# A permutation procedure for job-shop scheduling

## By T. A. J. Nicholson and R. D. Pullen\*

A new method is proposed for scheduling jobs througn a factory.

In jobs consist or a sequence of operations, each operation requiring a number of resources of different types. The objective is to plan the start times of the operations so as to minimise the cost of jobs being late, subject to the sequence constraints being satisfied and the demand for resources not exceeding the supply, to the sequence constraints being satisfied and the demand for resources not exceeding the supply. The problem is formulated in terms of optimising a permutation, and conditions for a locally optimal permutation are defined. A procedure is described for obtaining such locally optimal permutations and subsequent results show significant improvements over heuristic techniques such as the shortest operation and least slack rules.

(First received July 1967)

#### 1. Introduction

operations should be delayed. In small workshops it may be possible to schedule efficiently without any formal schemes, but in larger concerns the volume and essential to use systematic methods for the control to be forward work load in a factory so as to complete the as possible. Usually the jobs consist of a sequence of operations which have to be performed in turn, and the problem is to determine the start times of the operations The difficulties arise because of the queues of operations which build up on particular resources, and a scheduling method is a means of controlling these queues by deciding which The implementation of a scheduling system Scheduling methods are concerned with progressing the jobs by their due dates and use the resources as efficiently of the workload generally means that will often be supported by a computer program. so as to achieve the chosen objective. effective.

Past research on scheduling problems falls into two categories, and these have been well reviewed (Sisson, 1962; Mellor, 1966). Firstly, there are methods for finding optimum solutions to very simple problems. The three-machine scheduling problem is the classic case. The problems have had to be simplified to keep the formulation mathematically tractable and to apply an optimisation method. The methods include integer-linear programming (Bowman, 1959; Manne, 1960; Wagner, 1959), and branch and bound techniques (Ignall et al., 1965). The weakness of these methods is that they cannot be applied to problems of more than a very few variables, nor do they appear to suggest suitable lines of advance for practical situations.

Secondly, there is a group of heuristic studies which have aimed at finding rules for scheduling efficiently in special practical situations (Bulkin *et al.*, 1966; Gere, 1966; Conway and Maxwell, 1961; Rowe, 1960). The criteria are usually chosen intuitively. Although these methods are usually computationally quick, they provide no indication of how close to the optimum the answers lie. and they tend to be very special purpose.

, and they tend to be very special purpose. This paper describes a scheduling method which tries

\* Mathematics Branch, A.E.R.E., Harwell, Didcot, Berkshire.

to preserve the best features of both categories. A realistic factory model is formulated and a formal optimisation method is devised for the associated scheduling problem. The factory model is based on the central features experienced in many practical workshops, and the objective commonly occurs in practice.

### The factory model and notation

The model has the following structure of jobs, operations, and resources.

#### (i) The jobs

There is a known forward load of work consisting of a number of separate jobs which require processing on the available resources. Each job has a given arrival time in the factory and a due time by which the job must be completed, to avoid incurring penalty costs. Jobs are also given a value and a priority relative to other jobs. The cost of a job being late depends on the value of the job, its priority, and the extent to which it is late.

#### (ii) The operations

Each job consists of a number of separate operations which must be performed in a specified sequence. The sequence may vary with different jobs. The durations of all the operations are known in advance, and are independent of one another. Each operation requires a constant number of resources from a specified variety of resource types while it is being processed. Once an operation has been started it cannot be interrupted by any other operation.

#### ii) The resources

The resources are classified into homogeneous types, and the supply levels of the various types are known and may vary over time.

#### (iv) The objective

The objective is to plan the start times of the operations so as to minimise the cost attributable to jobs exceeding their due dates.

Some common practical features of workshops such as transit and set-up times or limitations on in-process

stocks are not explicitly included in the model, but it is often possible to reinterpret these aspects within the above framework.

The following notation is used in the formulation of the problem:

N is the number of jobs

M is the number of resource types

A(j) is the arrival time of job j

T(j) is the due time of job j

v(j) is the value of job j

u(j) is the priority of job j

n(j) is the number of operations of job j

d(j, k) is the duration of the kth operation of job j

r(j, k, m) is the number of resources of type m required by operation k of job j at every time interval in which the operation is being performed

x(j,k) is the scheduled start time of the kth s(l, m) is the supply of resource type m at time l

operation of job j.

