 0.31 and 0.5. Other control methods driving the PT at fixed frequency were presented using pulse width modulation control (PWM) or a combination of PWM and PFM to increase the regulation capabilities [17], [18]. However, even in fixed frequency or hybrid control, the operating frequency is not necessarily close to the resonance frequency, the latter depending on output gain and load. The consequence is a drop of efficiency for some operating points since the efficiency is decreasing severely when the driving frequency moves away from the converter resonance frequency [1] . Some control strategies, like those discussed in [19], [20] enable to operate at the optimum frequency but quantum control solution [19] is not inductorless and needs a bulky output capacitor. Moreover, the self-oscillating loop method [20] requires digital control and a piezoelectric current estimation. A control scheme using a tunable piezoelectric transformer (TPT) was described in [21]. This method enables a voltage regulation under both load and input voltage variations operating at the optimum frequency. This converter requires an inductor, a supplementary capacitor and a supplementary switch (compared to classical half bridge topology). The TPT, where a part of the piezoelectric transformer is dedicated to the control, limits by its nature the range of load variation.

In this paper, a new topology with a completely new control strategy is presented. This structure is totally inductorless, works very close to the converter resonance frequency (slightly above the resonance) and enables to work naturally with ZVS conditions. There is only one single piezoelectric element (not a PT) having the same energy storage function as a traditional magnetic based inductance in a flyback or buck-boost converter. The new converter requires one supplementary switch comparing to the common half bridge piezoelectric converter but it enables unlike many classical design to keep excellent efficiency for a very large range of output power and for numerous voltage gains. The major drawback is a more complex control, driving the switches inside a resonant period (see explanations in section II). The conversion principle is similar to existing state-of-the art electrostatic converters where a variable capacitance plays a similar role than the piezoelectric ceramic [22], [23]. However, the very high quality factor of piezoelectric ceramic resonators and their higher power conversion capability make them a more advantageous solution. The converter working principle is given in section II and the method to characterize the model parameters is presented in section III. An analytical analysis is presented in section IV; it is compared to simulation and experimental results in section V and VI. Finally, a discussion on the operation and limitations of this new converter is proposed in section VII.

II. CONVERTER DESCRIPTION

The converter generic topology is represented in Fig.2-a. This structure allows both step-up and step-down conversion depending on how the switches are controlled. Thanks to the very high quality factor of the ceramic, the mechanical deformation of the resonator and therefore the associated piezoelectric current i are assumed to be sinusoidal. The output capacitance is considered large enough to assume a constant output voltage V_{out}. When the resonator is connected to a voltage source, charges are exchanged leading to an energy transfer. Depending on the sign of the internal piezoelectric current, the material accumulates or releases energy. On the contrary, if the resonator is isolated (all the switches are turned off), the energy stored in the material and its global electric charge remains constant. The material keeps resonating leading to a sinusoidal piezoelectric voltage variation.

Fig.2-f. SDC Phase 5 circuit configuration (phase 6 SUC)

Fig.2-g. SUC Phase 4 circuit configuration

The conversion principle consists of applying a switching cycle, synchronized with the piezoelectric current waveform, alternating constant voltage phases to exchange energy at different voltage levels and constant charge phases to let the piezoelectric material change its voltage enabling to switch in ZVS mode.

The description phase by phase of the two cycles (step-down and the step-up operation) is presented below. Fig.2-(b)-(g) present the circuit configurations with the corresponding current flow.

Step-down operation (Fig.3-a and Fig.3-c)

Phase 1, $t \in [0-t_1]$ (fig.2-b): The cycle starts when the piezoelectric current i reaches 0A (i (0⁻)<0). k_{in} is turned on and k_{out} and k_3 are off. The resonator accumulates energy from the

input source (V_p equals V_{in}) until t_1 where k_{in} is turned off. t_1 is chosen so as to have the desired output voltage/current and is therefore the control parameter.

Phase 2, $t \in [t_1-t_2]$ (fig.2-c): All the switches being off, the resonator is isolated leading to a sinusoidal variation of V_p. Since i is positive, C_p is discharged and the piezoelectric voltage drops until 0V (at t_2).

