Abstract. The northern Antarctic Peninsula (NAP) is a highly dynamic transitional zone between the subpolar and oceanic-coastal environments, and it is located in an area affected by intense climate change, including intensification and spatial shifts of the westerlies as well as atmospheric and oceanic warming. In the NAP area, the water masses originate mainly from the Bellingshausen and Weddell seas, which create a marked regional dichotomy thermohaline characteristic. Although the NAP area has relatively easy access when compared to other Southern Ocean environments, our understanding of the water masses' distribution and the dynamical processes affecting the variability of the region is still limited. That limitation is closely linked to the sparse data coverage, as is commonly the case in most Southern Ocean environments. This work provides a novel seasonal three-dimensional high-resolution hydrographic gridded data set for the NAP (version 1), namely the NAPv1.0. Hydrographic measurements from 1990 to 2019 comprising data collected by conductivity, temperature, depth (CTD) casts; sensors from the Marine Mammals Exploring the Oceans Pole to Pole (MEOP) consortium; and Argo floats have been optimally interpolated to produce maps of in situ temperature, practical salinity, and dissolved oxygen at ~ 10 km spatial resolution and 90 depth levels. The water masses and oceanographic features in this regional gridded product are more accurate than other climatologies and state estimate products currently available. The data sets are available in netCDF format at <https://doi.org/10.5281/zenodo.4420006> (Dotto et al., 2021). The novel and comprehensive data sets presented here for the NAPv1.0 product are a valuable tool to be used in studies addressing climatological changes in the unique NAP region since they provide accurate initial conditions for ocean models and improve the end of the 20th- and early 21st-century ocean mean-state representation for that area.

1 Introduction

The northern Antarctic Peninsula (NAP; Kerr et al., 2018a) encompasses the Bransfield and Gerlache Straits, the north-western Weddell Sea, the southernmost Drake Passage and the northern end of the west Antarctic Peninsula (WAP) environments (Fig. 1a). The NAP is a sensitive region to climate changes because it is located under the influence of the west-

erly winds, which are prone to current intensification and poleward migration (Marshall, 2003; Swart and Fyfe, 2012; Lin et al., 2018). The region also receives considerable freshwater input from the melting of glaciers from the Antarctic Peninsula (Cook et al., 2016; Rignot et al., 2019). Moreover, the NAP has been showing significant alterations in its water masses' physicochemical properties, such as warming,

freshening, and acidification (Gordon et al., 2000; Meredith and King, 2005; Hellmer et al., 2011; Dotto et al., 2016; Kerr et al., 2018b; Lencina Avila et al., 2018; Ruiz Barlett et al., 2018), a decline in sea ice extension, and a shortening of sea ice cover season (Stammerjohn et al., 2008; Turner et al., 2013). Consequently, the local marine ecosystem is being impacted (Moline et al., 2004; Montes-Hugo et al., 2009; Mendes et al., 2013; Ferreira et al., 2020).

Water masses with different properties and origins reach the NAP and mix to form the dense water masses that sink and fill the deep basins of the Bransfield Strait (Gordon et al., 2000; Dotto et al., 2016; Huneke et al., 2016; van Caspel et al., 2018). High-Salinity Shelf Water (HSSW) and Low-Salinity Shelf Water (LSSW) from the Weddell Sea enter the NAP from the east, mainly contouring the Antarctic Peninsula (von Gyldenfeldt et al., 2002; Heywood et al., 2004; Thompson et al., 2009; Collares et al., 2018) and then sinking along the slope and at the Bransfield Strait's several canyons (van Caspel et al., 2018; Fig. 1b). A branch carrying modified HSSW flows southwestward along the continental shelf to the west of the Antarctic Peninsula and reaches as far as the Gerlache Strait (Sangrà et al., 2017; Kerr et al., 2018b). Conversely, modified Circumpolar Deep Water (mCDW) from the Bellingshausen Sea – a relatively warm, salty, nutrient-rich, and deoxygenated water mass derived from the intermediate waters of the Antarctic Circumpolar Current (ACC) and modified over the western Antarctic Peninsula continental shelf – enters the NAP mainly through the Bransfield Strait western basin (Smith et al., 1999; Ruiz Barlett et al., 2018), flowing northeastward along the South Shetland Islands slope as the Bransfield Current (Sangrà et al., 2011; Fig. 1b). The mCDW also intrudes into the Bransfield Strait from the southern Drake Passage between King George and Elephant islands (López et al., 1999; Gordon et al., 2000). Therefore, a cyclonic circulation pattern is created within the Bransfield Strait from currents of completely different origins defining a strong transitional signature for that whole area (García et al., 2002). Two main fronts are observed in this region: the Bransfield Front and the Peninsula Front (Sangrà et al., 2011; Fig. 1b). The Bransfield Front is the mid-depth front separating the warm waters flowing along with the Bransfield Current and the cold waters within the deep basins of the Bransfield Strait. The Peninsula Front separates, in shallow depths, the cold waters from Weddell influence and the Bransfield Strait waters. In the Gerlache Strait, mCDW from the Bellingshausen Sea also intrudes from the south and through the gaps near Anvers Island (Smith et al., 1999; García et al., 2002; Torres Parra et al., 2020; Fig. 1b). The mCDW interacts with the HSSW-sourced waters and a relatively colder mixture leaves the Gerlache Strait towards the western basin of the Bransfield Strait (Niiler et al., 1991; Zhou et al., 2002; Savidge and Amft, 2009). In the north-western Weddell Sea, the Antarctic Slope Front separates the coastal from the open ocean waters circulating within the Weddell Gyre (Heywood et al., 2004). Part of the dense wa-

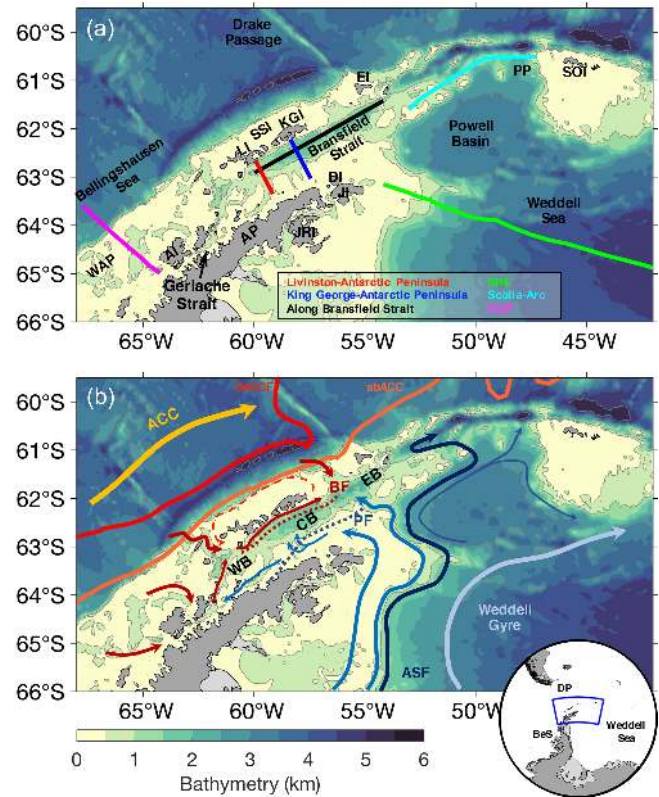

Figure 1. Map of the northern Antarctic Peninsula (NAP). (a) Bathymetry of the study region. South Shetland Islands (SSI), Antarctic Peninsula (AP), Elephant Island (EI), Joinville Island (JI), D’Urville Island (DI), James Ross Island (JRI), King George Island (KGI), Livingston Island (LI), Anvers Island (AI), Philip Passage (PP), and South Orkney Island (SOI) are shown. The coloured lines depict the sections used to analyse the NAPv1.0 climatology (see legend). Bathymetry from ETOPO1. The isobaths of 500, 1000, 3000, and 5000 m are shown by the grey line. (b) Schematic of the mean circulation at the NAP. Blue (red) arrows show the cold (warm) water masses that inflow in the region. The cyan arrow shows the Weddell Gyre circulation and the dark blue arrow shows the path of the Antarctic Slope Front (ASF). Dotted blue and red lines depict, respectively, the Peninsula Front (PF) and the Bransfield Front (BF). The dashed line shows the recirculation around the SSI. The Antarctic Circumpolar Current (ACC), the Southern ACC Front (SACC), and the southern boundary of the ACC (sbACC), are shown in orange tones. Within the Bransfield Strait, the area is divided into the eastern basin (EB), central basin (CB), and western basin (WB). The inset shows the study region among the Weddell Sea, Bellingshausen Sea (BeS), and the Drake Passage (DP). Coastline from SCAR Antarctic Digital Database.

ters that circulate in the Powell Basin eventually leak through the Philip Passage and are exported from the Weddell Sea as Antarctic Bottom Water (Franco et al., 2007; Fig. 1b). Other routes of Antarctic Bottom Water export from the Weddell Sea are the Orkney, Bruce, and Discovery passages located to the east of South Orkney Island (Naveira Garabato et al., 2002).

For at least the past fifty years, the deep waters of the Bransfield Strait have shown significant trends of freshening and lightening, with impacts on the volume of these regional dense waters (Azaneu et al., 2013; Dotto et al., 2016; Ruiz Barlett et al., 2018). Considering that these waters are formed by a parcel of $\sim 60\%$ – 80% of HSSW+LSSW (Gordon et al., 2000; Dotto et al., 2016), the freshening signal may be driven by modification of the water masses sourced in the Weddell Sea continental shelf (van Caspel et al., 2015, 2018), possibly due to the melting of ice shelves and glaciers in the Antarctic Peninsula (Cook et al., 2016; Rignot et al., 2019). In addition, the decreasing sea ice concentration and the shortening sea ice season in the NAP (Stammerjohn et al., 2008; Turner et al., 2013) may also play a role in the freshening trend due to a reduction of the salt flux into these shelf waters (Hellmer et al., 2011).

Such a mixture of distinct water masses creates good conditions for the development of a rich biological activity in the NAP. High concentrations of phytoplankton have been documented in the Bransfield and Gerlache straits, with implications for local carbon dioxide uptake (Costa et al., 2020; Monteiro et al., 2020a, b). The high primary production also supports an abundant krill stock (Atkinson et al., 2020), which is the base of the food chain up to top predators (Seyboth et al., 2018). If the changes reported for the region continue (e.g. sea ice cover and seasonality declining, land ice melting, atmospheric and oceanic temperature warming), an imbalance or even a collapse in the regional food chain is expected (Ferreira et al., 2020). A change in the composition of phytoplankton, from diatoms to cryptophytes, has already been observed in the NAP (Mendes et al., 2013) as well as a reduction in the recruitment of juvenile krill and a general decline of krill stocks in areas of the Atlantic sector of the Southern Ocean, including the NAP (Atkinson et al., 2020).

A better understanding of the NAP oceanic and shelf circulation, as well as the connection to the Weddell and Bellingshausen seas, is important to help assess the evolution and impacts of the ocean on the ice shelves and glaciers melting downstream (Cook et al., 2016; Rignot et al., 2019). Currently, the overall change in the glaciers' area is relatively small in the Bransfield and Gerlache straits compared to the adjacent Bellingshausen Sea coastline, which is under the influence of warmer waters. However, changes in proportions of the inflowing water masses could potentially lead these regions to a Bellingshausen Sea-like scenario, where warmer oceanic conditions shape the local glacier fronts' behaviour and higher melting rates are observed (Cook et al., 2016). Ruiz Barlett et al. (2018) suggest that persistent northerly and westerly wind conditions, concurrent with La Niña and positive phases of the Southern Annular Mode (SAM), are favourable drivers for mCDW inflow into the NAP. These warm inflows are likely facilitated by the poleward displacements of the oceanic fronts associated with the ACC during La Niña events (Loeb et al., 2009). Additionally, positive SAM may restrict the connections between the Weddell Sea

and the Bransfield Strait (Renner et al., 2012), with the potential of reducing the inflow of cold waters into the NAP (Dotto et al., 2016). Also, the changes in the ocean dynamics along the NAP driven by SAM and El Niño–Southern Oscillation have been recently associated with the variability of the dissolved organic carbon inventory (Avelina et al., 2020). The ongoing changes in the Southern Hemisphere wind pattern, i.e. poleward and intensification associated with positive trends in the SAM, and an increase in the energetics of the ACC (Meredith and Hogg, 2006; Hogg et al., 2015) could then lead to higher mCDW inflow into the NAP by advection (e.g. Ruiz Barlett et al., 2018) and/or eddies shed by the ACC (Martinson and McKee, 2012; Couto et al., 2017). Although the strengthening of winds tends to increase the inflow of warm waters toward the WAP continental shelf, it does not necessarily mean higher ice shelf basal melting (except for the shallower ice shelves). Conversely, models suggest a reduction of sea ice concentration associated with an enhancement of the upper ocean heat fluxes (Dinniman et al., 2012). In the NAP, mixing rate measurements are scarce, hampering the understanding of how heat fluxes in the upper and deeper ocean will respond to future wind changes in the region. In addition, there is still a lack of information regarding the water masses' fluxes and mixing between the Powell Basin in the Weddell Sea and the Bransfield Strait (Thompson et al., 2009; Azaneu et al., 2017), which would help increase our understanding of the complex coastal Antarctic system.

In this context, forecasts of the evolution of the dynamics of these regional seas and their interconnections in future climate change scenarios are needed to better understand the integrated consequences, which are being modified by the complex physical, chemical, and biological processes across the NAP environments. In general, in situ measurements in the Southern Ocean are scarce in space and time due to logistical constraints. Moreover, that scarceness impacts a proper understanding of the oceanographic processes and their interactions with the atmosphere and cryosphere, which requires robust and long-term Southern Ocean observing systems to provide high-quality measurements of the different ocean and cryosphere compartments (Meredith et al., 2013; Newman et al., 2019). Hence, high-resolution regional models are needed to integrate these data and to simulate future scenarios. In this sense, quality-controlled gridded products to feed these models are important to properly create the initial conditions in terms of the three-dimensional structure of the water masses, which are needed to capture the main oceanographic and glaciological interactions and, consequently, their future evolution.

Here, we present version 1 of a hydrographic gridded product, called NAPv1.0, comprising robust high-resolution measurements from different platforms: ship-based measurements, Argo profilers and tagged marine mammals. The gridded product covers the period from 1990 to 2019, and it has in situ temperature, salinity, and dissolved oxygen fields. NAPv1.0 can be used for several applications, including in-

put data for ocean and climate model initialization and/or assessment and ocean reanalysis evaluation, as well as to produce and reconstruct biogeochemical properties. Finally, the NAPv1.0 represents the ocean mean state on seasonal scales for the NAP in the end 20th-century and early 21st-century.