All quantities are assumed to be positive integers or zero.

### 3. The formal optimisation problem

the individual operations. We will denote by the vector  $\{X\}$  an assignment of values to the problem variables. All other quantities are given data for the particular The problem variables are the start times x(j,k) of problem.

The objective function is defined in terms of the cost of jobs being late. A job is late if it is completed after its due time, and we assume that the cost steadily increases the later the job is completed. We therefore define by g(j, t(j)) the cost of job j being completed at time t(j), and the function g will have the properties:

$$g(j, t(j)) = 0$$
 for  $t(j) \leqslant T(j)$  (1)

$$\frac{\partial g}{\partial t(j)} \geqslant 0. \tag{2}$$

the job, and in particular we will study the objective function for which the cost is the product of the job's Also the cost may depend on the value and priority of value and its lateness taken to the power of its priority. Therefore

$$g(j,t(j)) = v(j)$$
. Max  $(x(j,n(j))$   
  $+ d(j,n(j)) - T(j), 0)^{u(j)}$ . (3)

The objective function then becomes:

$$F\{X\} = \sum_{j=1}^{N} g(j, x(j, n(j)) + d(j, n(j))). \tag{4}$$

The constraints on the values of x(j, k) are expressed as follows. Firstly, a job cannot start before it arrives in the factory. Therefore we require

$$x(j,1) \geqslant A(j).$$
 (5)

Secondly, the operations must be processed in the correct sequence, i.e.

Job-shop scheduling

$$x(j,k) \ge x(j,k-1) + d(j,k-1)$$
 for  $k = 2, n(j)$ . (6)

Thirdly the demand for resources must not exceed the supply at any time. Therefore

$$\sum_{j=1}^{N} \sum_{k=1}^{n(j)} \delta(j,k,l) . r(j,k,m) \leqslant s(l,m)$$
 for all  $l$  and  $1 \leqslant m \leqslant M$ 

0

where

$$\delta(j, k, l) = 1$$
 for  $x(j, k) \le l < x(j, k) + d(j, k)$ 

= 0 otherwise.

Therefore the optimisation problem is to determine the values x(j, k) so as to minimise the objective function

methods to this scheduling problem. A total search of the feasible schedules would be a massive undertaking the problem could be translated into the framework of integer-linear programming the computational task would still be impossibly large. (4) subject to the constraints (5), (6) and (7). It is not possible to apply standard optimisation Branch and bound methods would be equally impractical (Ignall et al., 1965). Also, although in certain circumstances (Giffler et al., 1960; Heller et al., 1960).

into a permutation problem in which a number of items have to be arranged in a sequence of positions. A definite level of optimality is set for the permutation solution and a method is described for constructing such In the following sections we propose a new technique for tackling this problem, which is an extension of a method which has been used successfully on a number of smaller problems of a similar type (Nicholson, 1967). The basic scheme is to convert the optimisation problem a permutation.

## 4. The scheduling problem as a permutation problem

number pair (j(i), k(i)) denote the operation in position i of the list, being the k(i)th operation of job j(i). Then the total set of operations can be represented by a The scheduling problem is translated into a permutation problem in the following way. First, the total set of operations is arranged as an order list. permutation [P] where

$$[P] = [(j(1), k(1)), (j(2), k(2)), (j(T), k(T))]$$
 (9)

where  $T = \sum_{j=1}^{n} n(j)$ .

Secondly we need a means of transforming the set of operation start times e therefore construct the following Determine x(j(i), k(i)) for i = 1 to Tpermutation [P] into a set x(i(i), k(i)). We therefore transformation. in that order as

$$x(j(i), k(i)) = Z(j(i), k(i))$$
 (10)

where Z(j(i), k(i)) is the smallest integer which satisfies

$$Z(j(k), 1) \geqslant A(j(i)) \tag{11}$$

$$Z(j(i), k(i)) \geqslant X(j(i), k(i) - 1) + d(j(i), k(i) - 1)$$
  
for  $k(i) = 2, n(j(i))$  (12)

(12)

$$\sum_{L=1}^{i} \delta(j(L), k(L), l) . r(j(L), k(L), m)$$

$$\leq s(l, m)$$
 for all  $m$ ,  
for  $x(j(i), k(i)) \leq l < x(j(i), k(i)) + d(j(i), k(i))$ .