Phase 3, $t \in [t_2-t_3]$ (fig.2-d): When V_p equals 0V, k_3 is turned on ensuring a ZVS operation (V_{k3} is null). V_p is kept constant until the piezoelectric current reaches 0A (half of the current resonant period, $t_3=T/2$).

Phase 4, $t \in [t_3-t_4]$ (fig.2-e): In this constant charge phase, k_3 is turned off and since i is negative, C_p is charged and V_p increases until $V_{out.}$ at t_4.

Phase 5, t ϵ [t₄-t₅] (fig.2-f): At t₄, k_{out} is turned on with no switching losses (ZVS achieved since V_{kout} equals zero) and V_p equals V_{out} until t₅. The energy taken during phase 1 is now released to the output. t₅ is set so that V_p reaches precisely V_{in} at T.

Phase 6, t ϵ [t₅-T] (fig.2-e): At t₅, k_{out} is turned off. In this constant charge phase (all switches being off), i is still negative and therefore V_p increases until reaching precisely V_{in} at T and then a new cycle begins.

Step-up operation (Fig.3-b and Fig.3-d)

Phase 1, t ϵ [0-t₁] (fig.2-c): The cycle starts when the piezoelectric current i reaches 0A (i (0⁻)<0) and V_p equals V_{out}. In phase 1, all the switches are off and since i is positive, V_p decreases until reaching V_{in} at t₁.

Phase 2, t ϵ [t₁-t₂] (fig.2-b) : k_{in} is turned on at t₁ when V_{kin} is 0V (ZVS mode). The resonator accumulates energy from the input source (V_p equals V_{in}) until t₂ where k_{in} is turned off. t₂ is set so that V_p equals 0V at t₃ precisely (half of the current resonant period, t₃=T/2).

Phase 3, t ϵ [t₂-t₃] (fig.2-c): Since i is still positive and all the switches are off, V_p decreases until reaching 0V at t₃.

Phase 4, t ϵ [t₃-t₄] (fig.2-g) : When V_p (and therefore V_{k3}) equals 0V, k_3 is turned on ensuring a ZVS commutation. V_p is kept constant until t₄ which is chosen so to have the desired output voltage/current. t₄ is therefore the control parameter.

Phase 5, t ϵ [t₄-t₅] (fig.2-e): k_3 is turned off at t₄ and i being negative, V_p rises until reaching V_{out} at t₅.

Phase 6, t ϵ [t₅-T] (fig.2-f): k_{out} is turned on at t₅ when V_p equals V_{out} and V_{kout} equals 0V (ZVS mode). The energy taken during phase 2 is now released to the output. After the end of the piezoelectric resonant period, (i becomes positive), k_{out} is turned off and a new cycle begins.

Fig.3 synthetizes the whole 6-phases steady state cycles for both step-up and step-down configurations. For each case, the piezoelectric voltage waveform with its associated piezoelectric current is represented. The mechanical deformation is phased shift by 90 degrees relative to the current. The voltage and current waveforms of each switch is illustrated as well.

In steady state, an energy balance is ensured at each resonant period. The energy transferred from the input source to the resonator (during phase 2 for the SUC and 1 for SDC) is exactly the same as the energy restituted to the load (phase 6 for SUC and 5 for SDC) assuming no losses. In a mechanical point of view, this corresponds to self-sustainable oscillations. The principle is similar to a traditional magnetic based buck-boost converter where an inductance receives energy from an input source, stores it temporarily and releases it back to the load. However, the storage is, in this case, mechanical instead of magnetic. In the cycle, a third constant voltage phase (phase 4 in SUC and phase 3 for SDC) is imperative to ensure energy balance at each cycle and brings a degree of freedom to the system.

With this structure, this third voltage is zero volt, but it could be different, for example -V_{out} for a SDC, but it would require more switches. For the boost converter, phase 4 duration, where the resonator is short-circuited, has a direct impact on the total amount of energy exchanged in the whole cycle. Therefore, controlling t₄ (opening of k_3) enables to regulate either the output power, output voltage or output current and to compensate the losses. Since the system has only one degree of freedom, the 5 other times are imposed to get the desired cycle of Fig.3-b. For a buck operation, t₁ plays the role of t₄.