2 Hydrographic data and ancillary data set

In situ temperature, practical salinity, and dissolved oxygen (DO) data from five main sources were used to build the database for the gridded product. Conductivity, temperature, depth (CTD) profiles were acquired from the World Ocean Database (<https://www.ncei.noaa.gov/products/world-ocean-database>, last access: 13 November 2020) and Pangaia (<https://www.pangaia.de/>, last access: 13 November 2020) for the period from 1990 to 2019. In addition, CTD profiles from the Brazilian High Latitude Oceanography Group (GOAL; Mata et al., 2018) are included for the years spanning from 2003 to 2019 while data from Hutchinson et al. (2020; <https://doi.org/10.5281/zenodo.3357972>) are included for the region off the Larsen C Ice Shelf. Since 2003, the GOAL has been conducting research cruises on a quasi-annual basis in the NAP area during summer periods. Most of the efforts have focused on the Bransfield and Gerlache straits, due to their relatively easier access, logistics, and favourable meteorological conditions. Argo floats data were retrieved from the Coriolis website (<http://www.coriolis.eu.org/>, last access: 16 November 2020). Profiles from tagged marine mammals were obtained from the consortium Marine Mammals Exploring the Oceans Pole to Pole (MEOP; <http://www.meop.net/>, last access: 13 November 2020). Although all platforms measure in situ temperature and conductivity data, only CTD and Argo provide DO. The study region was limited to 42–68° W and 59.5–66° S, and the time span was from 1990 to 2019 (Fig. 2). The data sets were grouped in different seasons to allow a better representation of the region: summer (January to March), autumn (April to June), winter (July to September), and spring (October to December). Only reliable data according to the quality flags of each data set were used. In addition, a visual inspection was carried out to double check any spurious data. Once the profiles were quality controlled, each profile was linearly interpolated onto 90 standard depths ranging from 5 to 6000 m depth (Table 1). The depth spacing ranges from 5 m in the upper 50 to 500 m below 4000 m depth in oceanic regions. The spacing between layers were arbitrarily selected.

A total of 37 009 profiles of in situ temperature and 32 562 of salinity were used in this study (Fig. 3a–b). Most of these data were sampled by MEOP, followed by CTD and Argo. In autumn and winter, the amount of data collected by MEOP can be as high as 18 times compared to the other platforms. Summer and autumn were the seasons with the higher amount of data collected, followed by winter and spring.

Table 1. Standard depth levels (m) used to linearly interpolate the profiles and the gridded data set.

Level number	Depth interval	Depth range
1 to 10	5 m	5–50 m
11 to 30	10 m	60–250 m
31 to 52	25 m	275–800 m
53 to 66	50 m	850–1500 m
67 to 81	100 m	1600–3000 m
82 to 86	200 m	3200–4000 m
87 to 90	500 m	4500–6000 m

Note, however, that the high amount of data in autumn and winter is due to MEOP measurements (Fig. 3). In regards of DO, a total of 1810 profiles were used (Fig. 3c). Most of the data were sampled in summer by ship-based CTD. From this total, 701 DO profiles were acquired from GOAL in the Bransfield and Gerlache straits, eastern Bellingshausen Sea, and northwestern Weddell Sea (Kerr et al., 2018a). All years, except 2012, were covered by CTD temperature and salinity samples (Fig. S1a–b in the Supplement). Argo and MEOP data were available from 2002 and 2008, respectively, for the study region (Fig. S1 in the Supplement). DO had a better sampling covering after 2003, when the GOAL carried out studies in the region quasi-annually (Fig. S1c in the Supplement).

Most of the samples were collected in the upper ocean (up to ~2000 m depth; Fig. 3d–f). This happens because Argo profiles have a limit depth range up to 2000 m and the MEOP data are mostly restricted to the upper ~1000 m due to the physiology and behaviour of the animals (Fig. S2 in the Supplement). Below 2000 m depth, our climatology relies only on CTD data. Consequently, seasons with reduced CTD profiles will have less representativeness. In addition, the study region is dominated by shallow seas (Fig. 1a), and deep areas are found only adjacent to the Antarctic Peninsula. The first standard depth (i.e. 5 m) had fewer samples than the second standard depth (i.e. 10 m). For this reason, we repeated the second level in the gridded product as our first level.

The different platforms have different accuracies. The initial CTD accuracy reported for the World Ocean Database typically ranges from ± 0.001 – 0.005 °C for temperature and approximately ± 0.003 – 0.02 for salinity (Boyer et al., 2018). For the Pangaia data set, the accuracy is documented as ± 0.001 °C for temperature and approximately ± 0.003 for salinity (Driemel et al., 2017). The accuracy of the GOAL CTD data is also ± 0.001 °C and ± 0.003 for temperature and salinity, respectively. For the DO, the accuracy can be 2 % of saturation or more, depending the sensor (Boyer et al., 2018). The GOAL DO data showed a mean absolute difference of ~ 0.09 mL L⁻¹ between the double sensors used in the cruises. The accuracy of the delayed-mode Argo is ± 0.002 °C and ± 0.01 for temperature and salinity, respec-

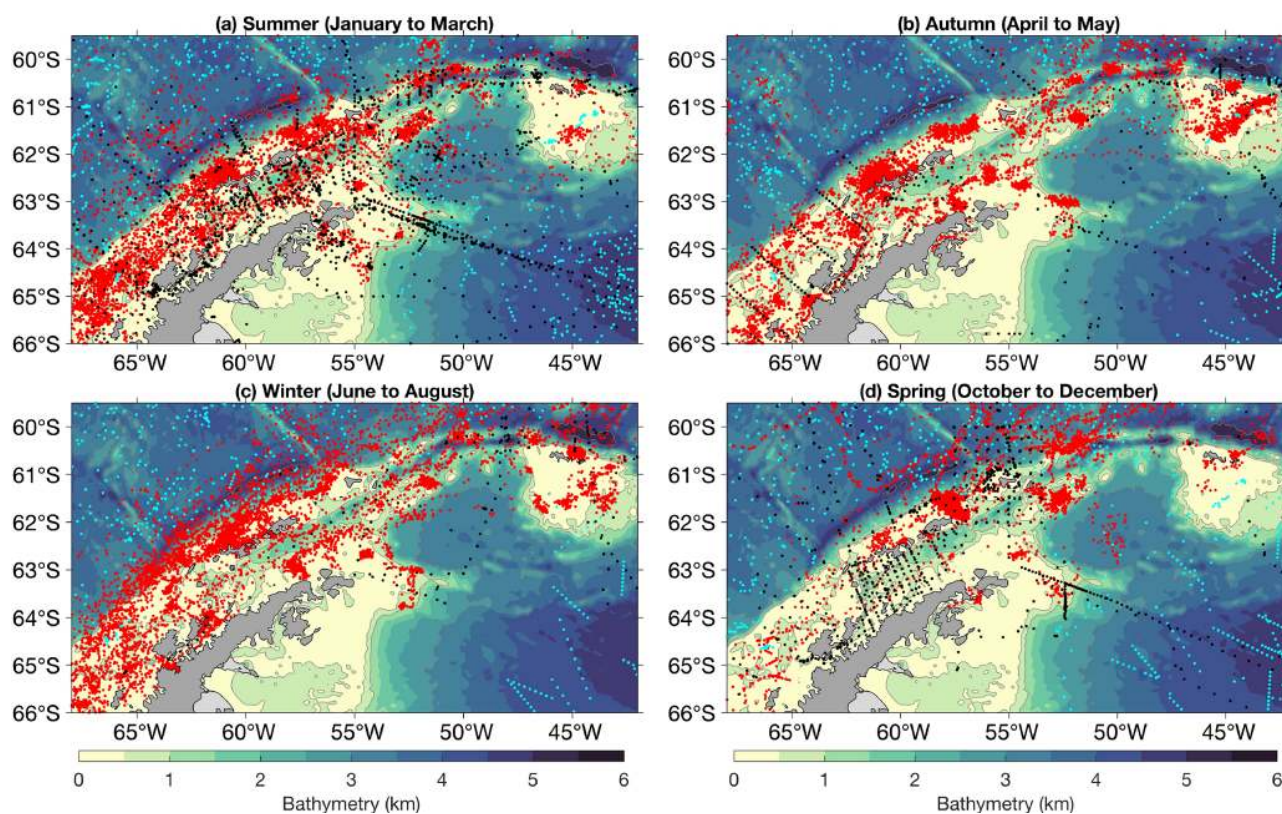

Figure 2. Distribution of the hydrographic data sets used to build the NAPv1.0 climatology in (a) summer, (b) autumn, (c) winter, and (d) spring. CTD (black), MEOP (red), and Argo (cyan) casts are shown. The data set was restricted to 1990 to 2019. The ETOP01 isobaths of 500, 1000, 3000, and 5000 m are depicted by grey lines. Coastline from SCAR Antarctic Digital Database.

tively (Wong et al., 2020). The initial accuracy of the Argo DO sensors range from 2%–5% of saturation, according to the manufacturers. The CTD satellite relay data logger (CTD-SRDL) from MEOP is reported to have an accuracy of ± 0.02 – 0.04 °C for temperature and ± 0.03 for salinity (Treasure et al., 2017; Siegelman et al., 2019).

Given the higher resolution and accuracy, the CTD data were used for a reasonableness check to verify if the gridded products can represent the expected and accepted values of the hydrographic properties in the NAP. For this exercise, we chose to compare only those CTD profiles closer than ~ 6 km from each grid point of the climatologies evaluated. In addition, we present a section comparing different climatologies for the NAP. Summer-averaged temperature and salinity from the World Ocean Atlas 2018 (WOA; <https://www.ncei.noaa.gov/access/world-ocean-atlas-2018/>, last access: 23 December 2020; Locarnini et al., 2019; Zweng et al., 2019) was used for comparison with the NAPv1.0 results. WOA has a spatial resolution of $1/4^\circ$ and 102 vertical levels. DO is available only in coarser resolution, thus it is not used here. The Commonwealth Scientific and Industrial Research Organisation (CSIRO) Atlas of Regional Seas (CARS; <http://www.marine.csiro.au/~dunn/cars2009/>, last access: 29 January 2020; Ridgway et al., 2002) was also used in the same

way. CARS has a spatial resolution of $1/2^\circ$, 79 vertical levels and it comprises gridded fields of the mean ocean temperature, salinity, and DO. The summer season mean conditions are estimated from the annual and semi-annual coefficients distributed with the climatological fields; however, these coefficients are limited to the mid- and upper levels. Finally, the Southern Ocean State Estimate (SOSE; <http://sose.ucsd.edu/>, last access: 20 April 2020; Mazloff et al., 2010), coupled with the biogeochemical–sea-ice–ocean state estimate (Verdy and Mazloff, 2017), was used to compare with our regional gridded product. Outputs from the months January, February, and March, from the iterations 106 and 133, were averaged to produce a summer mean state for the period 2008–2018 (the biogeochemical outputs are not available prior to this period). Potential temperature, salinity, and DO were selected with a spatial resolution of $1/6^\circ$ and 52 vertical levels. Conservative temperature (Θ), absolute salinity (S_A) and neutral density (γ^n) were then computed for all data sets prior to the assessment (Jackett and McDougall, 1997; McDougall and Barker, 2011).

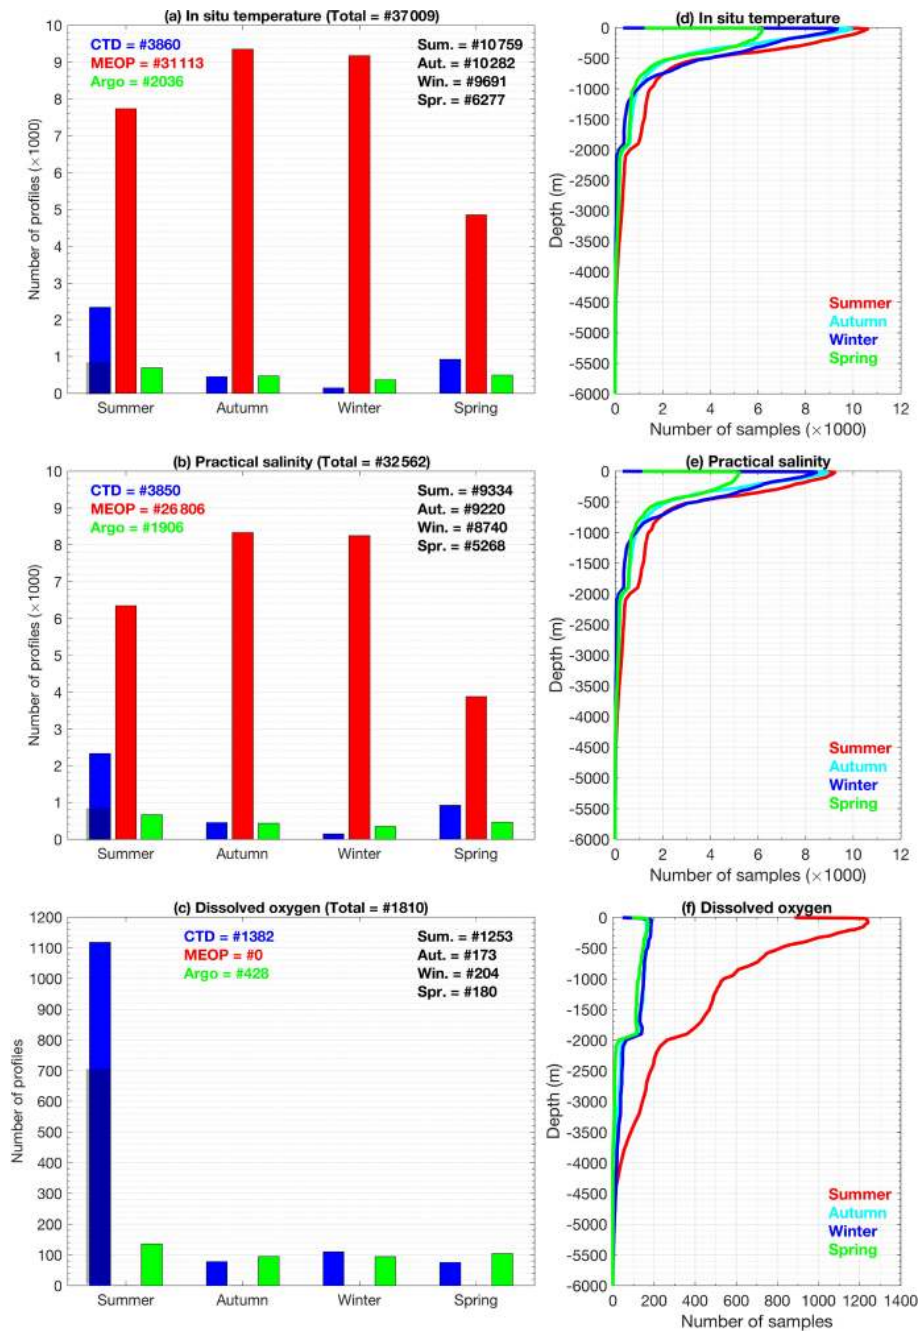

Figure 3. (a) The number of in situ temperature profiles per season and platform (CTD in blue, MEOP in red, and Argo in green) for the study region. (b) Same as panel (a), but for practical salinity. (c) Same as panel (a), but for dissolved oxygen. MEOP platforms do not carry oxygen sensors. The black shading in the summer bars shows the contribution of GOAL profiles. The total number of profiles is shown in each panel title, the total number of profiles per season is shown in black in the right upper corner of each panel, and the total number of profiles per platform is shown by colours in the left upper corner of each panel. Note the different y-axis scales for the dissolved oxygen. (d) Total number of samples per depth for in situ temperature considering all platforms in summer (red), autumn (cyan), winter (blue), and spring (green). (e) Same as panel (d), but for practical salinity. (f) Same as panel (d), but for dissolved oxygen.

3 Methods

The scattered hydrographic data were objectively interpolated onto a regular grid of ~ 10 km resolution. The grid spacing is 0.09° along latitudes and 0.2° along longitudes (i.e. 0.09° latitude $\times 0.09^\circ/\cos(63^\circ \text{ S})$ longitude, where 63° S is the mean latitude of our domain). The limits of the domain are 59.5 to 66° S and 42 to 68° W . The study region covers the transitional oceanographic regimes between the adjacent areas and the NAP, hence representing in more detail the regional oceanic features. We note that even with the addition of distinct platforms, the area of the western Weddell Sea is still poorly sampled (Fig. 2). Due to this lack of data coverage, we masked that region from the climatology. Bathymetry and land masks were applied using the 1 arcmin ETOPO1 Ice Surface data set (<https://www.ngdc.noaa.gov/mgg/global/>, last access: 15 August 2015) interpolated onto a grid of the same resolution.