(13)

and (13) may be denoted by  $\alpha$  so that the relationship may The transformation represented by (10), (11), (12) be written concisely as

$$\{X\} = \alpha[P] \tag{14}$$

where  $\{X\}$  denotes the vector of values x(j(i), k(i)) for

order that this transformation will provide a A feasible permutation is feasible schedule we need to impose a feasibility condefined as any permutation [P] such that l > i, dition on the permutation.

$$k(i) < k(l)$$
 if  $j(i) = j(l)$ . (15)

It should be noted that this is the only constraint on the permutation. All the other conditions for feasibility have been automatically built into the transformation a.

optimisation problem is equivalent to the optimum of the corresponding permutation problem with the given transformation  $\alpha$ . The proof of this equivalence is It remains to show that the optimum to the original established in an Appendix.

## 5. Neighbouring exchange optimal permutations

amongst the T! possible permutations. But as in practice T may be of the order of  $10^2$  or  $10^3$ , it is impossible to conduct a total evaluation of all possibilities. We will therefore define characteristics of permutations which are locally optimal, and in particular we will define permutations which are optimal with to the exchange of any two neighbouring Formally there exists one or more optimal schedules operations. respect

two neighbours a predecessor and a successor neighbour. Given any operation  $(j(i_1), k(i_1))$ , in position  $i_1$ , the operation  $(j(i_2), k(i_2))$  is a predecessor neighbour if it is the operation nearest in the permutation which uses some of the same resources as operation  $(j(i_1)k(i_1))$ . Therefore  $(j(i_2), k(i_2))$  is a predecessor neighbour of Firstly we define the neighbours of an operation in a Any operation in the permutation has  $(j(i_1), k(i_1))$  if  $i_2 < i_1$ , permutation.

$$\sum_{m=1}^{M} r(j(i_1), k(i_1), m).r(j(i_2), k(i_2), m) > 0$$
 (16)

and 
$$\sum_{m=1}^{M} r(j(i_1), k(i_1), m) \cdot r(j(l), k(l), m) = 0$$
 (17) for  $i_2 < l < i_1$ .

successor neighbour if,  $i_2 > i_1$ , condition (16) holds, and condition (17) holds for  $i_1 < l < i_2$ .

We can now define the neighbouring exchange of an operation. Let  $l(i_1)$  be the second operation. define the operation  $(j(i_2), k(i_2))$ 

and let we define a neighbouring exchange of operation (j(i),k(i)) by exchanging the permutation [P] into the permutation operation. Let (j(i), k(i)) be any operation a (j(i), k(i)) be a neighbour of operation (j(i), k(i)). [P(i, l)] where

$$[P(i, l)] = [(j(1), k(1)), (j(2), k(2)), \ldots,$$

$$(j(l-1), k(l-1)), (j(i), k(i)), (j(l), k(l)), \ldots,$$

$$(j(i-1), k(i-1)), (j(i+1), k(i+1)), \ldots,$$

$$(j(T), k(T))$$
] if  $l < i$  (18)

ö

$$[P(i, l)] = [(j(1)), k(1)), (j(2), k(2)), \ldots,$$

$$(j(i-1), k(i-1)), (j(i+1), k(i+1)), \ldots,$$

$$(j(l), k(l)), (j(i), k(i)), (j(l+1), k(l+1)) \dots,$$

$$(j(T), k(T))$$
] if  $l > i$ . (19)

P. should be noted that the permutation [P(i, I)] feasible only if

$$j(L) \neq j(i)$$
 for  $L = l, i$ , if  $l < i$   
for  $L = i, l$ , if  $l > i$ .  $\}$  (20)

Therefore we define the exchange [P] to [P(i, l)] to be feasible if condition (20) holds.

Downloaded from https://academic.oup.com/comjnl/article/11/1/48/424352 by guest on 21 August 2022

Finally we define a permutation which is optimal with The permutation [P] is optimal with respect to all neighbouring exchanges if for any operation in position i and either of its neighbours in position I the condition respect to neighbouring exchanges.

$$F[P] \leqslant F[P(i,l)] \tag{21}$$

holds for all i and l, the permutation [P(i,l)] being feasible, and F[P] being the objective function value associated with the permutation [P].