For a SUC, since k_{in} has to sustain both negative and positive voltage (V_{in}−V_{out} and V_{in} as Fig.3-d states), k_{in} is composed of two MOSFETs placed head to tail. Because V_p is always equal or less than V_{out} and its current only in one way, k_{out} could be a simple diode, but in order to reduce losses, k_{out} is a MOSFET transistor and acts as an active rectifier. k_3 is also a MOSFET transistor. The key curves of fig.3 show clearly that the converter operates in ZVS mode for all switches. Similar switches are required for the SDC. For the following, this paper focuses only on the step up operation.

III. PIEZOELECTRIC RESONATOR CHARACTERIZATION

A model of the piezoelectric resonator is required to foresee the general behavior of the converter. The piezoelectric characterization enables knowing the operating frequency, the losses, and the maximum output power. This characterization is therefore useful to design the material and the switches.

At resonance, the ceramic can be represented by the well-known and accurate electrical equivalent model of Fig.4. C_0 corresponds to the real capacitance of the ceramic material and the other branch reflects the mechanical behavior (motional branch). Indeed, L is related to the mass, C to the stiffness, R to the mechanical losses (damping). The current amplitude flowing inside this motional branch represents the mechanical oscillations velocity. A simple impedance analysis gives the value of all parameters of this model and enables to compute the mechanical quality factor, the resonance frequency and the coupling factor. At resonance, L and C can be replaced by a sinusoidal current source because of the very high quality factor. The quality factor is directly linked to the damping and

is inversely proportional to R. The coupling factor represents the electrical/ mechanical conversion capability.

Fig. 4. Piezoelectric resonator equivalent model

The simulations shows that the resonator must have a high quality factor (>500) and a quite high coupling factor (> 0.3) [24]. For these reasons, Lead Zirconate Titanate (PZT) ceramic are attractive candidates for this converter. A PZT ceramic (Fuji ceramic C213 ®) was characterized and gives both a high quality factor (1030) and coupling factor (0.57) with a resonant frequency around 90 kHz. This disc-shaped

ceramic is the better one we found to maximize the power and efficiency of this converter. The following simulation and experimentations are done with this ceramic. The values of the parameters are gathered in TABLE I including the geometry parameters.

TABLE I

CHARACTERIZATION OF THE CERAMIC

Element	Value
Diameter	25 mm
Thickness	0.75 mm
Resonant frequency	88.9 kHz
R	0.6 Ω
L	1 mH
C	4 nF
C_0	8.4 nF

IV. STEP-UP CONVERTER WORKING ANALYSIS

A. Model without losses

The piezoelectric step-up converter analysis is set up with an energetic approach for a resistive load R_L. The model is based on three principles defining the converter operation: energy balance (1), charge balance (2), and ZVS equations (3)-(5). Indeed (3), (4) and (5) guarantee that the voltage across respectively k_{in}, k_3 and k_{out} is null when they are turn on (at respectively t_1, t_3 and t_5) and that the cycle described in Fig.3-b and Fig.3-d is well respected. Q_{in}, Q_3 and Q_{out} are the algebraic electric charges in Coulomb transferred respectively during phases 2, 4 and 6 for the step up converter (SUC) and 1, 3 and 5 for the step down converter (SDC). The piezoelectric motional current is assumed to be sinusoidal (6). This current operates slightly above the resonance frequency in the inductive part (necessary to achieve ZVS operations) but can be assumed to work at resonance without affecting the model. ω is therefore the resonance pulsation and I is the piezoelectric current amplitude. R equals zero assuming no loss in the material. For the case of the step-down converter (described in Fig.3-a and Fig.3-c), (1), (2) and (6) remain correct but (3)-(5) must be adapted.

$$V_{in}.Q_{in} + V_3.Q_3 + V_{out}.Q_{out} = 0 \tag{1}$$

$$Q_{in} + Q_3 + Q_{out} = 0 \tag{2}$$

$$V_p(t_1) - V_p(0) = V_{in} - V_{out} \tag{3}$$

$$V_p(t_3) - V_p(t_2) = -V_{in} \tag{4}$$

$$V_p(t_5) - V_p(t_4) = V_{out} \tag{5}$$

$$i(t) = I.sin(\omega.t) \tag{6}$$

To solve the system, the equation implying the load resistance R_L is added (7). *Pout* is the output power, I_{out} is the mean output current. Per convention, we will consider that a positive current is a current that brings charges to the piezoelectric ceramic. Since the piezoelectric material transmits charges to the output, *Pout* and I_{out} are negatives.