The objective interpolation uses scattered observations to generate a regular gridded and smoothed version of the original data field analysed (Bretherton et al., 1976; Thomson and Emery, 2014). The method is based on the Gauss–Markov theorem, which consists of an application of linear estimation techniques for interpolating data from the multiple platforms combined. While this improves the spatial coverage, it also smooths out the temporal and spatial variability, resulting in a pattern that is more representative of the large-scale mean state rather than of a specific period. The interpolation of each grid point is affected by the neighbouring data that fall within the smoothing lengthscales (or radius of influence) and the relative error chosen a priori. The interpolation method also assumes a weight to sum all observations within a specific smoothing lengthscale. The weight is a function of the distance to the grid point and the location of the observation only. Because the objective interpolation fits a Gaussian function, the nearest neighbours have higher weight than the data located closer to the edge of the radius of influence. A series of tests were made to find the appropriate smoothing lengthscale and the a priori relative error in order to find a balance between smoothness and feature representativeness. The final smoothing lengthscale chosen (i.e. the radius of influence of the interpolation) was 1° in latitude and longitude, and the a priori relative error allowed was set to 0.2 for the objective interpolation algorithm. The same constants were set for all depth levels, all variables (i.e. in situ temperature, practical salinity and DO), and all seasons. Regions where the mapping relative error was higher than 0.5 were excluded. The matrices of relative errors are provided together with the gridded variables so the user can choose the relative error level to work with (between 0 and 0.5). The representativeness of the interpolated maps decreases as the number of measurements being used reduces. This is reflected in higher relative errors, such as those seen closer to the (i) Weddell Sea, (ii) regions where the gaps between data are large, and (iii) at deeper levels (Fig. 4). The reduction

of the amount of data among the seasons also affects the interpolation, mainly in the deeper levels where fewer CTD profiles are available (Fig. 4). In regions of the upper ocean where a vast number of MEOP profiles are available (i.e. Bransfield Strait, Gerlache Strait, and WAP), the errors are comparable among the seasons (Fig. 4). For the purposes of this study, Θ , S_A , and γ^n are presented.

4 Results and discussion

4.1 Reasonableness check of the gridded product

The term reasonableness check is used here to ensure that the gridded data set meets the expected range, type, or value based on its individual measurements. We want to examine how reasonably the NAPv1.0 can represent the CTD profiles closer than ~ 6 km from each grid point. Although the data sets are not independent, this comparison shows how well the interpolation captured the real data set's magnitude, structure, and spatial variability.

The NAPv1.0 shows a good agreement with the CTD profiles for the hydrographic parameters. Approximately 62% , 70% , 74% , and 65% of the data points fall within the difference range of $\pm 0.2^\circ \text{C}$ for summer, autumn, winter, and spring, respectively (Fig. 5a). The higher percentage of agreement in autumn and winter is due to the reduced number of CTD profiles in those seasons, which become more influential in the interpolation in those cases. The higher Θ difference, as expected, occurs in the upper ocean due to interannual variability (Mendes et al., 2013; Gonçalves Araújo et al., 2015) that is smoothed out in the interpolation process (Fig. S3a–b in the Supplement).

A good agreement between the NAPv1.0 and the CTD profiles is also observed for S_A . Approximately 67% , 74% , 84% , and 75% of the data points fall within the difference range of $\pm 0.04 \text{ g kg}^{-1}$ for summer, autumn, winter, and spring, respectively (Fig. 5b). The S_A differences over the water column are also higher in the upper levels due to the interannual variability and smaller towards the deep ocean (Fig. S3c–d in the Supplement), where the interannual variability tends to be relatively smaller (Dotto et al., 2016; Ruiz Barlett et al., 2018).

With regards to DO, approximately 65% , 87% , 87% , and 80% of the data points fall within the difference range of $\pm 0.2 \text{ mL L}^{-1}$ for summer, autumn, winter, and spring, respectively (Fig. 5c), which clearly suggests the influence of less data affecting the resemblance between the gridded product and the CTD stations. The NAPv1.0 shows relatively higher differences related to DO data, which is a non-conservative property. The largest differences are observed in the upper ocean, but also along the water column where it is not uncommon to observe differences of up to $\pm 0.5 \text{ mL L}^{-1}$ (Fig. S3e–f in the Supplement). The histograms previously presented (Fig. 3 and Figs. S1 and S2 in the Supplement)

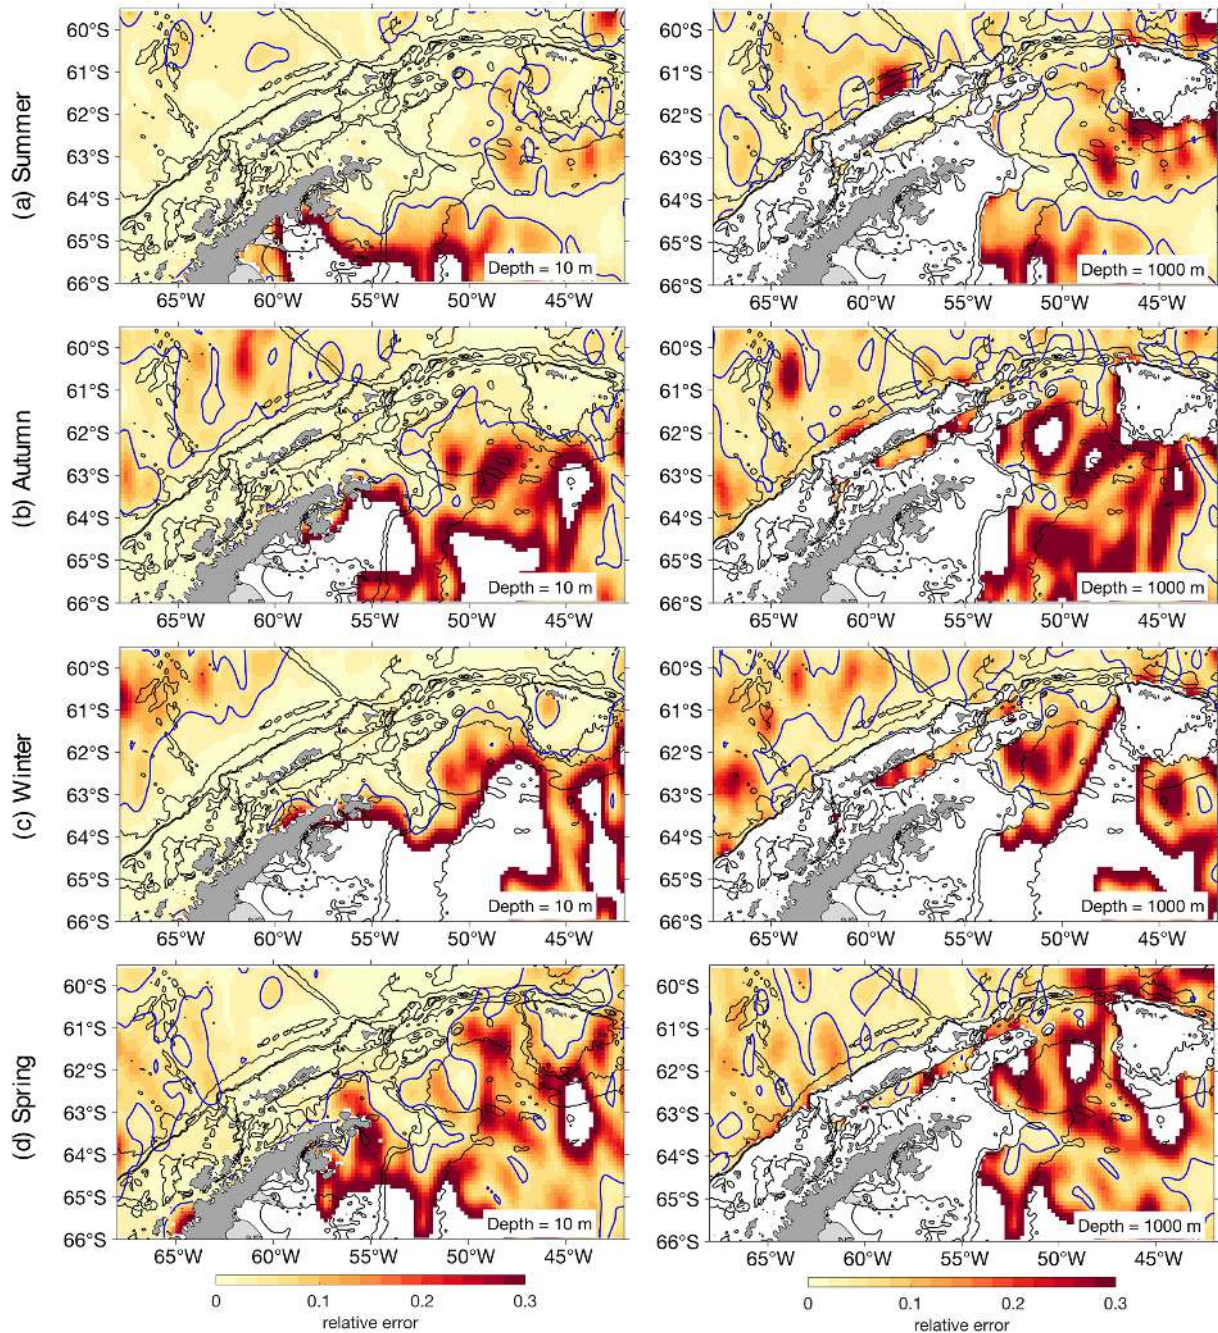

Figure 4. The relative error for in situ temperature calculated in the objective interpolation at 10 m (left panels) and 1000 m (right panels) depth for (a) summer, (b) autumn, (c) winter, and (d) spring. The relative error of 0.05 is marked by the blue line. Areas where the relative error is >0.5 are blank. The ETOPO1 isobaths of 500, 1000, 3000, and 5000 m are depicted by black lines. Coastline from SCAR Antarctic Digital Database.

show evidence of the weaker representation of DO compared to the other properties in autumn, winter, and spring.

4.2 Representation of the main hydrographic features in the NAP

The NAPv1.0 represents qualitatively well the surface thermal dichotomy regime of the NAP waters: a warm variety with Bellingshausen Sea and ACC influence to the west and a cold Weddell Sea-sourced water to the east (Fig. 6a).

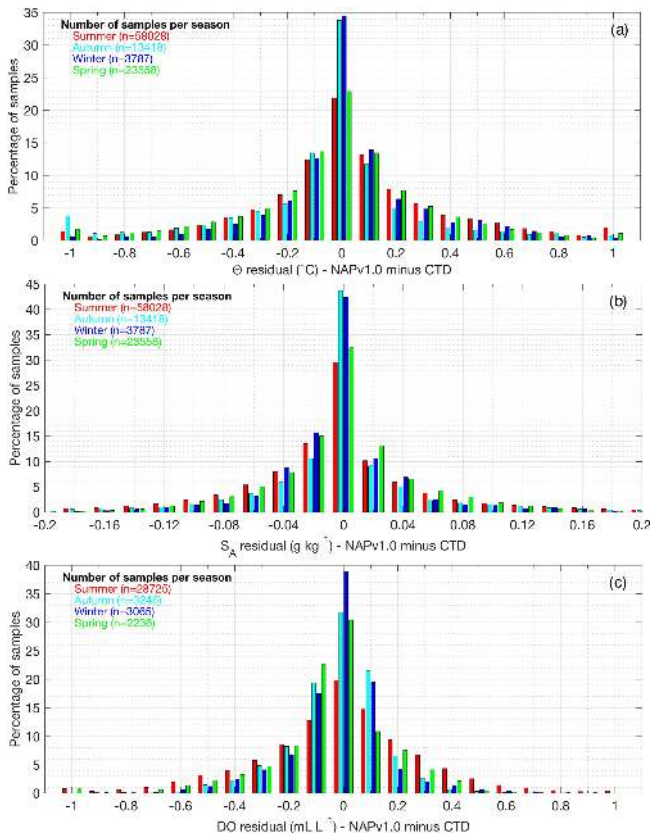

Figure 5. (a) Histogram showing the percentage of the residual difference of conservative temperature (Θ ; $^{\circ}\text{C}$) samples between the NAPv1.0 and the CTDs closer than ~ 6 km from each grid point at 0.1°C bins interval per season. The seasonal difference is shown by colour: summer (red), autumn (cyan), winter (blue), and spring (green). The number of samples per season is shown in the upper left corner of the panel according to the respective colours. (b) Same as panel (a), but for absolute salinity (S_A ; g kg^{-1}) at 0.02 g kg^{-1} bins. (c) Same as panel (a), but for dissolved oxygen (DO; mL L^{-1}) at 0.1 mL L^{-1} bins.

A surface thermal front that splits these two regimes near the Antarctic Peninsula, likely depicting the Peninsula Front (López et al., 1999; Sangrà et al., 2011), is more visible in summer (Fig. 6a–d). On the surface, the coastal Weddell Sea-sourced waters are saltier and denser compared to the warm waters to the west of the NAP (Figs. 6e–h and 7a–d). Thus, the Peninsula Front seems to be baroclinic (Sangrà et al., 2011). The DO is relatively supersaturated everywhere, with higher concentrations found close to the James Ross Island, the Gerlache Strait, and the northern end of the WAP (Fig. 7e–h). These regions are generally associated with high primary productivity, which could explain the relatively higher values of DO (Mendes et al., 2012; Detoni et al., 2015; Costa et al., 2020). Seasonally, the NAPv1.0 represents a general decrease in Θ , an increase in S_A due to sea ice formation in the region, and consequently a γ^n gain from autumn to winter (Figs. 6 and 7a–d). In spring, Θ increases and

S_A and γ^n decrease slightly due to sea ice melting in the upper layers (Figs. 6 and 7a–d). The DO field is less represented in seasons other than summer because of less availability of in situ data (Fig. 7e–h).

In deeper layers, the dichotomy regime of the NAP is still evident, reflecting the presence of warm and salty waters associated with the CDW to the west of the NAP and the Warm Deep Water (WDW; a warm, salty, and poorly oxygenated intermediate water mass presented in the Weddell Sea and derived from the mixing between CDW and Winter Water) within the offshore zone of the Weddell Sea and Powell Basin (Figs. S4–S7 in the Supplement). Intrusions of mCDW are observed in the eastern Bellingshausen Sea through deep channels, reaching the Gerlache Strait and the western basin of the Bransfield Strait (Figs. S4a–S7a in the Supplement). After entering the Bransfield Strait, the mCDW warm signal follows the slope of the South Shetland Islands as the narrow Bransfield Current (Niiler et al., 1991; López et al., 1999; Zhou et al., 2006; Sangrà et al., 2011). However, given the lengthscales chosen, this current is not well represented in the NAPv1.0. Although the routes of mCDW inflow are relatively well known, few studies focused on the periodicity of these inflows into the NAP (e.g. Ruiz Barlett et al., 2018) or on the fast response of these inflows associated with the wind forcing (e.g. McKee and Martinson, 2020a). WDW is another water mass that composes the deep waters of the Bransfield Strait (Gordon et al., 2000). Although the NAPv1.0 suggests the existence of an intrusion of this water mass into the eastern basin at $\sim 61.5^{\circ}\text{S}$ and 55°W (Fig. S4e in the Supplement), we still need to increase our comprehension of the contribution to the water mass mixture and the access routes of WDW into the Bransfield Strait via Powell Basin to resolve the local circulation in more detail (e.g. Thompson et al., 2009; Azaneu et al., 2017). The comprehension of these mechanisms is important to better resolve the heat, salt, and carbon fluxes into the NAP.