(21)In the following sections we describe a method for Section 8 describes the construction of an initial permutation and Section 9 describes how to modify this Section 10 describes a fast method for modifying the initial constructing permutations to satisfy condition so that the final permutation permutation to the required level of optimality. satisfies condition (21). permutation

## 6. The construction of an initial permutation

be modified until it was optimal with respect to neighbouring exchanges. But it is important to aim for an initial permutation which is as near optimal as possible so that the number of subsequent exchanges is as small We now describe how to construct an initial feasible Clearly any feasible permutation would suffice as an initial permutation, as it could subsequently permutation.

as possible. Equally, the calculation of the initial permutation should not be too expensive in computing time. We therefore propose the following procedure. The permutation is built up one operation at a time, the tth operation to be selected being placed in position t. We restrict the choice of operations which can be selected at the tth iteration so as to ensure feasibility and reduce computation. Also we estimate statistically the increase in the objective function value which will result from the selection of an operation, and choose that operation for which the estimated increase in the objective function value is a minimum.

This procedure may be formalised as follows. Let  $J_t$  denote the set of operations available for selection for the tth position in the permutation. Also let  $f_t(j,k,t)$  denote the estimated increase in the objective function value which would result from selecting operation (j,k) for position t. Then if  $(j,k_t)$  denotes the selected operation,  $(j,k_t)$  is determined for t=1 to T by the equation:

$$f_t(j_t, k_t, t) = \min_{(j,k) \in I_t} f_t(j, k, t).$$
 (22)

The set of operations  $J_t$  consists of a restricted group of the next operations of all jobs which are not completed. An operation is included in  $J_t$  only if its earliest possible start time is not greater than the latest finish time of the operations which have already been scheduled. Furthermore the operation selected by equation (22) is scheduled only on condition that no other operation in the  $J_t$  set can be completed before the selected operation in will be started. If this is possible then the  $J_t$  set is revised to include only those operations which can be completed before the selected operation such this way the  $J_t$  set is determined in an iterative manner. This scheme for determining  $J_t$  with relatively few operations which can be started in the neighbourhood of the scheduled operations is aimed at reducing computation and encouraging high resource utilisation.

It remains to determine a suitable expression for  $f_i(j, k, t)$ . The function  $f_i(j, k, t)$  measures the increase in the value of the objective function which would result from selecting operation (j, k) for position t. Clearly this increase can only be estimated, as the permutation is incomplete, and we will derive a convenient formula for this estimate.

Firstly it is necessary to estimate the completion time of job j after t-1 operations have been scheduled. Denote this estimate by  $T_{t-1}(j)$ , and let  $n_{t-1}(j)$  and  $Z(j, n_{t-1}(j))$  be the number of the next operation of job j and the earliest time at which it could be started. The value of  $T_{t-1}(j)$  is based on the earliest possible start time of the next operation of job j, together with the processing time of the remaining operations and the delays which these operations expect to experience. Let  $\mu_t$  denote the expected delay on an operation after t operations have been scheduled. Then  $T_{t-1}(j)$  may be estimated as

$$T_{t-1}(j) = Z(j, n_{t-1}(j)) + \sum_{k=n_{t-1}(j)}^{n(j)} (\mu_t + d(j, k))$$
 (23)

where  $\mu_i$  is calculated adaptively as:

$$t = \frac{t-1}{t} \mu_{t-1} + \frac{1}{t} \left( x(j_t, n_{t-1}(j_t)) - x(j_t, n_{t-1}(j_t) - 1) - d(j_t, n_{t-1}(j_t) - 1) \right).$$
(24)

We can now estimate the increase in the objective function value which would result from selecting operation (j,k) at selection t. The significance of selecting operation (j,k) is that it may delay the progress of other jobs. We can estimate the rate of increase in the value of the objective function if job i is delayed beyond its currently estimated completion time  $f : \lambda_{o} = 1$ 

$$T_{t-1}(i)$$
 as  $\begin{bmatrix} \frac{\partial g}{\partial t(j)} \end{bmatrix}_{t(j)=T_{t-1}(j)}$  where the function  $g$  is defined by expression (3). Since the jobs which are likely to be delayed directly by selecting the next operation of job  $j$  will all have their next operations included in the  $J_i$  set, the total rate increase in the value of the objective function due to selecting operation  $(j, n_{t-1}(j))$  is estimated as

$$\sum_{\substack{(i,n_{l-1}(t))\in J_t\\i\neq j}} \left[\frac{\partial g}{\partial t(i)}\right]_{t(i)} = T_{l-1}(i)}.$$
 (25)

We will use this rate of increase as a measure of the increase in the value of the objective function.