$$P_{out} = -V_{out}^2/R_L = V_{out}.I_{out} \tag{7}$$

$$I_{out} = \frac{1}{T}\int_{t_5}^{T} I.\sin(\omega.t).dt = \frac{I}{2.\pi}.(\cos(\omega.t_5) - 1) \tag{8}$$

Combining all these equations, all unknown variables can be found, and expressed as a function of the input and control parameters. Since this model presents the step-up converter, the output voltage gain G and the current amplitude depend on the control parameter t_4 and are given by:

$$G = \frac{V_{out}}{V_{in}} = \frac{2 + R_L.C_0.\omega.(1 + \cos(\omega.t_4))/(2.\pi)}{1 - \cos(\omega.t_4)} \tag{9}$$

$$I = \frac{-2.\pi.P_{out} + C_0.\omega.V_{out}.V_{in}}{2.V_{in}} \tag{10}$$

Assuming a constant output voltage, (10) states that the current amplitude increases linearly with the output power.

B. Effect of the mechanical damping of the piezoelectric material

In this part the mechanical losses are taken into account (R is considered) but semiconductors losses are not. The purpose is to foresee the behavior of the converter with respect to a selected piezoelectric resonator. All the constitutive equations remain correct except the energy balance one (1), which is replaced by (11).

$$V_{in}.Q_{in} + V_3.Q_3 + V_{out}.Q_{out} = \frac{R.I^2.T}{2} \tag{11}$$

The new voltage gain G is expressed below.

$$G = \frac{2.g_1 - C_0.\omega}{2.\frac{\pi}{R_L} + g_1^2.R.\pi} \tag{12}$$

$$where \; g_1 = \frac{I}{Vs} = \frac{R_L.C_0.\omega + 2.\pi}{R_L.(1 - \cos(\omega.t_4))} \tag{13}$$

g_1 is an admittance (Ω^{-1}) that links the output voltage to the piezoelectric current amplitude.

In the case where the output voltage is fixed at the desired V_{out} value thanks to the control of t_4, the current I can be deduced from the quadratic equation (14).

$$R.\pi.I^2 - 2.V_{in}.I + C_0.\omega.V_{out}.V_{in} + \frac{2.\pi.V_{out}^2}{R_L} = 0 \tag{14}$$

The physical solution of the previous quadratic equation is found by considering the continuity of I with (10) when R tends to zero. Expression (15) gives the piezoelectric current amplitude, Δ_I is the discriminant of (14).

$$I = \frac{(2.V_{in} - \sqrt{\Delta_I})}{2.\pi.R} \quad (15)$$

The suitable piezoelectric PZT ceramic characterized in section III with the element of TABLE I is used in the following simulations. Fig.5 compares the two models with and without losses for an input voltage of 10 Volts.

For a 400 Ω resistive load, the output gain is represented with respect to Cos($\omega.t_4$) in Fig.5, a function of the control time t_4. Since $\omega.t_4$ is higher than π, Cos($\omega.t_4$) is an increasing function of t_4. For low powers, both models are very close but for higher powers, the output current increases, losses became more influent and a mismatch is observed. The curve which is including losses indicates the theoretical highest output voltage ratio that can be reached with the material characterized in section III. The graph is very similar to the classical one representing the evolution of the output voltage with respect to the duty cycle for a traditional boost converter. Considering the mechanical losses, the converter enables theoretically to boost the voltage up to 5 times the input voltage with this particular load but the converter can achieve an even higher output ratio if the resistive load is increased.