In all seasons, the Bransfield Strait is colder, fresher, denser, and oxygen-richer compared to the adjacent regions in deeper basins (Figs. S4–S7 in the Supplement) and is associated with the higher contribution of HSSW (Gordon et al., 2000; Dotto et al., 2016). Moreover, the water masses in the Bransfield Strait central basin are also slightly denser than in the eastern basin (e.g. Fig. S4g in the Supplement), suggesting a different origin of these waters (Gordon et al., 2000; van Caspel et al., 2018). The NAPv1.0 represents quite well a narrow cold and oxygen saturated path along the continental slope of the Weddell Sea at 500 m depth (Fig. S4a–d in the Supplement). At the Powell Basin, these water masses follow the bathymetry and enter the Bransfield Strait, thus connecting the Weddell Sea and the NAP (Heywood et al., 2004). Although slightly less visible than in summer, the narrow thermal signal along the continental slope of the Weddell Sea is observed entering the Bransfield Strait in autumn and spring (Figs. S5a–S7a in the Supplement). In winter, likely due to limited in situ data, this signal is not totally clear (Fig. S6 in

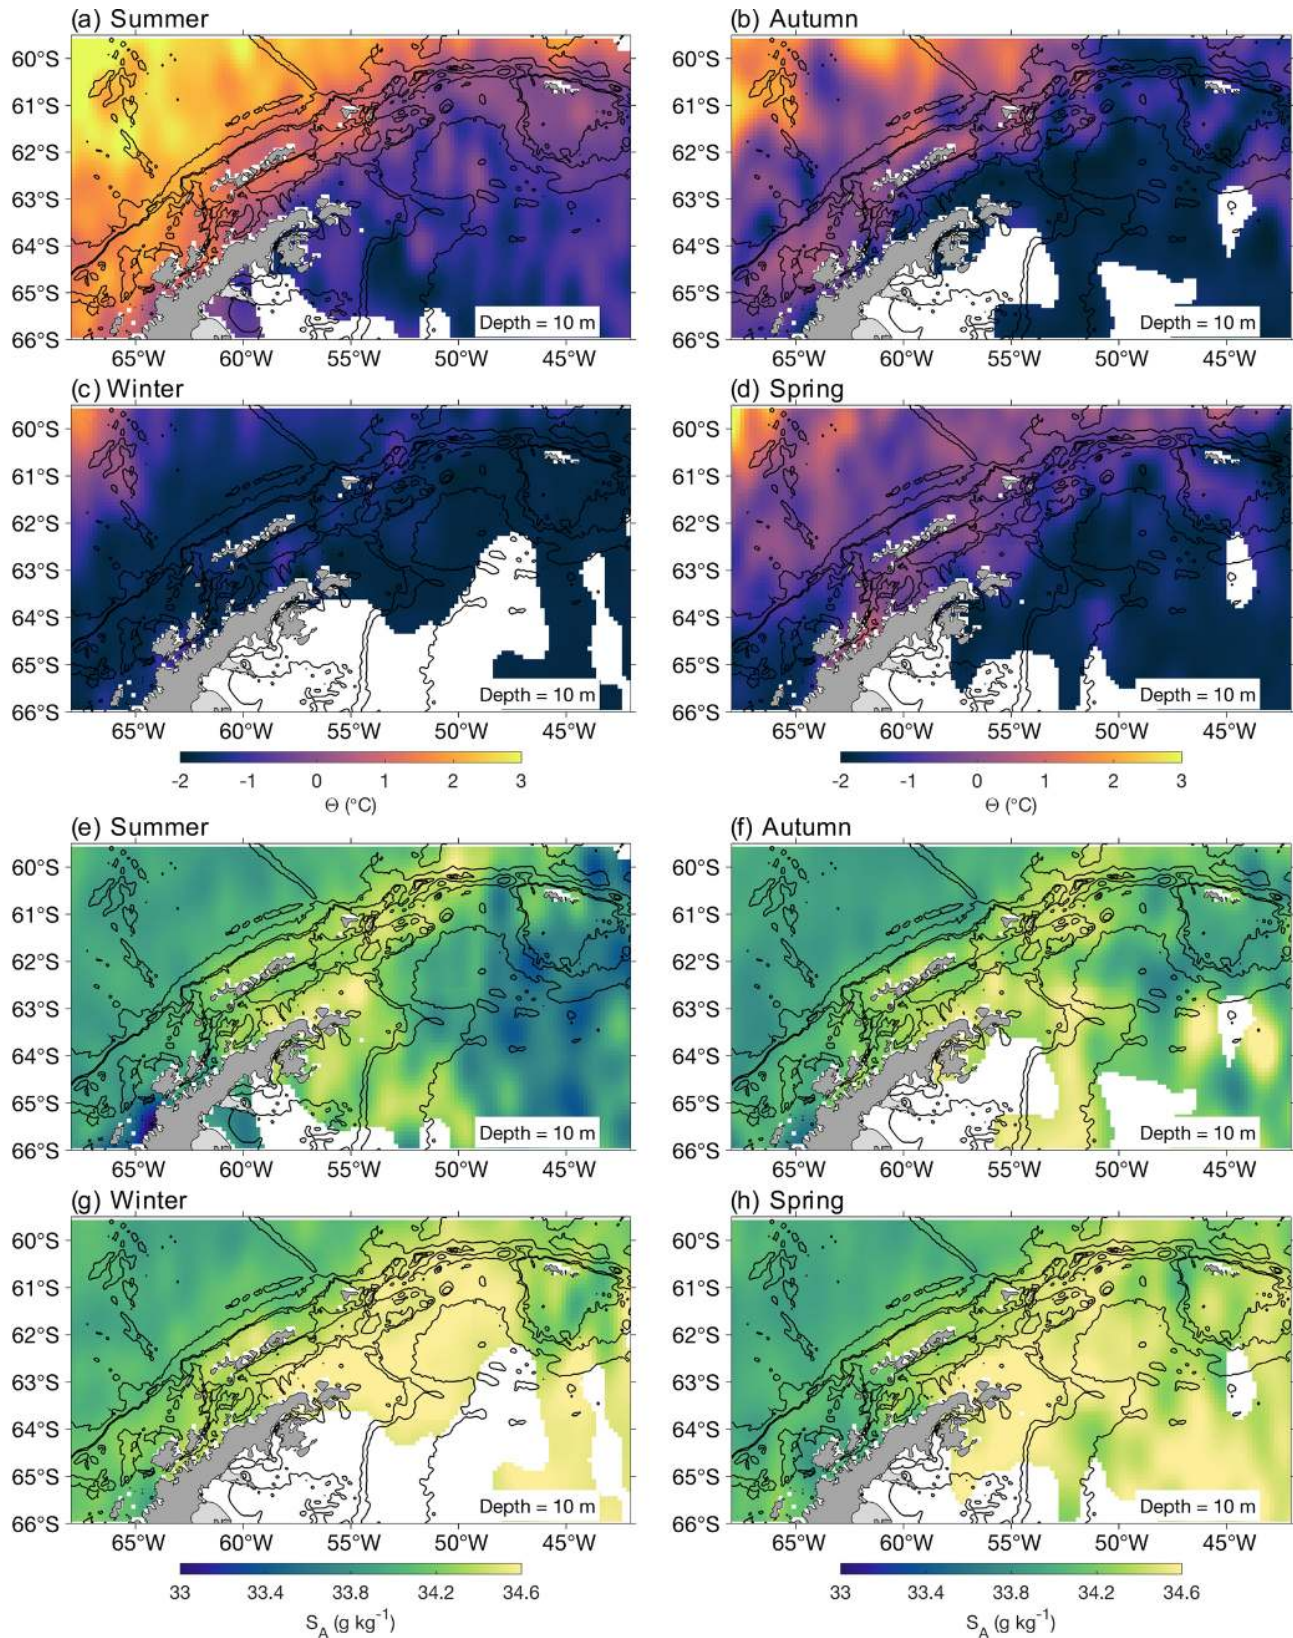

Figure 6. Surface maps of NAPv1.0 at 10 m depth for conservative temperature (Θ ; °C) in (a) summer, (b) autumn, (c) winter, and (d) spring. The 10 m absolute salinity (S_A , g kg⁻¹) in (e) summer, (f) autumn, (g) winter, and (h) spring. The ETOP01 isobaths of 500, 1000, 3000, and 5000 m are depicted by the black lines. Coastline from SCAR Antarctic Digital Database.

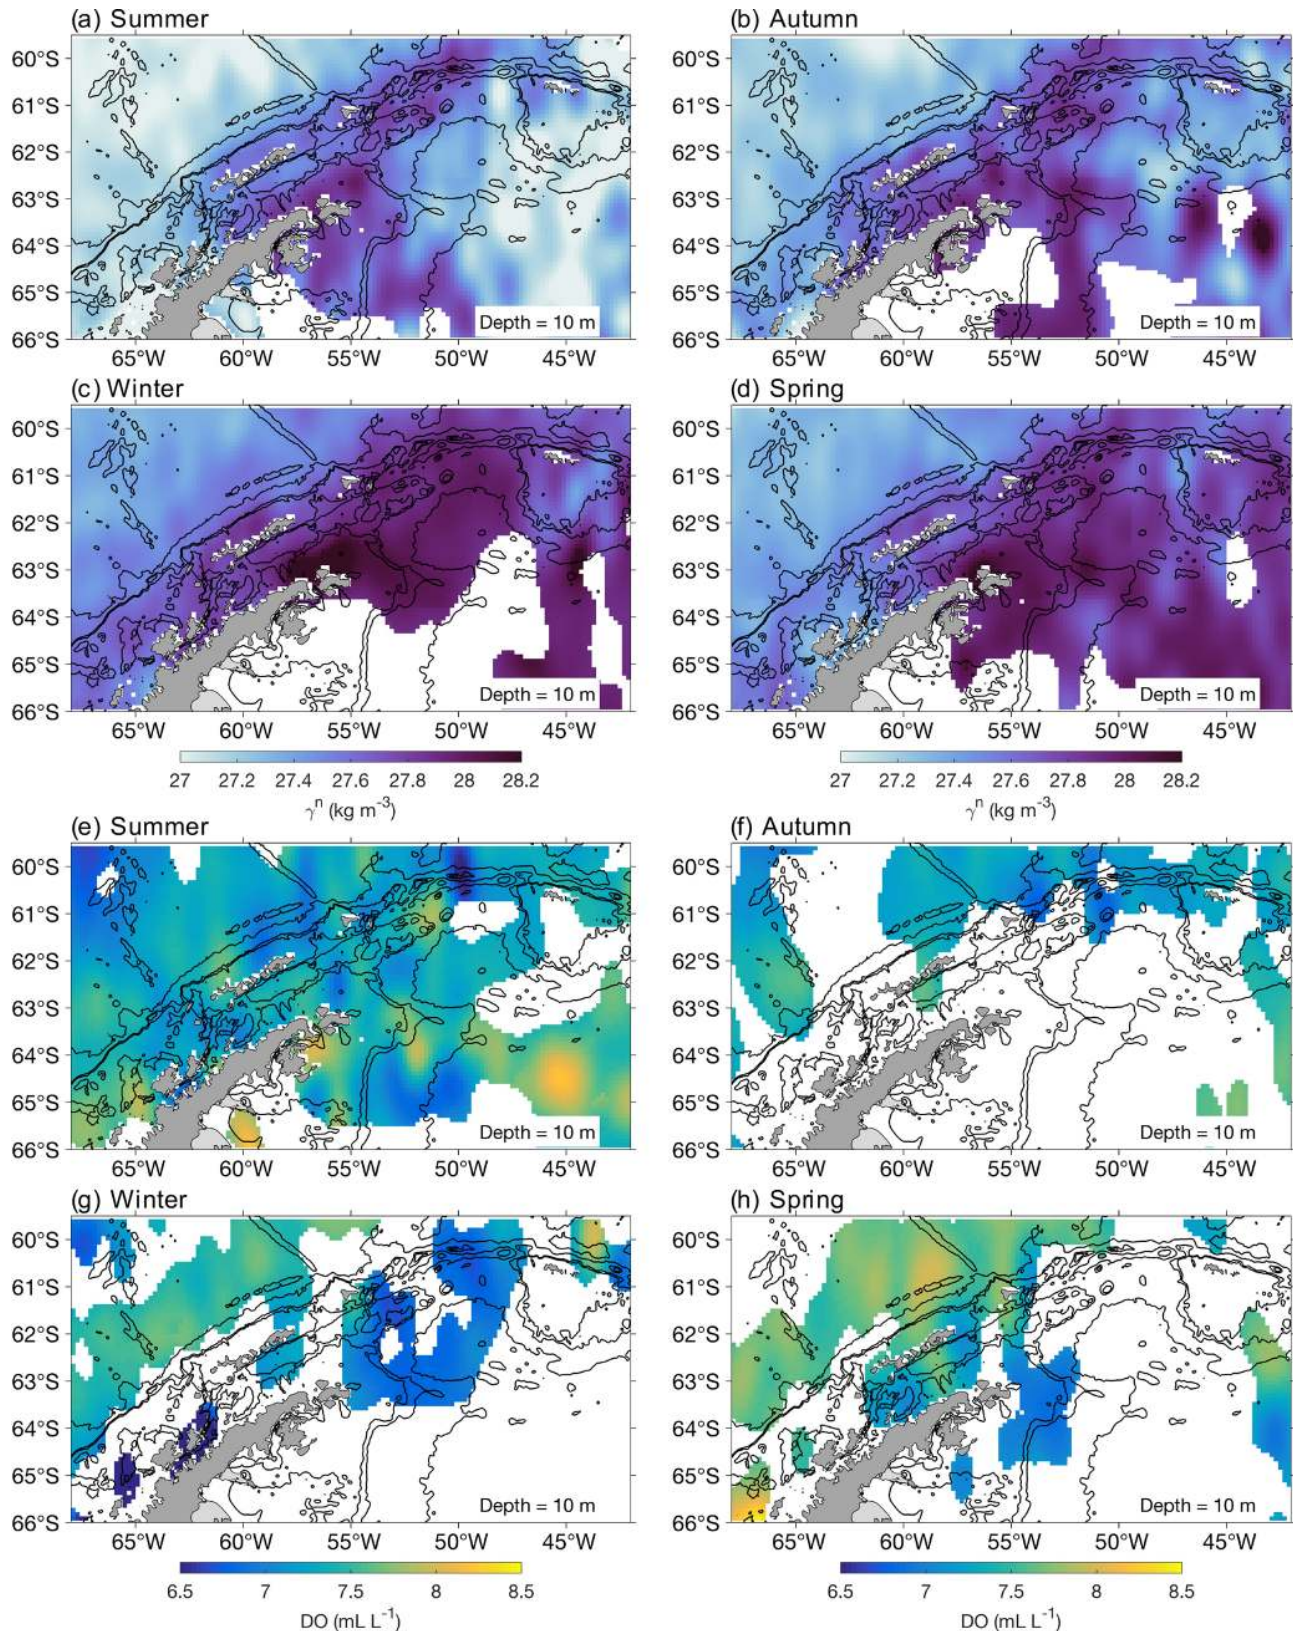

Figure 7. Surface maps of NAPv1.0 at 10 m depth for neutral density (γ^n ; kg m^{-3}) in (a) summer, (b) autumn, (c) winter, and (d) spring. The 10 m dissolved oxygen (DO, mL L^{-1}) in (e) summer, (f) autumn, (g) winter, and (h) spring. The ETOPO1 isobaths of 500, 1000, 3000, and 5000 m are depicted by the black lines. Coastline from SCAR Antarctic Digital Database.

the Supplement). These dense waters that flood the central NAP deep levels seem to follow the shortcuts of the canyons that cut across the Antarctic Peninsula continental shelf in the Bransfield Strait (Figs. S4–S7 in the Supplement). The higher DO in that deep region indicates a fast route of Weddell Sea shelf waters and hence a relatively small residence time (van Caspel et al., 2015, 2018). At deeper levels, the bathymetric constraints restrict the connection of the shelf waters from the Weddell Sea, and the dense waters that sink into the Bransfield Strait retain their quasi-pure properties (Figs. S4e–S7e in the Supplement; Gordon et al., 2000; Dotto et al., 2016). The horizontal maps clearly show the importance of the Bransfield Strait in trapping the shelf waters of the Weddell Sea, making it an *in situ* laboratory to study temporal changes of these water masses. Given the spatial scales and the smoothing following the gridding procedure, Bransfield Strait mesoscale and submesoscale eddies (Sangrà et al., 2011) are not observed in the NAPv1.0.