This formula for  $f_i(j, n_{t-1}(j), t)$  may be simplified. The operation on  $f_i(j, k, t)$  in equation (22) is a minimisation, and a minimisation is unaffected by subtracting a constant from all members of the set to be minimised. Since  $\sum_{(i,n_{t-1}(i))\in I_t} \left[\frac{\partial g}{\partial t(j)}\right]_{t(j)=T_{t-1}(j)}$  is a constant independent of  $(j, n_{t-1}(i))$ , it can be subtracted from expression (25) to obtain the estimate of  $f_i(j, n_{t-1}(j), t)$  as

$$f_i(j, n_{t-1}(j), t) = -\left[\frac{\partial g}{\partial t(j)}\right]_{t(j)} = \tau_{t-1(j)}.$$
 (26)

For the particular objective function of expression (3) and (4) we will obtain the value of  $f_i(j, n_{i-1}(j), t)$  as

$$f_t(j, n_{t-1}(j), t) = -\nu(j)u(j) \max (T_{t-1}(j)) - T(j), 0)^{u(j)-1}.$$
 (27)

If all the operations in the set  $J_t$  are such that  $T_{t-1}(j) < T(j)$ , then the function  $f(j, n_{t-1}(j), t)$  will be zero, and the selection procedure of (22) will be indeterminate. This corresponds to a factory situation in which there is more than adequate time to complete the jobs by their due times and it does not matter which operation is selected next. When this situation arises, the convention will be adopted of choosing the next operation as the operation which is nearest to becoming late, i.e. the operation for which  $(T(j) - T_{t-1}(j))$  is a minimum. This completes the definition of the function f(j,k,t).

When all the operations have been included in the permutation, the initial permutation is complete.

### 7. Obtaining a locally optimal permutation

To do this we make a series of neighbouring exchanges at We now need to modify the initial permutation so as to obtain a permutation which is optimal with respect to neighbouring exchanges as defined in Section 6. To each iteration reducing the value of the objective function.

We select the job which currently contributes most to the objective function and which has not been selected since the last iteration on which the objective function was reduced. If at the tth iteration this job is denoted by j, and the set of job numbers which have been selected since the last iteration on which the objective We determine the sequence of exchanges as follows. function was reduced is  $U_{t-1}$ , then  $j_t$  is determined by the equation

$$g(j_t, T_{t-1}(j_t)) = \max_{\substack{1 \leqslant n \leqslant N \\ j \in I_{t-1}}} g(j, T_{t-1}(j))$$
 (28)

where  $T_{t-1}(j)$  is the completion time of job j with the current permutation.

the operations of job  $j_t$  starting with the last operation and proceeding to the first operation and repeating the cycle until a full cycle has been made with no improvement in the objective function. If this occurs on the first cycle then the set  $U_t$  contains the elements of  $U_{t-1}$ We now make a series of neighbouring exchanges with and the number  $j_i$ . Otherwise the set  $U_i$  contains only

to N then a permutation has been obtained which is the job number  $j_r$ . When the set  $U_t$  contains all the job numbers j=0optimal with respect to neighbouring exchanges.

### 8. Nearly optimal permutations

The procedure described in the previous section for bouring-optimal permutation may be too costly in computing time. In this case we can significantly reduce the amount of computation by considering a job only once for trial exchanges of its operations. The promodifying the initial permutation to obtain a neighcedure is identical to that described in Section 7 except that the set  $U_i$  is always set to the elements of  $U_{i-1}$  and the job number  $j_i$ . This will mean that we lose any guarantee that an optimal permutation will be obtained, but as the results will show, good answers may be obtained which may be satisfactory for practical purposes. once for trial exchanges of its operations.