Fig. 5. Output voltage gain with respect to cos ($\omega.t_4$) with and without mechanical losses

C. Efficiency and remarkable points analysis

The efficiency (not including the driving power neither switching losses) η can be computed as follow:

$$\eta = \frac{-Q_{out}.V_{out}}{Q_{in}.V_{in}} = 1 - \frac{R.I^2.\pi}{V_{in}.(2.I - C_0.\omega.V_{out})} \quad (16)$$

The impact of the control time t_4 on keys values of the converter is exposed in Fig.6 with a 1000 Ω resistive load (the input voltage is still 10 V). The converter keeps an excellent efficiency for a very large range of control time. All the curves

evolves smoothly with Cos($\omega.t_4$) at first but become more sensitive for higher values of Cos($\omega.t_4$). The current amplitude I and mechanical losses increase with t_4 and the efficiency drops (because Cos is an increasing function in the operating points). The output power rises at first, reaches a maximum value and finally drops significantly after this peak value. The right part after this maximum should be avoided because the same power can be converted with a higher efficiency on the left part. However, this theoretical maximum output power is not accessible experimentally because the resonator we chose is not able to carry a 5 A current. Nevertheless, this maximum output power (with respect to t_4) is reachable with the same material by just reducing the input voltage, which reduces the exchanged energy and then the piezoelectric current amplitude.

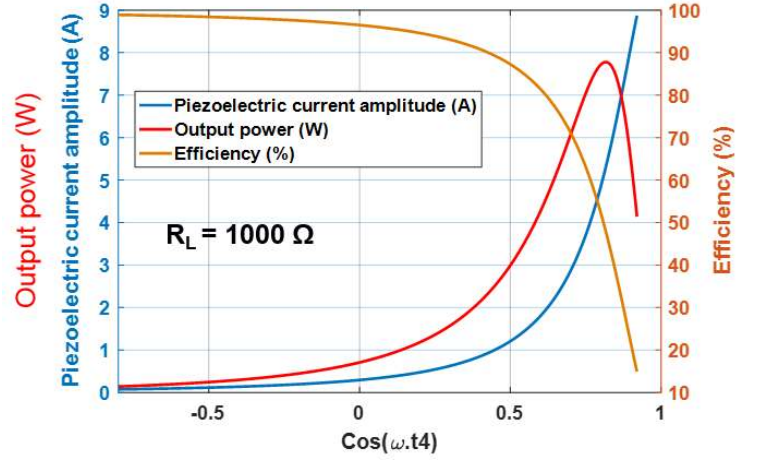

Fig. 6. Impact of control on keys values of the converter

For a fixed output voltage, the efficiency is derived for different output powers from (15) and (16). Fig.7 shows the theoretical efficiency as a function of the output powers, for two output voltages and two piezoelectric damping values. The results are very promising with an efficiency higher than 95% for a very large operating range up to 1.5 W (for R = 0.5 Ω). At the same output power, the efficiency decreases when the output gain increases. The impact of R on the efficiency is illustrated by the dotted curve where this resistance has been doubled. The efficiency and maximum output power are clearly reduced when R is increased, which confirms that the material must be chosen with a mechanical resistance as low as possible, meaning a material with a high quality factor.
Fig. 7. Theoretical power-efficiency curves for 2 output voltages and mechanical damping

The analytical model reveals a maximum of efficiency at a given output power and a maximum power transfer point due to the mechanical losses. There is also a maximum theoretical efficiency in classical half-bridge topology with PT [25].

1) Maximum power point and corresponding efficiency

The discriminant of the quadratic equation (14) must be positive in order to get real solutions. This leads to a maximum limit for the output power P_{out_max} . At this maximum output power (computed with (17)), the efficiency is given by (18).

$$\left| P_{out\_max} \right| = \frac{\frac{V_{in}^2}{R.\pi} - C_0.\omega.V_{in}.V_{out}}{2.\pi} \qquad (17)$$

$$\eta(P_{out\_max}) = \frac{\frac{1}{2} - \frac{C_0.\omega.G.R.\pi}{2}}{1 - \frac{C_0.\omega.G.R.\pi}{2}} \qquad (18)$$

With a traditional disc-shaped piezoelectric ceramic, the common part of the numerator and denominator of (18) is very small compared to 1 and therefore, as an impedance matching, the efficiency at maximum output power is around 50% whatever the gain. The global maximum output power is reached when the output gain G tends to 1 and equals 8.37 W with the piezoelectric element of TABLE I and an input voltage of 10 V. This global maximum output power is approximated by neglecting the second term of the numerator of (17) (8.44 W). This maximum output power depends of the square of the input voltage.