To exemplify the representation of the water column of NAPv1.0, we selected six sections crossing different parts of the NAP and adjacent regions (Fig. 1a). To the southwest of the Bransfield Strait, along the section between Livingston Island and the Antarctic Peninsula, relatively warmer conditions are observed from the upper ocean to the bottom layers (Fig. 8a). An intrusion of mCDW is observed between 62.7–62.8° S, where the isotherms are sharply tilted towards the South Shetland Islands (Fig. 8a), S_A is above 34.72 g kg⁻¹ (Fig. 8b), and the DO is relatively low <6 mL L⁻¹ (Fig. 8d). The tilt of the isotherms is a signature of the Bransfield Front, which in turn is associated with the mid-depth Bransfield Current (Niiler et al., 1991; López et al., 1999; Sangrà et al., 2011). In the section between King George Island and the Antarctic Peninsula the warm, salty, and deoxygenated mCDW is still present; however, it is located in slightly shallower levels (Fig. 8e–h). Towards the bottom, Θ decreases to the lowest values in the region, characterizing the Bransfield Strait central basin. In this section, the surface Peninsula Front is visible and associated with the cold regime from the western Weddell Sea continental shelf. In both sections, the dome-like shape of the isopycnals supports the cyclonic gyre presence in the region (Fig. 8c, g; Zhou et al., 2002; Sangrà et al., 2011; Collares et al., 2018). The circulation, mixing rates, and turbulent processes are poorly explored in the NAP, thus there is a need for further studies on these processes to better comprehend the local water mass transformation in the different depth layers (e.g. Brearley et al., 2017) as it ultimately impacts the physicochemical properties and biology of the region. The NAPv1.0 also distinguishes well the difference between the central and eastern basins of the Bransfield Strait (Fig. 8i–l). Colder, denser, and more oxygenated deep waters are observed in the former basin, whereas the latter is relatively warmer, lighter, and less oxygenated. This dichotomy occurs because the central basin has restricted connections with the adjacent regions due to bathymetric constraints and it also receives more contribution from HSSW than the east-

ern basin (Gordon et al., 2000; Dotto et al., 2016). Within the Bransfield Strait, more mCDW accesses the region in autumn coming from Livingston Island and reaching the eastern basin, increasing temperature and salinity in deep waters in all basins (Fig. S8 in the Supplement). Moreover, the Peninsula Front migrates toward the South Shetland Islands due to higher inflow of Weddell-sourced waters (Fig. S8e in the Supplement) until it vanishes in winter due to surface cooling (Fig. S9d in the Supplement). In spring, the hydrographic properties of the Bransfield Strait resemble more those of summer in subsurface levels (Fig. S10 in the Supplement). Although the winter DO suggests the presence of deep convection in the eastern basin, the distribution of the isopycnals refutes this idea, which reinforces the conclusion of Whitworth et al. (1994) that it is unlikely that deep convection occurs in Bransfield Strait. Due to lack of data from autumn to spring, we will focus on the summer conditions.

We now evaluate the NAPv1.0 in sections crosscutting the WAP at the WOCE-SR4 West (hereafter, SR4) and along the Scotia Arc – a route of Antarctic Bottom Water export (Fig. 1a; Franco et al., 2007). At the WAP (Fig. 9a–d), the NAPv1.0 shows high values of Θ and S_A and lower values of DO, associated with CDW, intruding onto the continental shelf. Θ as high as 1 °C, sourced from upper CDW, floods the continental shelf in those regions (Moffat and Meredith, 2018) and are a heat source for the glacier retreating (Cook et al., 2016). Although the salinity values are high, they are not as high as the lower branch of CDW offshore (Fig. 9b). The isopycnals offshore tilt upwards near the continental slope, suggesting upwelling of CDW (additionally, several hypotheses have been developed to explain the origin of these warm waters, such as eddies shed by the ACC, current deflection by the cross-shelf-cutting canyons, or advections of the ACC onto the continental shelf; e.g. Prézelin et al., 2000; Martinson et al., 2008; Martinson and McKee, 2012; Couto et al., 2017; McKee and Martinson, 2020b). On the Weddell Sea side, the NAPv1.0 shows the main water masses of the region (Fig. 9e–h), including the Winter Water at the subsurface, the WDW with the largest (lowest) values of Θ and S_A (DO), the Weddell Sea Deep Water, and the Weddell Sea Bottom Water, the latter of which is restricted to below 4000 m (Farhbach et al., 2004; Kerr et al., 2018c). Another important feature observed in the climatology is the downslope flow of the cold, fresh, dense, and recently ventilated waters at the continental slope (van Caspel et al., 2015). At the shelf break, the isotherms tilt suggesting the presence of the Antarctic Slope Front (Farhbach et al., 2004; Heywood et al., 2004). Once the Weddell Sea Deep Waters enters the Powell Basin, a fraction is exported across the Scotia Arc (Fig. 1b; Franco et al., 2007). This region is transitional between the Weddell Sea and the northward parts of the Southern Ocean and generally has a warm and weak density structure. The export of dense waters may occur at Philip Passage, where the upper parcel of Weddell Sea Deep Water can overflow the bathymetric constraint, as shown in Fig. 9i–l. On

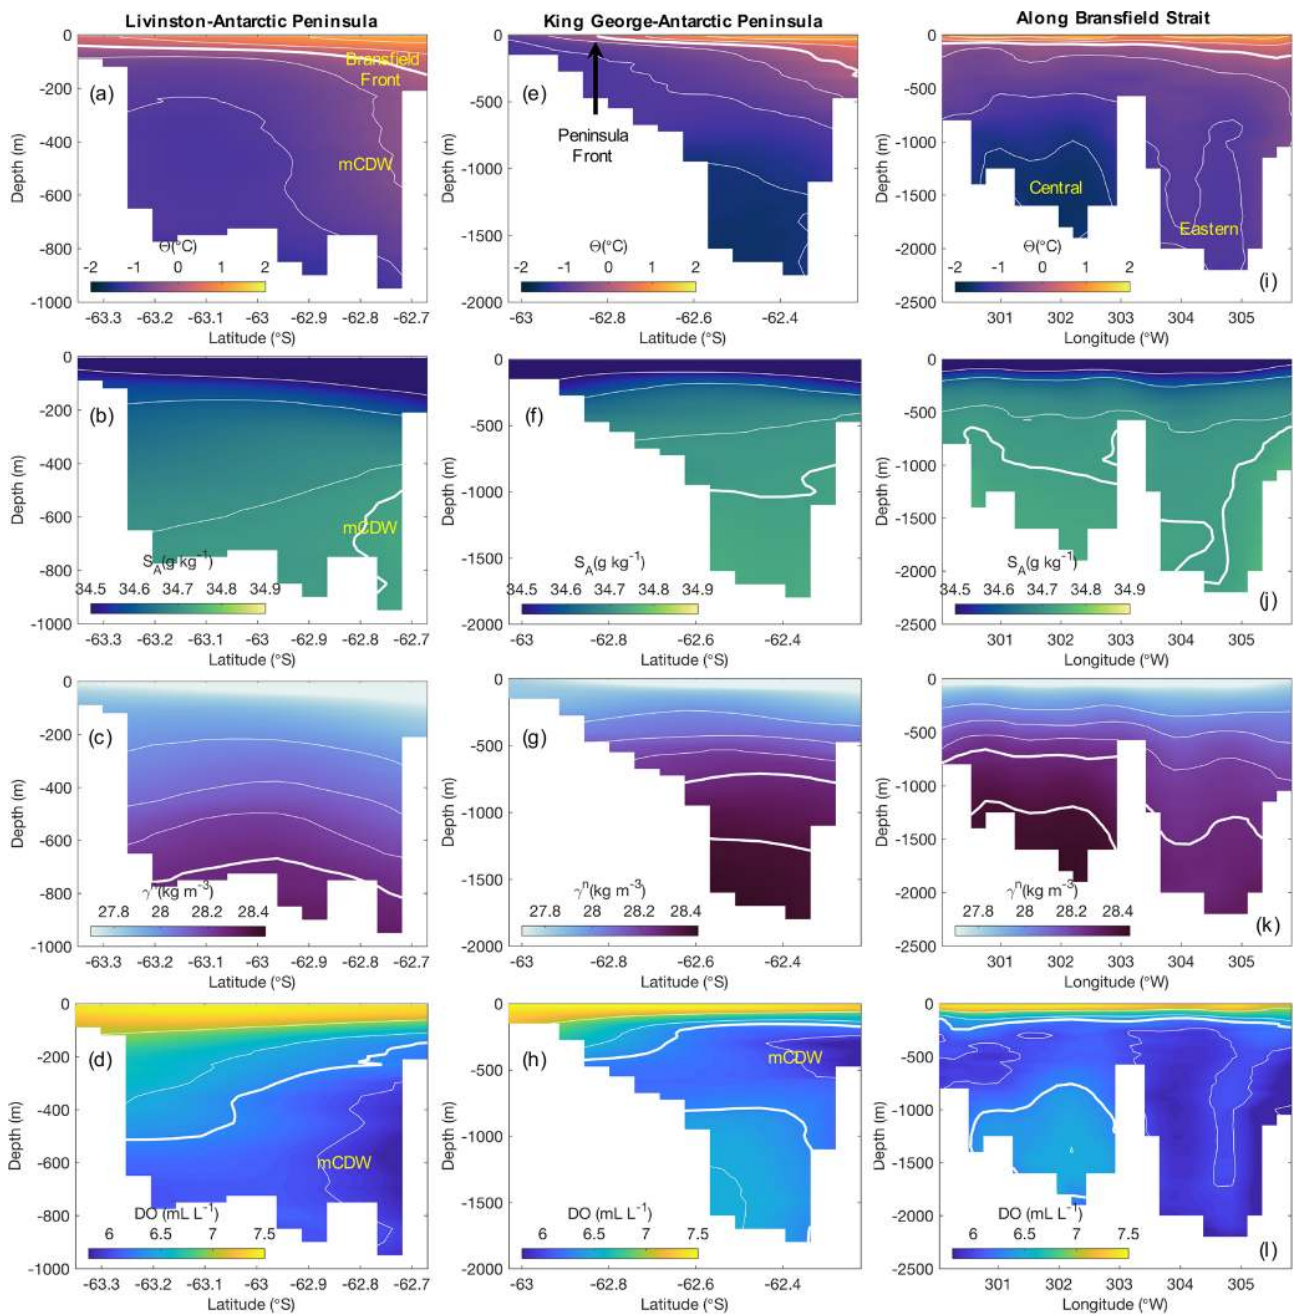

Figure 8. Summer vertical sections crossing the Bransfield Strait between Livingston Island and the Antarctic Peninsula (a–d; red line in Fig. 1a), King George Island and the Antarctic Peninsula (e–h; blue line in Fig. 1a), and along the Bransfield Strait (i–l; black line in Fig. 1a). Conservative temperature (Θ ; $^{\circ}\text{C}$) is shown in panels (a), (e), and (i). The isotherm of 0°C is shown by the thick white lines. Thin lines show the isotherms of -1.5 to $+1.0^{\circ}\text{C}$ every 0.5°C . Absolute salinity (S_A ; g kg^{-1}) is shown in panels (b), (f), and (j). The isoline of 34.72 g kg^{-1} is shown by the thick white lines. Thin lines show the isolines of 34.5 to 34.7 g kg^{-1} every 0.1 g kg^{-1} . Neutral density (γ^n ; kg m^{-3}) is shown in panels (c), (g), and (k). The isolines of 28.27 and 28.40 kg m^{-3} are shown by the thick white lines. Thin lines show the isolines of 28.00 to 28.20 kg m^{-3} every 0.1 kg m^{-3} . Dissolved oxygen (DO; mL L^{-1}) is shown in panels (d), (h), and (l). The isoline of 6.3 mL L^{-1} is shown by the thick white lines. Thin lines show the isolines of 5.5 to 7.0 mL L^{-1} every 0.5 mL L^{-1} . The Bransfield Front, Peninsula Front, and mCDW inflows are identified in panels (a), (b), (d), (e), and (h). The Bransfield Strait central and eastern basins are identified in panel (i). Note the difference in the depth ranges.

seasonal time scales, the NAPv1.0 represents the natural intraseasonal variability in the upper ocean as well as changes in the isopycnals tilting, suggesting small changes in the circulation across the sections. However, mainly in winter, the data is spatially sparse. For all seasons except summer, DO distribution is flawed (Figs. S11–S13 in the Supplement).

4.3 Comparison against other climatological products

Most climatological products are built to represent the global ocean and its large-scale basins, such as the Southern Ocean. The NAP, on the other hand, is a relatively small region but highly dynamical and ecologically important to connect regional environments (Kerr et al., 2018a). In this context, we now compare the NAPv1.0 with some other available gridded products, widely used by the ocean community, to show how effective it is to have regional climatologies, especially in areas of intense spatial and temporal variability. For these comparisons, we chose to use the WOA and CARS climatologies and the SOSE state estimate previously described in Sect. 2. Although SOSE is based on a model, and one could argue that comparing it with a gridded product is not a fair comparison, we decided to use it because the data coverage of the Southern Ocean is relatively poor in space and time, and many studies have used SOSE as a benchmark to evaluate other ocean model outputs (e.g. Spence et al., 2017; Russell et al., 2018). In addition, SOSE has been used as initial conditions for simulations within the Bransfield Strait (e.g. Zhou et al., 2020). Despite the limitations of state estimate and ocean reanalysis (e.g. Mazloff et al., 2010; Azaneu et al., 2014; Dotto et al., 2014; Aguiar et al., 2017; Verdy and Mazloff, 2017), combining model and observations, such as in SOSE, leads to great improvements on the comprehension of the Southern Ocean dynamics (e.g. van Sebille et al., 2013; Abernathy et al., 2016; Rodriguez et al., 2016; Tamsitt et al., 2017).