#### 9. Results

The permutation method was programmed in FORTRAN for the IBM 7030 computer, and it was tested against some well known scheduling rules which have been used for machine loading problems and resource allocation associated with critical path planning procedures. The rules are:

- First-come-first-served.
- (ii) The shortest operation discipline.

- operation is determined dynamically as the difference between the latest time at which the The slack associated with the job being late, and the earliest time in view of the operations The operation with the least operation may be started, to avoid The least slack rule. already scheduled. slack is chosen. In **Table 5** we study the objective of minimising average job lateness by setting all job values and priorities to unity. In **Table 6** we study an objective in which heavy penalties are placed on jobs being late by setting the job priorities to 4. This table records maximum job lateness in the 5 cases.

In **Table 7** we record the computing time on the IBM 7030 required by the various techniques.

#### 10. Conclusions

From the above tables of results we can draw some clear conclusions about the permutation procedure both as regards the quality of optimisation obtained and the computation involved.

nearly Part of the weakness of the their failure to bring predecessor operations forward in thus be finished earlier. The neighbouring exchanges achieve this adjustment, and as a by-product this will Firstly the permutation procedure offers significant improvement over the heuristic scheduling methods with This is true for both the by the permutation procedures are consistently good whereas the best heuristic technique varies from case to case. Gere (1966) also found the same inconsistency in the time close to the final operation of the job, thereby freeing resources for other final operations which may one-pass heuristic scheduling methods seems to lie the reached and lead to reductions in work-in-progress. the results neighbouring optimal permutations which it has been compared. heuristic rules he studied. Furthermore optimal.

Table 7

Computing times in seconds

#### 

But with an adjusted formulation the same type of independent of particular mathematical forms for the objective functions and constraints, and it is therefore of Secondly the permutation procedure is very flexible be used for a wide range of scheduling Tables 5 and 6 have shown how the proof minimising procedure could be applied either to other objectives such as maximising resource utilisation or to different set-ups are The scope of a permutation procedure is average job lateness or minimising maximum lateness. for example where deal with the objectives problem structures, cedure can important. could problems.

wide application.

Thirdly, the computational time required to obtain a neighbouring optimal permutation is quite small for

small problems but rapidly increases. However, the nearly optimal method offers answers which are nearly as good for a significant reduction in computing time. Also, the initial permutation as derived for this particular problem offers consistently better results than the heuristic methods for a very small increase in computing time. For larger problems the best policy may be to partition the schedule into segments and apply the neighbouring exchange procedure to each segment in

turn, or else to terminate the exchanges automatically when a given amount of computing time has been expended.

The permutation procedure therefore promises considerable returns over some of the established job-shop scheduling techniques. The method is being used as the basis for some scheduling studies currently being undertaken in the rubber industry in co-operation with the Rubber and Plastics Research Association.

#### Appendix

In this appendix we establish the result which was assumed in Section 6, namely that the original optimisation problem formulated in Section 5 can be solved optimally as a permutation problem using the transformation proposed in Section 6. The same notation will be used. We establish the result by proving two theorems and a lemma.

#### heorem 1

Given any optimal feasible solution  $\{X'\}$ , and any positive integer q, there exists another solution  $\{X^*\}$  satisfying the following three conditions:

$$\{X^*\}$$
 is feasible (A1)

$$\{x^*(1, 1), x^*(1, 2), \ldots, x^*(j, k) - q, \ldots, x^*(N, n(N))\}\$$

is not feasible for any individual pair (j, k) (A2)

and 
$$F\{X^*\}$$
 is a minimum. (A3)

Proof

We assume that an optimal feasible solution exists and denote it by  $\{X'\}$ . We now note that inequalities (5) and (6) impose a lower bound on the x(j,k) variables. Therefore if each of the variables x(j,k) is taken in turn, as many times as necessary, their values may be reduced by unit steps from x'(j,k) to new values  $x^*(j,k)$ , maintaining feasibility throughout so that the set  $\{X^*\}$  satisfies conditions (A1) and (A2).

Also, as the functions g(j,t(j)) satisfy conditions (1) and (2), and  $x^*(j,n(j)) \leqslant x'(j,n(j))$ ,  $F\{X^*\} \leqslant F\{X'\}$ . But as  $\{X'\}$  is an optimal solution,  $\{X^*\}$  is also an optimal solution satisfying condition (A3). This proves Theorem 1.