2) Maximum efficiency and corresponding power

To find the maximum efficiency η_{max}, the efficiency is expressed as a function of Δ_I. Finally, the maximum output power is calculated using (19) by finding first the power that leads to the maximum efficiency (20). At the end, this leads to a very simple expression (21) for the maximum efficiency,

which depends of the main piezoelectric parameters (C_0, ω, R) and of the desired output gain G. This simple formula makes the pre-designing fast and reliable.

$$\frac{d\eta}{d(-P_{out})} = \frac{d\eta}{d\Delta_I}.\frac{d\Delta_I}{d(-P_{out})} \qquad (19)$$

$$Pout(\eta_{max}) = \frac{C_0.\omega.V_{out}}{2.\pi}.(V_{out}.C_0.\omega.R.\pi - V_{in}) \quad (20)$$

$$\eta_{max} = 1 - C_0.\omega.R.\pi.G \qquad (21)$$

The global maximum efficiency reachable with our selected ceramic is 99.1% (computed using (21) with G = 1).

3) Maximum output gain

For a given resistive load, a maximum output gain V_{out_max} and therefore output power can be found choosing the appropriated t_{4_opt} time. This is illustrated by Fig.6. To find this maximum value, a method similar to the one expressed by (19) is used. Δ_g is the discriminant of the quadratic form that appears solving the system. g_{1_opt} corresponds to the value of g_1 from (13) that gives the highest V_{out}. V_{out_max} is an increasing function of R_L (25) with an asymptotic limit value (27). The piezoelectric current amplitude leading to this maximum voltage, given by (26), is independent from R_L.

$$\Delta_g = (C_0.\omega)^2 + \frac{8}{R.R_L} \qquad (22)$$

$$g_{1\_opt} = \frac{C_0.\omega + \sqrt{\Delta_g}}{2} \qquad (23)$$

$$t_{4\_opt} = \frac{1}{\omega}.(-arccos(1 - \frac{2.R_L.C_0.\omega + 4.\pi}{R_L.(C_0.\omega + \sqrt{\Delta_g})}) + 2.\pi) \quad (24)$$

$$V_{out\_max} = \frac{2.V_{in}.g_{1\_opt} - C_0.\omega.V_{in}}{\frac{2.\pi}{R_L} + R.\pi.g1\_opt^2} \qquad (25)$$

$$I(V_{out\_max}) = \frac{V_{in}}{R.\pi} \qquad (26)$$

$$\frac{V_{out\_max}}{V_{in}}(R_L \to +\infty) = \frac{1}{R.\pi.C_0.\omega} \qquad (27)$$

The higher the piezoelectric quality factor is, the higher the converter gain can be. The theoretical maximal output gain that can be reached with the chosen piezoelectric is 112. This structure can therefore theoretically achieve very large step-up operations taking great benefice from the piezoelectric high quality factor.

V. CONVERTER SIMULATION

A simulation of the converter was performed on Matlab/Simulink. The piezoelectric material is modeled using the impedance transfer function derived from the equivalent electrical circuit of Fig.4 and expressed in (28).

output voltage. The simulations enable also to understand and manage the transient part since the analytical model only considers steady states operations.

VI. Experimentations and results

A. Converter presentation

The converter was fabricated and tested. A first experimentation had already been done successfully and presented in [24] with an efficiency up to 87 %. In this paper we present an update of this proof of concept with a significant improvement in term of efficiency and power level. The diodes had been replaced by MOS transistors which have been chosen for their low on-state resistance. Furthermore, the parasitic inductances of the switching paths due to the layout have been significantly reduced. A finite-state machine is used to switch from one state to another and to achieve the voltage regulation with the help of an analog to digital converter (ADC). This finite-state machine is implemented with a Field Programmable gate array (FPGA). The switch k_{in} must be bidirectional and is therefore composed of two N channel MOSFET k_{in1} and k_{in2} (IRLML0040TRPbF, Infineon®). Switches k_3 and k_{out} are N channel MOSFETs as well. Nevertheless, since the 6 phases cycle must be synchronized with the piezoelectric current, a Schottky diode D_{out} with a lower voltage drop than the inherent reverse diode of k_{out} is added in parallel. Indeed, in phase 6, the MOSFET is conducting most of the time but just before the end of the period, it is turned off to let the parallel diode conduct to have a precisely synchronized cycle. An isolated driver receives the signals from the FPGA and allows to control the switches with a valid gate-source voltage. The overall operation of the converter is resumed in Fig.10 and the picture of the power circuit is presented on Fig.11.