The vertical water mass structure of the NAP and adjacent regions is well represented by the NAPv1.0 (Fig. 10a–b). The density distribution and thermohaline ranges agree well with the CTD casts (closer than 6 km from the grid points), as previously shown (Sect. 4.1). The summer-averaged WOA is colder and saltier at the surface, but the intermediate to deep ocean seems to have thermohaline range and density structure similar to observations (Fig. 10c–d). The summer-estimated CARS seems to represent well the NAP region, despite being a product with coarser resolution. It has the range of Θ and S_A in agreement with the observations throughout the water column (Fig. 10e). A good agreement is also observed for the dense waters, where CARS has similar levels of γ^n compared to the measured data (Fig. 10f). Contrary to WOA, the NAPv1.0 and the CARS climatologies do not show supercooled waters centred at S_A 34.6–34.7 g kg⁻¹ (and $\Theta \sim -2^\circ\text{C}$), which is in agreement with the observations (Fig. 10b, d, f). The 2008–2018 summer averaged SOSE represents the upper ocean considerably fresher,

whereas the water masses with $\gamma^n < 27.6 \text{ kg m}^{-3}$ are colder than the observations (Fig. 10g). The dense water masses ($\gamma^n > 28.27 \text{ kg m}^{-3}$) are not well represented in SOSE for the region analysed, being considerably warmer and saltier than the observations (Fig. 10h). However, due to higher temperatures, lighter waters flood the bottom layers of SOSE. The similarity of the NAPv1.0 and the WOA and CARS climatologies to the observations is because these data sets are totally fed by in situ data, whereas SOSE is based on a model run fed by in situ data.

Now, to present the water mass structure, we show the representation of these products along the several sections at the NAP and adjacent regions. We start showing the representation of the climatologies in the central area of the NAP, i.e. the Bransfield Strait, because it has a transitional regime between cold and warm conditions and it is highly dynamical. WOA unveils the upper ocean considerably colder, and despite having similar ranges of Θ as the NAPv1.0 in the mid- to deep ocean, the distinction between the Bransfield Strait's central and eastern basins is not well represented (Fig. 11a and Fig. S14a in the Supplement). The S_A distribution in WOA is slightly saltier than the NAPv1.0 and it does not show a clear spatial variability (Fig. 11b). Consequently, the WOA is generally denser than NAPv1.0, mainly in the eastern basin (Fig. 11c and Fig. S15a in the Supplement). The Θ climatology in CARS is in closer agreement with the NAPv1.0, both in the upper ocean and deeper layers (Fig. 11d). Although the deep Θ is not as low as the NAPv1.0 (Fig. S14g in the Supplement), a clear thermal distinction is observed between the central and eastern basin of the Bransfield Strait. On the other hand, the S_A field is slightly saltier in CARS than the NAPv1.0 and the spatial distribution is less variable, as observed by the flatness of the isohalines (Fig. 11e). In general, CARS is slightly denser than NAPv1.0 for the Bransfield Strait (Fig. S15g in the Supplement). Interestingly, however, is the representation of DO in CARS, which resembles the NAPv1.0 in terms of magnitude and spatial distribution (Fig. 11g). In both products, the DO is higher in the central basin (although slightly overestimated in CARS climatology). SOSE is considerably warmer in most of the water column in both basins (Fig. 11h and Fig. S14m in the Supplement) when compared to the NAPv1.0 (Fig. 8i). As discussed previously, SOSE shows higher salinity than the NAPv1.0 in both basins below $\sim 250 \text{ m}$ depth (Fig. 11i). However, the deep density structure in the Bransfield Strait is lighter than NAPv1.0 because of the higher Θ values in SOSE (Fig. 11j and Fig. S15m in the Supplement). Regarding DO, SOSE is oversaturated in the upper layer and highly deoxygenated below $\sim 100 \text{ m}$ (Fig. 11k) compared to NAPv1.0 (Fig. 8l).

Regarding the other sections in the Bransfield Strait (Fig. 1a), no product captured the Peninsula and Bransfield fronts as well as NAPv1.0, likely due to their coarser resolution (Fig. 12a, b, f, g, k, l). The mid-depth inflow of mCDW is better represented in CARS, where it is restricted to the South

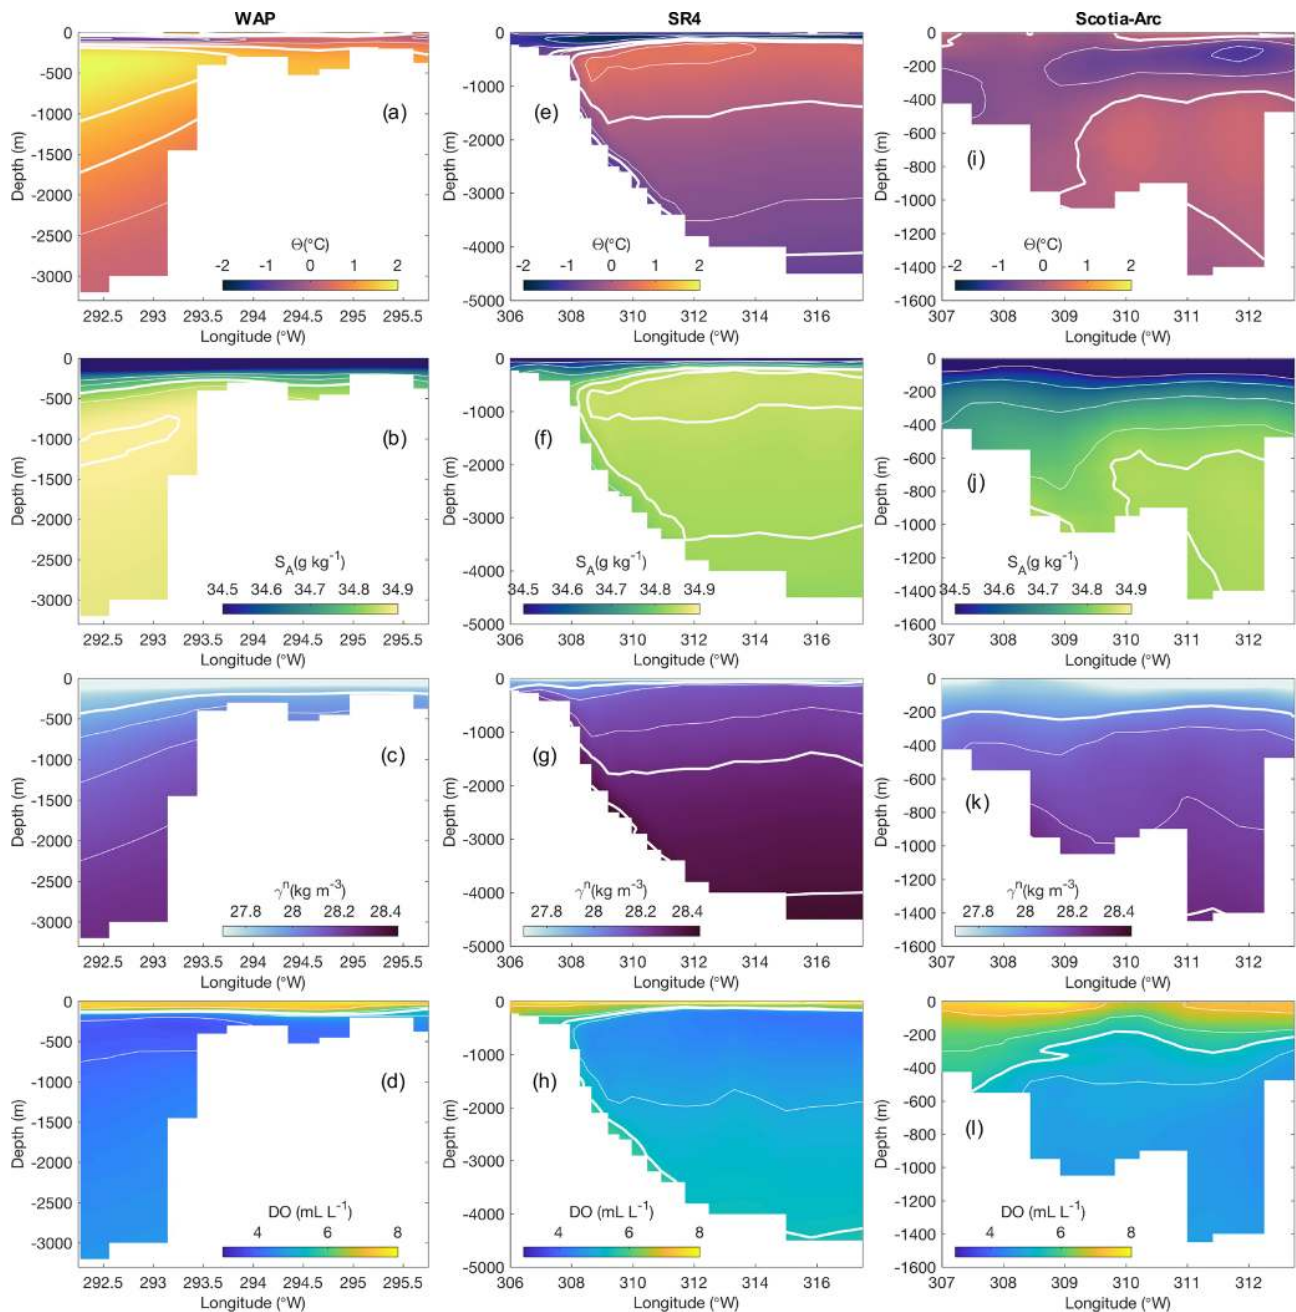

Figure 9. Summer vertical sections along the western Antarctic Peninsula (WAP; **a–d**; magenta line in Fig. 1a), WOCE SR4 across the Weddell Gyre (**e–h**; green line in Fig. 1a), and the Scotia Arc line over the south Scotia Ridge (**i–l**; cyan line in Fig. 1a). **(a)** Conservative temperature (Θ ; $^{\circ}\text{C}$) with isotherms of 1 and 1.5°C (-1.0 to 0.5°C every 0.5°C) shown by the thick (thin) white lines. **(b)** Absolute salinity (S_A ; g kg^{-1}) with isolines of 34.8 and 34.9 g kg^{-1} (34.7 to 34.85 g kg^{-1} every 0.05 g kg^{-1}) shown by the thick (thin) white lines. **(c)** Neutral density (γ^n ; kg m^{-3}) with the isoline of 27.9 kg m^{-3} (28.0 to 28.2 kg m^{-3} every 0.1 kg m^{-3}) shown by the thick (thin) white lines. **(d)** Dissolved oxygen (DO; mL L^{-1}) with the isoline of 5.5 mL L^{-1} (4 to 7 mL L^{-1} every 1 mL L^{-1}) shown by the thick (thin) white lines. **(e)** Θ with isotherms of -0.7 and 0°C (-1.5 to 0.5°C every 0.5°C) shown by the thick (thin) white lines. **(f)** S_A with the isolines of 34.83 and 34.85 g kg^{-1} (34.5 to 34.8 g kg^{-1} every 0.1 g kg^{-1}) shown by the thick (thin) white lines. **(g)** γ^n with isolines of 28.0 , 28.27 , and 28.4 kg m^{-3} (28.1 and 28.2 kg m^{-3}) shown by the thick (thin) white lines. **(h)** DO with the isoline of 5.5 mL L^{-1} (5 to 7 mL L^{-1} every 1 mL L^{-1}) shown by the thick (thin) white lines. **(i)** Θ with isotherms of 0°C (-1.0 and 1.5°C) shown by the thick (thin) white lines. **(j)** S_A with the isoline of 34.83 g kg^{-1} (34.5 to 34.8 g kg^{-1} every 0.1 g kg^{-1}) shown by the thick (thin) white lines. **(k)** γ^n with the isolines of 28.0 and 28.27 kg m^{-3} (28.1 and 28.2 kg m^{-3}) shown by the thick (thin) white lines. **(l)** DO with the isoline of 5.5 mL L^{-1} (5 to 7 mL L^{-1} every 1 mL L^{-1}) shown by the thick (thin) white lines.

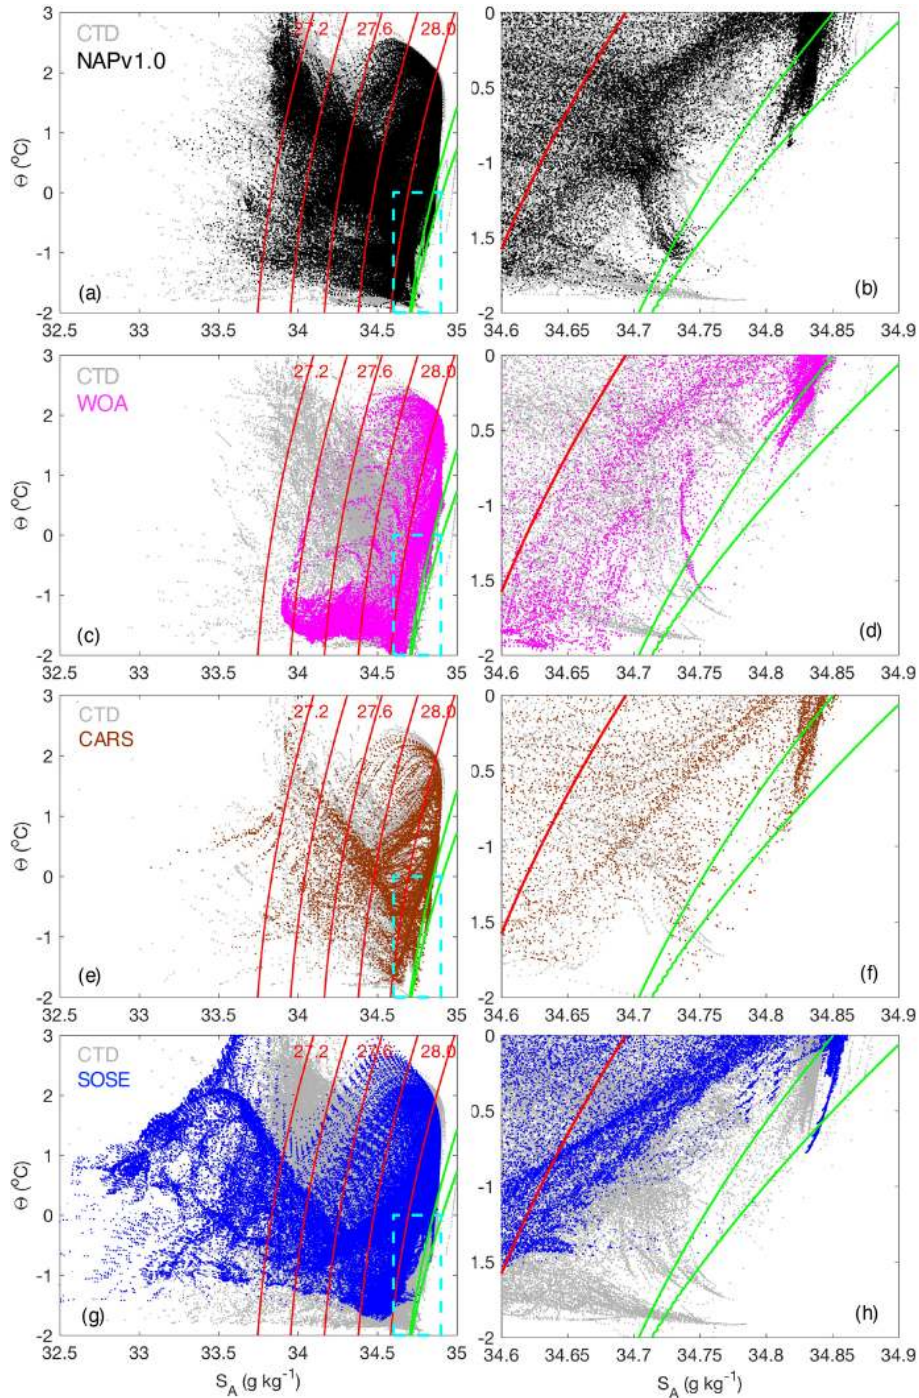

Figure 10. Summer conservative-temperature–absolute-salinity ($\Theta - S_A$) diagrams for the different climatologies analysed and profiles collected by CTD (represented by grey points) closer than ~ 6 km from the grid points. **(a, b)** NAPv1.0, **(c, d)** WOA, **(e, f)** CARS, and **(g, h)** SOSE. Neutral density isopycnals of 27.2 to 28.0 kg m^{-3} are shown every 0.2 kg m^{-3} . Green lines depict the 28.27 and 28.40 kg m^{-3} isopycnals. Cyan rectangles in **(a)**, **(c)**, **(e)**, and **(g)** show the dense water masses restriction presented in **(b)**, **(d)**, **(f)**, and **(h)**, respectively. The difference in the number of CTD points is because the grid points of each climatology is taken as a reference for the station positions.