#### етта

Referring to condition (A2), we now establish that the loss of feasibility resulting from reducing the variable  $x^*(j',k')$  to  $x^*(j',k')-q$  in the solution  $\{X^*\}$  is independent of the values of the variables x(j,k) for which

$$x^*(j,k) \geqslant x^*(j',k').$$
 (A4)

Proof

When the value of x(j, k) is reduced below  $x^*(j, k)$ , feasibility is lost through violating one or more of the

constraints (5), (6) or (7). Firstly, suppose k' = 1 and constraint (5) is violated. Since A(j) is a constant this violation is independent of the values of variables x(j,k) satisfying (A4). Secondly, suppose k' > 1, and constraint (6) is violated. This violation depends on the value of x(j', k' - 1). But since  $\{X^*\}$  is a feasible solution  $x^*(j', k' - 1) < x^*(j', k')$ , and again this violation is independent of the values of variables satisfying

Thirdly, suppose constraint (7) is violated by reducing x(j',k') to the value  $x^*(j',k')-q$ . This implies that the inequality

$$\sum_{\substack{j=1\\j \in A}}^{N} \sum_{k=1}^{n(j)} \delta(j,k,l) \cdot r(j,k,m) + r(j',k',m) > S(l,m)$$

$$G(k) \neq G'(k)$$
(A5)

holds for at least one value of l in the interval

$$x^*(j',k') - q \leqslant l < x^*(j',k') + d(j',k') - q.$$

But since  $\{X^*\}$  is feasible we have

$$\sum_{j=1}^{N} \sum_{k=1}^{n(j)} \delta(j,k,l) \cdot r(j,k,m) + r(j',k',m) \leqslant s(l,m)$$

$$\zeta(k,k) \neq (j',k)$$

in the interval  $x^*(j',k') \leqslant l < x^*(j',k') + d(j',k')$ . Therefore the inequality (A5) holds only for values of  $l < x^*(j',k)$ . But for any value of  $l < x^*(j',k')$ ,  $\delta(j,k,l) = 0$ , for all variables x(j,k) whose values are greater than  $x^*(j',k')$ . Therefore the violation of the constraint (7) is independent of the values of the variables satisfying (A4). This establishes the Lemma.

#### Theorem 2

Given the optimum solution  $\{X^*\}$  defined by (A1), (A2) and (A3), there exists a permutation  $[P^*]$  such that

$$\{X^*\} = \alpha [P^*].$$
 (A6)

Proof

First we construct the following permutation  $[P^*]$ . Given the solution  $\{X^*\}$  we can determine an ordering of the number pairs (j,k) as (j(i),k(i)) for i=1,T, such that

$$x^*(j(i), k(i)) < x^*(j(i+1), k(i+1)).$$

We can thus use these ordered number pairs to define the permutation  $[P^*]$  as

$$[P^*] = [(j(1), k(1)), (j(2), k(2)), \dots (j(T), k(T))].$$

of (10) to (13) when applied to the permutation  $[P^*]$  generates the solution  $\{X^*\}$ . We prove this by induction. Suppose we have generated the first (l-1) values by the transformation  $\alpha$  as  $x^*(j(i), k(i))$  for i=1, l-1. The transformation now determines the value of We know by condition (A1) that the value  $x^*(j(l), k(l)) - q$  is not Also by the lemma Secondly we need to show that the transformation x(j(l), k(l)) as the first feasible value. feasible for any positive integer q.

these results are independent of the value of variables Therefore the value of x(j(l),k(l))x(j(i), k(i)) for i > l.

But as  $\{X^*\}$  is feasible, k(1) = 1 and by condition Also the transformation (A2),  $x^*(j(1), k(1)) = A(j(1))$ . Also the transformation  $\alpha$  will determine the value of x(j(1), k(1)) as  $x^*(j(1), k(1))$ . will be determined as  $x^*(j(l), k(l))$ .

(A2), 
$$x^*(j(1), k(1)) = A(j(1))$$
. Also that will determine the value of  $x(j(1), k(1))$ . Hence by induction

$$\{X^*\} = \alpha[P^*]$$

and theorem 2 is proved.

We have therefore shown that the optimum to the permutation problem is also the optimum to the original optimisation problem expressed in the variables x(j, k).