Fig. 11. Picture of the fabricated inductorless piezoelectric DC-DC converter

B. Experimental results

The conversion cycle was successfully reproduced and experimental waveforms are presented in Fig.12 corresponding to a 10 V-20 V, 90 kHz conversion with an output power of 310 mW. The internal piezoelectric current cannot be directly measured but it is possible to observe it during constant voltage phases measuring i_m. Experimental voltage (V_p) and current (i_m) waveforms are compared to the one given by the analytical model including mechanical damping (section IV-B) for the same output power. The transition between the conduction of k_{out} and D_{out} is observable and highlighted by the vertical dotted line and proves that the system is well synchronized with the piezoelectric current. The experimental piezoelectric voltage waveform is very close to the theoretical one. The current is almost sinusoidal but has some harmonics contents due to the other piezoelectric resonance modes and to parasitic elements of the layout. This validates the analytical model since the current amplitude and the duration of phases are quite well corresponding.

Fig. 13-a. Power efficiency curve for 4 output voltage   Fig. 13-b. Comparison between experimental data and theoretical model for a 10-15V step-up operation

The efficiency was measured for different operating points with four different output voltages (input voltage of 10 V) and for different output powers. The power spent for the control part is not taken into account. The power efficiency graph is represented in Fig.13-a. Fig.13-b compares the power efficiency curve with the theoretical one for a step up 10-15 V converter. A high efficiency up to 98.4 % (10-15 V conversion, 160 mW) and a power conversion up to 1.45 W (10-15 V conversion, 78% of efficiency) were achieved. As expected, the efficiency remains high for a large range of power whatever the output gain ratio. The frequency has been measured for each points of Fig.13-a. It ranges from 89 to 104 kHz (resonance and anti-resonance) depending on the load and output gain. Nevertheless, since those variations have no real impact on the system behavior, the fixed frequency approximation of the analytical model remains very relevant.

The analytical model of section IV is in very good agreement with experimental results for low powers and is therefore validated. However, above 500 mW, the error increases and the efficiency drops more than expected. This can be explained considering that the piezoelectric current amplitude I increases with the power, the same for the constant voltage phase's duration. That increases the transistor conduction losses which are not taken into account in the model, and explains the increasing gap between the model and the experimental results with the increasing power. Another cause of the difference is that for high powers, the material temperature starts rising and induces a decrease of the mechanical quality factor. Compared to the theoretical power efficiency curve, the experimental measurement reveals also irregularities at some points (big points in Fig.13 (b)) with sudden drops in efficiency for specific values of the output power. This is due to the harmonics effect discussed in the next section.

The material temperature was observed with an infrared thermometer for a 1.2 W 10-20V conversion, the measured temperature elevation is only of 11°C compared to ambient although there is no cooler. Anyhow, it is far from the material Curie temperature (315°C).

VII. DISCUSSION

A. Harmonic analysis

As mentioned previously, there are some points in the power efficiency curves where the efficiency drops suddenly before increasing again. Those irregularities which are not predicted by the model, takes greater importance considering high output powers. The reason is that the voltage V_p applied to the resonator contains harmonics able to excite some other resonance modes of the piezoelectric material. The higher the output power is, the higher is the harmonic content, which increases the probability to encounter this problem. As a result, if the current has an important harmonic content, the transitions between the phases of the conversion cycle (based on ZVS conditions) occur at a different time compared to the sinusoidal case. Moreover, its RMS value increases, the same for losses. This creates a difference between the ideal 6 phase's cycle of Fig.3-b and the real applied conversion cycle. To avoid these points, the condition is therefore to have no harmonics at the other resonance mode of the material. Fig.14-a and Fig.14-b compare two cases: a normal case (A case 960mW) and a case where the thickness mode is excited (B case 580 mW). The current in the B case has a significant harmonic content corresponding to the thickness resonance mode. That is why the efficiency is lower compared to the A case although the global harmonic content is higher in this case. This effect is proved in Figure 15: in case B (580 mW) it can be observed that the piezoelectric current harmonic at 2.8 MHz matches exactly the thickness mode of the impedance curve of the resonator, but not for case A.
Fig. 14-a Case A: Piezoelectric waveforms for 960 mW