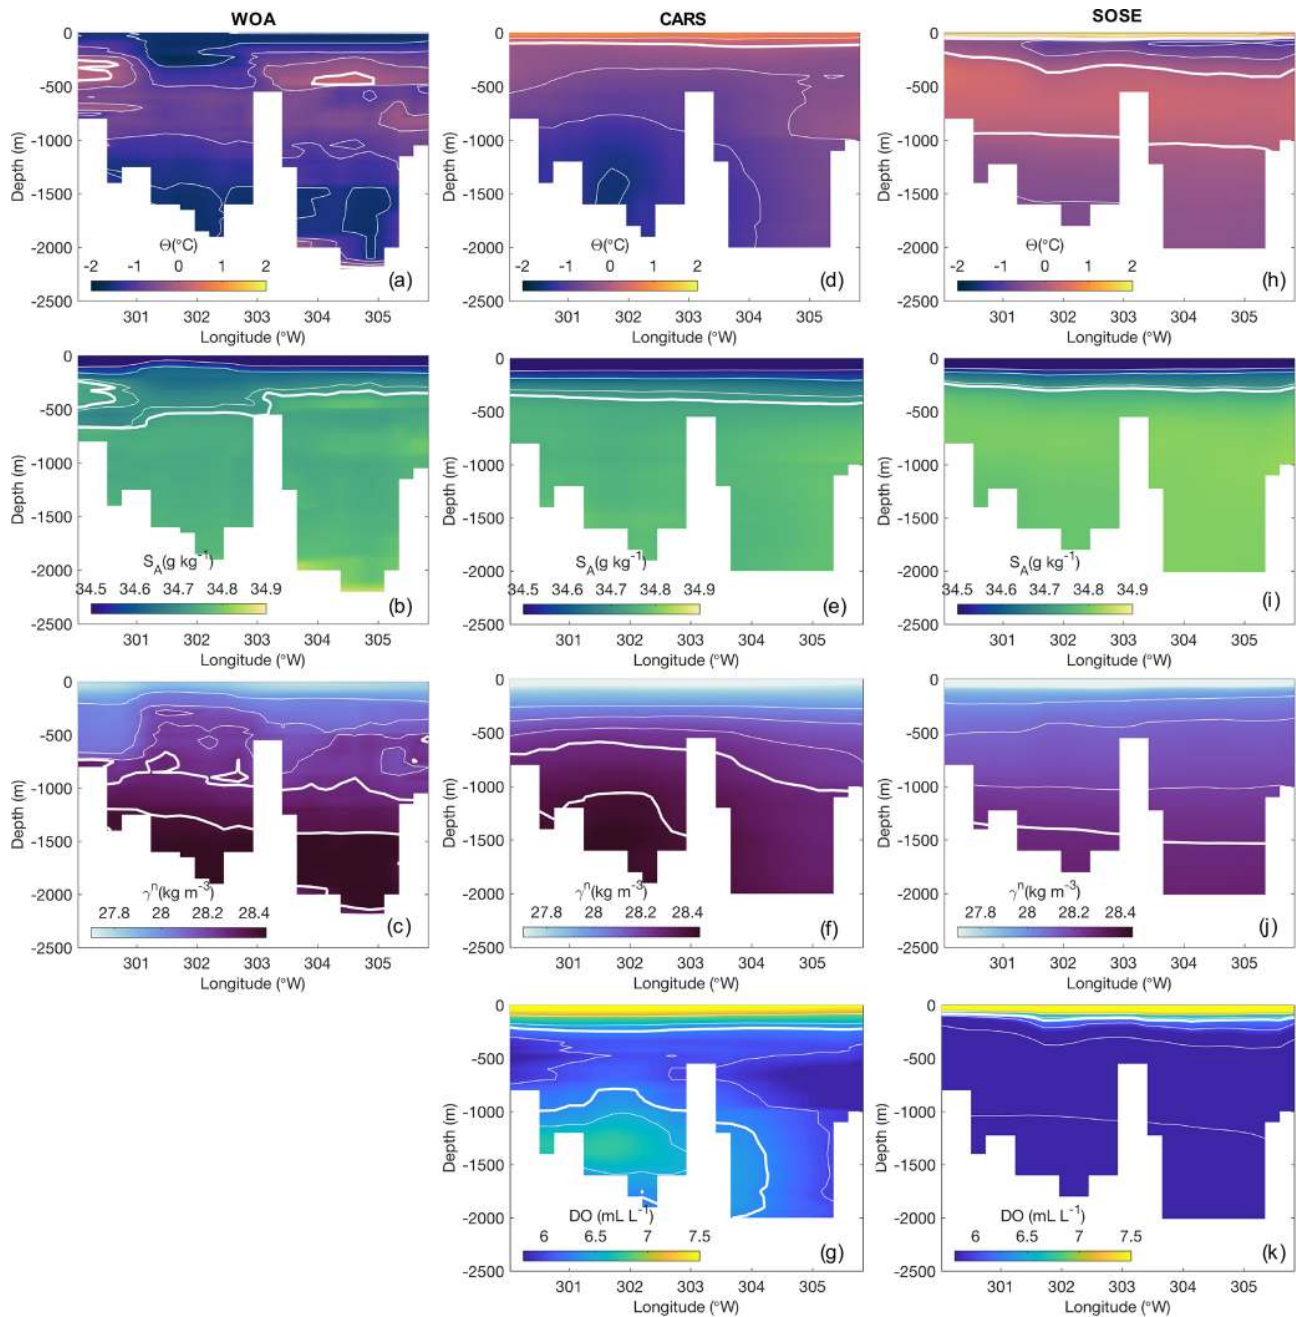

Figure 11. Summer vertical sections for WOA (left panels), CARS (middle panels), and SOSE (right panels) along the Bransfield Strait (Fig. 1a). **(a, d, g)** Conservative temperature (Θ ; $^{\circ}\text{C}$). The isotherm of 0°C (-1.5 to 1.5°C every 0.5°C) is shown by the thick (thin) white lines. **(b, e, i)** Absolute salinity (S_A ; g kg^{-1}). The isoline of 34.72 g kg^{-1} (34.5 to 34.7 g kg^{-1} every 0.1 g kg^{-1}) is shown by the thick (thin) white lines. **(c, f, j)** Neutral density (γ^n ; kg m^{-3}). The isolines of 28.27 and 28.4 kg m^{-3} (28.0 to 28.2 kg m^{-3} every 0.1 kg m^{-3}) are shown by the thick (thin) white lines. **(g, k)** Dissolved oxygen (DO ; mL L^{-1}). The isoline of 6.3 mL L^{-1} (5.5 to 7.0 mL L^{-1} every 0.5 mL L^{-1}) is shown by the thick (thin) white lines.

Shetland Islands side. In WOA and SOSE, the mCDW seems to be present in the whole meridional extent of the Bransfield Strait (Fig. 12a, b, f, g, k, l), which creates a band of higher temperatures in levels deeper than 200 m in both products compared to NAPv1.0 (Fig. S14 in the Supplement). As pre-

viously noticed, the temperature range of CARS is in better agreement with our regional climatology (Fig. S14 in the Supplement). In terms of γ^n , WOA and SOSE are considerably lighter than NAPv1.0 below ~ 300 m (Figs. 13a, b, f, g, k, l and Fig. S15 in the Supplement) because of their higher

temperature (Fig. S14 in the Supplement). For instance, the isopycnals of 28.27 and 28.4 kg m^{-3} are found deeper in the Livingston–Antarctic Peninsula and King George–Antarctic Peninsula sections in the WOA (Fig. 13a–b). In SOSE, the 28.27 and 28.4 kg m^{-3} isopycnals are respectively absent in the former and latter sections (Fig. 13k–l). CARS is more in agreement with NAPv1.0 in terms of magnitude and distribution of the isopycnals within the Bransfield Strait despite its larger resolution (Fig. 13f–g). However, in general, the dome-like structure of the isopycnals in the Bransfield Strait, associated with the cyclonic circulation, is not apparent in the other products analysed, which suggests a misrepresentation of the circulation pattern of the strait (Fig. 13).

In the adjacent regions of the NAP, where the oceanographic regime is less dynamical, WOA, CARS, and SOSE represent the vertical structure of the water masses relatively better than within the central NAP (Figs. 12 and 13). All of them successfully represent the core of CDW offshore, the upward tilting of the isotherms and isopycnals towards the continental slope, and the CDW accessing the WAP continental shelf (Figs. 12 and 13). In the Weddell Sea, all products represent the core of the WDW and the thermal and density distinction of Weddell Sea Deep Water and Weddell Sea Bottom Water. However, only CARS can represent the downslope flow of cold and dense waters at the continental slope, in agreement with NAPv1.0 and observations (Figs. 12 and 13). Along the Scotia Arc, despite all products roughly agreeing regarding the distribution of the warmer water parcel (Fig. 12), only CARS and SOSE represent the export of lighter Weddell Sea Deep Water through the Philip Passage (Fig. 13), in agreement with NAPv1.0 (Fig. 9k) and observations (Franco et al., 2007).

One must keep in mind that WOA and CARS are global climatologies, and their relatively low-resolution (i.e. $1/4$ and $1/2^\circ$ respectively) does not properly represent some local and regional environments of the Southern Ocean like in the NAP (for instance, the distance between the South Shetland Islands and the Antarctic Peninsula is slightly more than 100 km). Despite having lower resolution, CARS seemed to better represent the hydrographic properties in the Bransfield Strait than WOA. Although beyond the scope of this work, this discrepancy could be associated with the interpolation methods that are distinct for each climatology. On the other hand, SOSE is a state estimate where a model is constrained by observations. Although its output products are good to study and represent large-scale processes, SOSE did not seem fit to be used in regional seas, at least in the NAP, where complex dynamics and contrasting regimes set the local water mass structure and variability. In this sense, simulations of regional models could be significantly impacted by the use of those large-scale climatologies and reanalysis products.

4.4 Caveats of the NAPv1.0 climatology

In summary, the NAPv1.0 is robust in the representation of many described dynamic features of the region and, to our knowledge, its hydrographic fields closely follow the observations better than any other available product. Hence, the NAPv1.0 can be used to represent the mean state conditions as well as to feed ocean regional models of the highly transitional and dynamic NAP environments. However, a few caveats can be identified in the NAPv1.0.

In situ data are spatially and temporally sparse in the Southern Ocean. The Argo and MEOP data sets could have the potential to overcome this uneven sampling; however, a few regions are still undersampled, such as the western Weddell Sea (Fig. 2). To avoid creating larger errors (and unreal hydrographic values) in the interpolation procedure, we decided to avoid those regions by masking the final products.

CTD data are still the only data that can be used to measure deeper (>2000 m) levels in the region. Considering that most of the hydrographic cruises were conducted in summer (Fig. 3), deeper regions are not well represented in other seasons. In those cases, most of the climatology is developed to the upper ocean (<2000 m) given the measurement restrictions of the Argo and MEOP data sets. To avoid creating larger errors (and unreal hydrographic values) in the interpolation procedure, we decided not to interpolate where data are not available. Because of this choice, autumn, winter, and spring showed a lower representativeness than summer. This might be solved in the near future with the development of deep-Argo floats (Roemmich et al., 2019) and could potentially sample many deep parts of the adjacent regions of the NAP (e.g. Weddell Sea, Bellingshausen Sea, and Drake Passage).

Another limitation of our climatology regards the DO field. As most of the CTD measurements were conducted in summer, the greatest representation of this field is restricted to that season. In addition, a considerable number of DO measurements were conducted by the GOAL, restricted to the Bransfield and Gerlache straits during summer (Fig. 3c). The development of biogeochemical Argo floats could increase the amount of available DO data in the future for different seasons (Roemmich et al., 2019), which would improve the representation of the different climatologies.

The grid scale (~ 10 km) is similar or even higher than the first baroclinic Rossby radius of the region (Chelton et al., 1998), which limits the representation of some mesoscale and submesoscale features. In addition, the smoothing radius chosen in the objective interpolation and the mean state associated with the interpolation filter out most of the small dynamic features, such as eddies associated with the Peninsula Front (e.g. Sangrà et al., 2011) or at the WAP continental slope (Martinson and McKee, 2012).

Finally, the NAPv1.0 product brings a novel tool and opens plenty of possible future applications to better understand the regional circulation and hydrography along

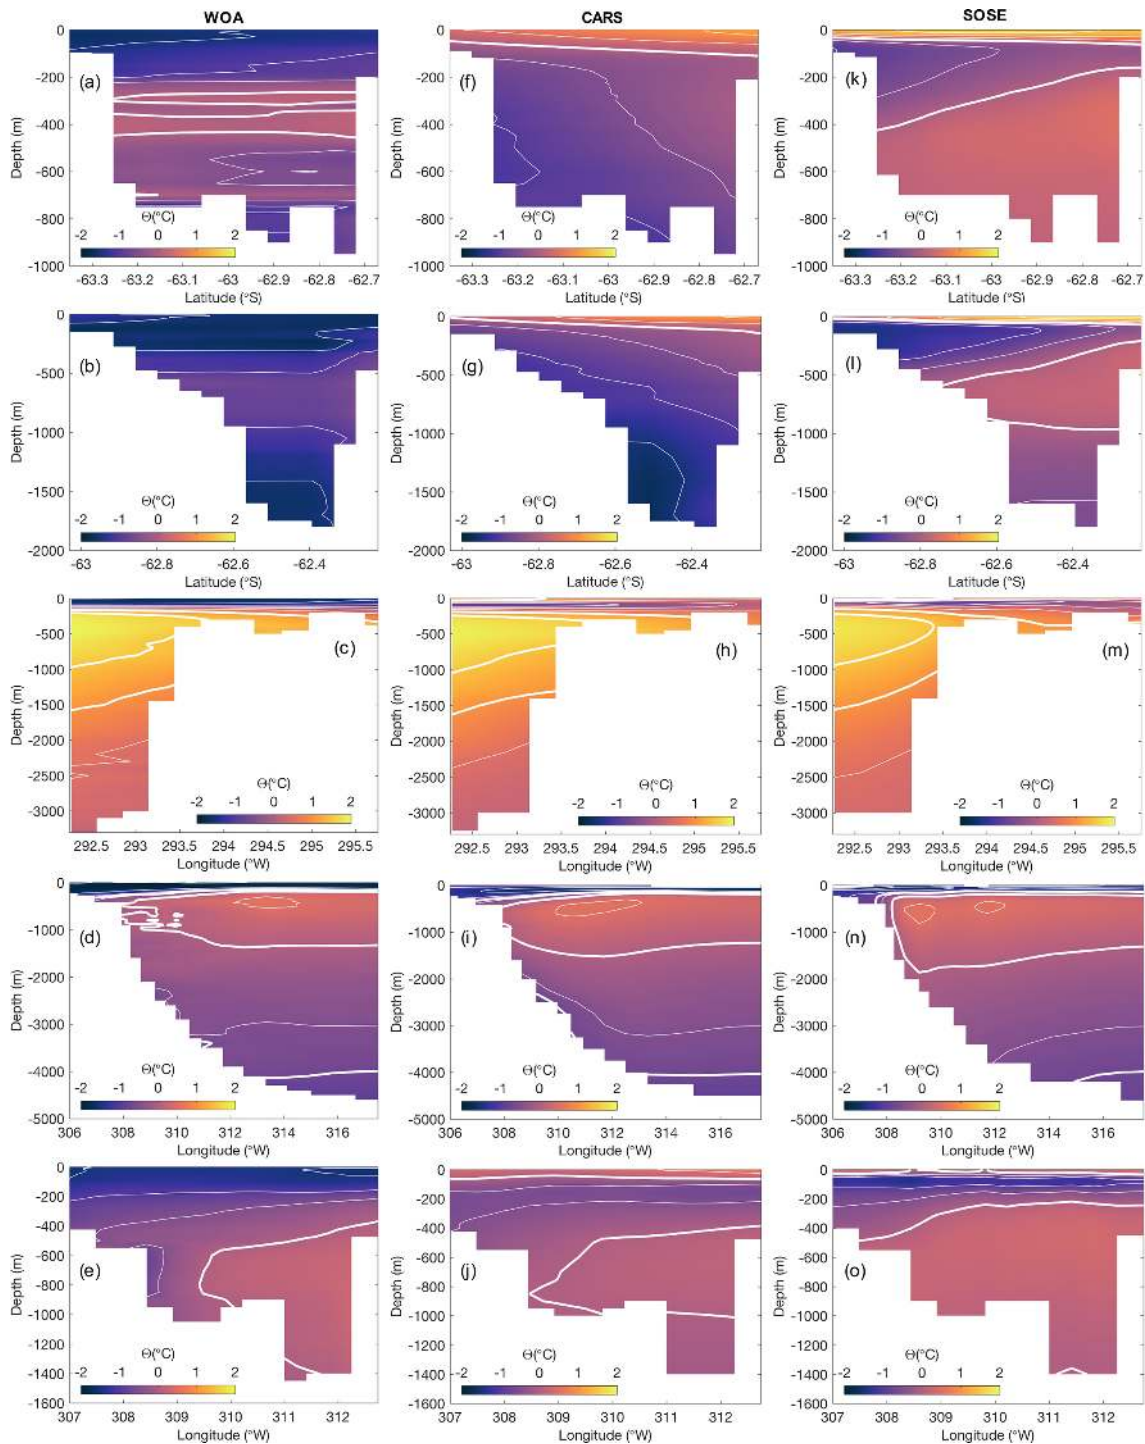

Figure 12. Summer vertical sections of conservative temperature (Θ ; $^{\circ}\text{C}$) for WOA (left panels), CARS (middle panels), and SOSE (right panels). (a, f, k) Sections between Livingston Island and the Antarctic Peninsula. The isotherm of 0°C (-1.5 to 1.5°C every 0.5°C) is shown by the thick (thin) white lines. (b, g, l) Sections between King George Island and the Antarctic Peninsula. The isotherm of 0°C (-1.5 to 1.5°C every 0.5°C) is shown by the thick (thin) white lines. (c, h, m) Section at the WAP. The isotherms of 1 and 1.5°C (-1.5 to 0.5°C every 0.5°C) are shown by the thick (thin) white lines. (d, i, n) Sections WOCE SR4. The isotherms of -0.7 and 0°C (-1.5 to 0.5°C every 0.5°C) are shown by the thick (thin) white lines. (e, j, o) Sections at Scotia Arc. The isotherm of 0°C (-1.5 to -0.5°C every 0.5°C) is shown by the thick (thin) white lines.

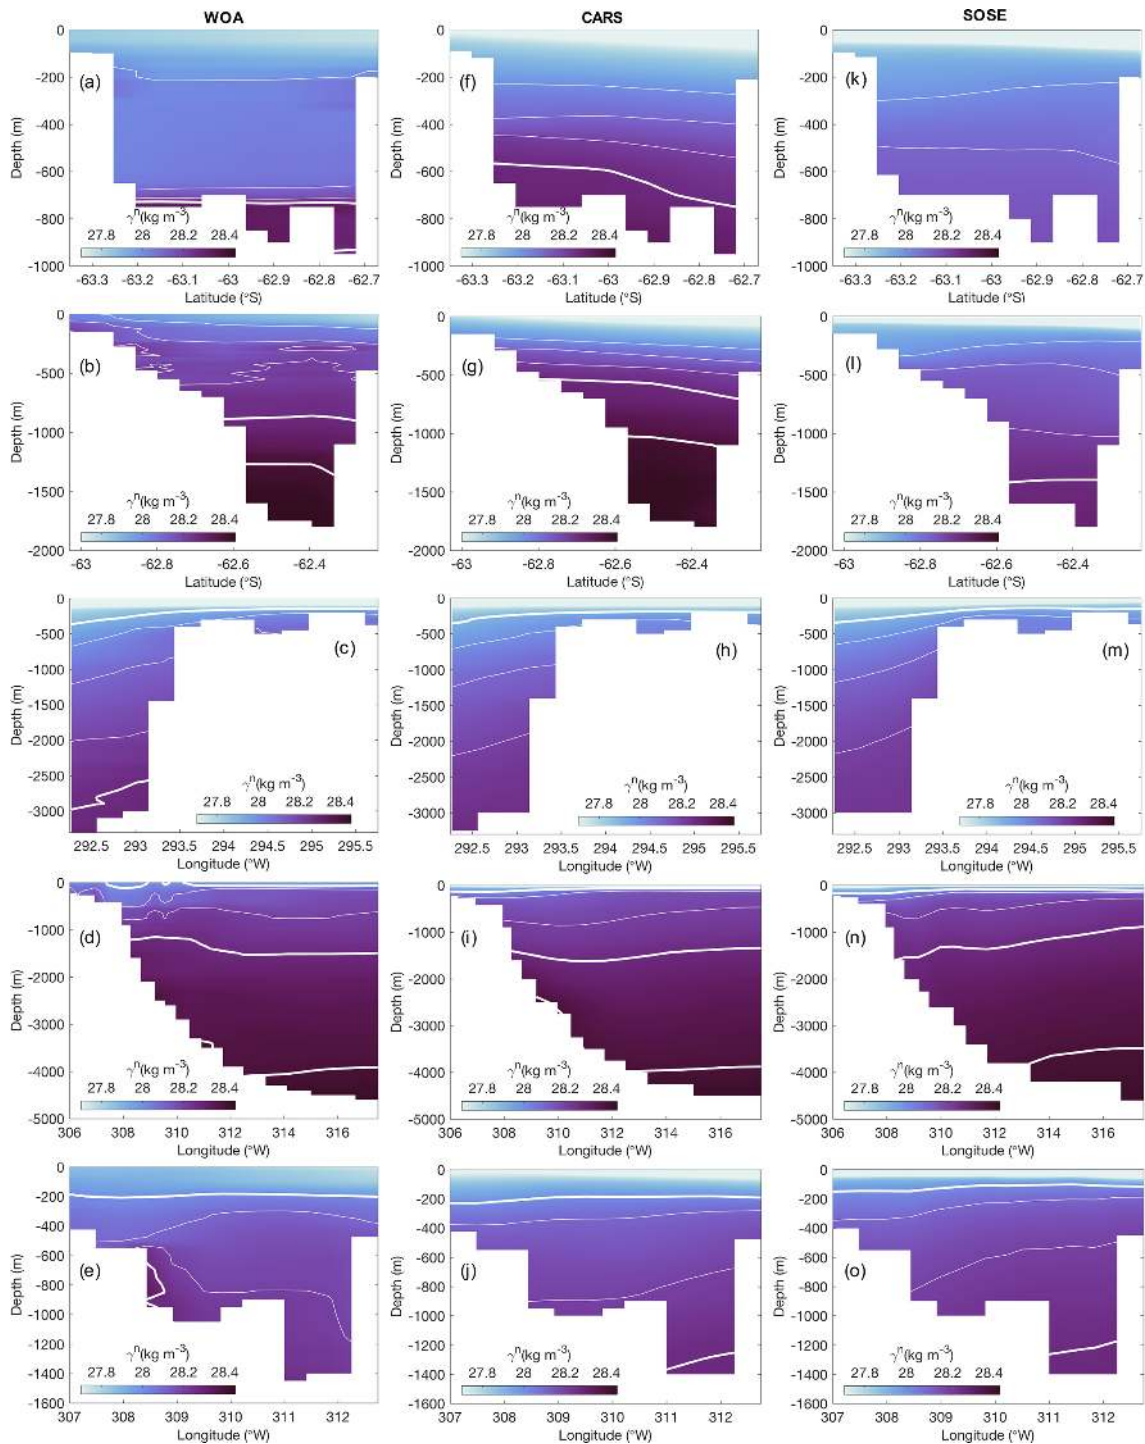

Figure 13. Summer vertical sections of neutral density (γ^n ; kg m^{-3}) for WOA (left panels), CARS (middle panels), and SOSE (right panels). **(a, f, k)** Sections between Livingston Island and the Antarctic Peninsula. The isopycnal of 28.27 kg m^{-3} (28 to 28.2 kg m^{-3} every 0.1 kg m^{-3}) is shown by the thick (thin) white lines. **(b, g, l)** Sections between King George Island and the Antarctic Peninsula. The isopycnals of 28.27 and 28.4 kg m^{-3} (28 to 28.2 kg m^{-3} every 0.1 kg m^{-3}) are shown by the thick (thin) white lines. **(c, h, m)** Section at the WAP. The isopycnals of 27.9 and 28.27 kg m^{-3} (28 to 28.2 kg m^{-3} every 0.1 kg m^{-3}) are shown by the thick (thin) white lines. **(d, i, n)** Sections WOCE SR4. The isopycnals of 28 , 28.27 , and 28.4 kg m^{-3} (28.1 and 28.2 kg m^{-3}) are shown by the thick (thin) white lines. **(e, j, o)** Section Scotia Arc. The isopycnals of 28 and 28.27 kg m^{-3} (28.1 and 28.2 kg m^{-3}) are shown by the thick (thin) white lines.

the NAP, a recognized marine climate hotspot (Kerr et al., 2018a). This climatology will be useful not only to observers and modellers, but also to ecologists and anyone interested in the oceanographic conditions and behaviour of the NAP region.

5 Data availability

The seasonal NAPv1.0 (Dotto et al., 2021) is available at <https://doi.org/10.5281/zenodo.4420006> and <https://www.goal.furg.br/producao-cientifica/supplementos/203-goal-gridded-nap> (last access: 7 January 2021) as a netCDF file. The file contains the three-dimensional gridded variables in situ temperature ($^{\circ}\text{C}$), practical salinity, and dissolved oxygen (mL L^{-1}) as well as their respective relative error matrices. Derived variables, such as absolute salinity, conservative temperature, and neutral density can be calculated by the user. Depth levels (in metres) and the two-dimensional gridded coordinates latitude and longitude are also included in the file. Missing values corresponding to relative errors >0.5 and land mask are marked as *not a number* (NaN).

6 Conclusions

We have presented a novel gridded hydrographic product for the NAP and adjacent regions generated by optimal interpolation using hydrographic data from CTD, Argo, and MEOP between 1990–2019. The gridded product has a spatial resolution of ~ 10 km and 90 standard depths with spacing ranging from 5 m in the upper ocean to 500 m in depths >4000 m. The NAPv1.0 represents quite well many oceanic features of the region such as (i) the inflows of Weddell Sea-sourced waters and the warm regime from the Bellingshausen Sea, (ii) the Peninsula and the Bransfield fronts, (iii) the cyclonic circulation within the Bransfield Strait, (iv) the Bransfield Strait central and eastern basins dichotomy hydrographic regime, (v) the inflow of CDW onto the WAP continental shelf, (vi) the narrow flow of cold and oxygen-rich water along the continental slope of the Weddell Sea inflowing toward the Bransfield Strait, and (vii) the downslope flow of recently ventilated dense bottom waters at the Weddell Sea continental slope. Many of the features described are not well observed in some of the other products evaluated, and depicting the mechanisms behind those differences still poses a challenge to the community. Due to the larger mapping errors, one must use caution when considering areas near the edge of the NAP and as well as areas of limited data coverage. As caveats, the NAPv1.0 is fed exclusively by in situ data and the reduced sampling in deeper levels and seasons other than summer limits the representation of many oceanographic features for autumn, winter, and spring. Nevertheless, the NAPv1.0 is a valuable tool for setting up regional ocean models and ocean reanalysis assessments or to any user who wants to use it to

characterize the mean-state hydrography of the NAP at the end of 20th-century and early 21st-century.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/essd-13-671-2021-supplement>.

Author contributions. All authors designed and conceptualized the study. TSD led the study, data processing, and writing of the manuscript. RK, MMM, and CAEG lead the GOAL projects and contributed substantially to writing the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors thank the officers and crew of the polar vessels *Ary Rongel* and *Almirante Maximiano* of the Brazilian Navy, and the several scientists and technicians participating in the cruises for their valuable help during data sampling and data processing. For their efforts, we also thank all the scientists, technicians, and crew involved in all data acquisition and processing of ship surveys and for making them freely available in international repositories. Argo data were collected and made freely available by the Argo international programme and the national programmes that contribute to it (<http://www.argo.ucsd.edu>, last access: 16 November 2020, <http://argo.jcommops.org>, last access: 16 November 2020). The Argo programme is part of the Global Ocean Observing System. The marine mammal data were collected and made freely available by the International MEOP Consortium and the national programmes that contribute to it (<http://www.meop.net>, last access: 13 November 2020). Finally, we thank Hartmut H. Hellmer and one anonymous reviewer for their contributions to improve the manuscript.

Financial support. This study is part of the activities of the Brazilian High Latitude Oceanography Group (GOAL) within the Brazilian Antarctic Program (PROANTAR). GOAL has been funded by and/or has received logistical support from the Brazilian Ministry of the Environment (MMA); the Brazilian Ministry of Science, Technology, and Innovation (MCTI); the Council for Research and Scientific Development of Brazil (CNPq); the Brazilian Navy; the Inter-ministerial Secretariat for Sea Resources (SECIRM); the National Institute of Science and Technology of the Cryosphere (INCT CRIOSFERA; CNPq grant nos. 573720/2008-8 and 465680/2014-3); and the Research Support Foundation of the State of Rio Grande do Sul (FAPERGS grant No. 17/2551-000518-0). This study was conducted within the activities of the REDE-1, SOS-CLIMATE, POLARCANION, PRO-OASIS, NAUTILUS, INTERBIOTA, PROVOCAR, and ECOPELAGOS projects (CNPq grant nos. 550370/2002-1, 520189/2006-0, 556848/2009-8, 565040/2010-3, 405869/2013-4, 407889/2013-2, 442628/2018-8 and 442637/2018-7, respectively). Financial support was also received from Coordination for the Improvement of Higher Education Personnel (CAPES) through the project CAPES

“Ciências do Mar” (grant no. 23038.001421/2014-30). CAPES also provided free access to many relevant journals through the portal “Periódicos CAPES” and the activities of the Graduate Program in Oceanology. Tiago S. Dotto acknowledges financial support from CNPq PDJ scholarship grant no. 151248/2019-2. Rodrigo Kerr, Mauricio M. Mata, and Carlos A. E. Garcia are granted with researcher fellowships from CNPq grant nos. 304937/2018-5, 306896/2015-0, and 309932/2019-0, respectively.

Review statement. This paper was edited by Giuseppe M. R. Manzella and reviewed by Hartmut Hellmer and one anonymous referee.