Fig. 14-b Case B: Piezoelectric waveforms for 580 mW

Fig. 15. Harmonic spectra of piezoelectric current for A and B cases: large scale and thickness mode centered

The harmonics excitation frequencies and related level can be theoretically predicted thanks to the Fourier decomposition of the piezoelectric voltage V_p. From these frequencies and related level, knowing the various resonance and related amplification of the piezoelectric material one can deduce the final current amplitude for each harmonic frequency. In Fig.16, the theoretical spectrum of V_p is compared to the measured one for the same conditions (960 mW and 10-20 V conversion). The main frequencies peaks observed are quite well predicted by theory. The small difference is because the experimental cycle is not perfectly synchronized with the fundamental current waveform and also because some losses are not taken into account like the conduction losses in the transistors. However, some harmonic frequencies are not theoretically predicted, they are caused by parasitic elements as the stray inductance of the wires that connect the piezoelectric to the electronic. They resonate with the parallel capacitance Cp of the piezoelectric material. When designing the converter, the theoretical 6 phase's cycle spectrum should not have a significant harmonic that matches with a higher frequency resonance mode.

B. Elements for future work

The analytical model including the mechanical damping is very relevant for a large set of operating points (until 500 mW in this case). In the first part of the power efficiency curve, it constitutes an excellent approximation of the converter keys waveforms and is therefore reliable for design issues. To be more accurate for the second part of the graph, other elements than the mechanical resistance R should be added in the model like the transistors conduction losses. The decrease of the quality factor can be modelled by making R depending on temperature. This would enable to predict the limits of the material and the maximal current it can withstand.

For design issues, the impact of geometry parameters such as the resonator diameter and thickness must be studied. This could be done by expressing each term of the piezoelectric electrical equivalent circuit as a function of the piezoelectric geometry using [26] . It should be noted that reducing the diameter increases the radial resonance frequency (control dynamic must increase) and reducing the thickness increases the thickness resonance frequency. The analytic model developed in section IV highlights the necessity of a low mechanical damping (R as low as possible). Since [26] states that R can be linearly reduced by reducing the radius or thickness of the disk, it means that theoretically, efficiency and

output power can be increased by reducing the size of the resonator. However, the limits of the material must also be included in the model. The converter should therefore be tested and compared for different piezoelectric sizes at different output powers and conversion ratios. Based on experimental results, efficiency and maximum output power should be expressed as a function of the resonator dimensions. A design procedure using the model described in IV and taking the material limits into consideration should be established. For a desired input and output voltage and a given output power this procedure should use (20) and (21) to optimize the efficiency or (17), (18) and thermal limits to optimize the power density.

A 1.45 Watt conversion was achieved (10-15 V conversion, 78% of efficiency) but with the same piezoelectric resonator, higher powers and therefore higher power densities can be easily reached by increasing the input voltage as (17) states.

VIII. Conclusion

A new piezoelectric DC-DC converter is presented. The PZT material replaces the traditional magnetic-based inductance as an energy storage element. At steady state, a conversion cycle is applied at each resonant period in which the converter's input and output are successively connected to the material to accumulate or release energy. The driving strategy of the converter ensures both ZVS operations and output current/voltage regulation allowing to keep very high efficiencies for a large range of output gain and power. The presented analytical model, validated by simulation and experimentation, enables a fast and reliable converter predesigning. This concept has been very successfully validated getting an efficiency up to 98.4 % at 160 mW and achieving a conversion up to 1.4 W.

This new concept, being very promising, can be extended to other topologies of classical power converters based on temporary energy storage. Putting several piezoelectric resonator in parallel or operating in an interleaving mode to increase the output power, performing an AC-DC conversion or achieving an isolated piezoelectric-based converter are other possibilities that we are studying.
