Abstract

Bounding privacy leakage over compositions, i.e., privacy accounting, is a key challenge in differential privacy (DP). However, the privacy parameter (ϵ or δ) is often easy to estimate but hard to bound. In this paper, we propose a new differential privacy paradigm called estimate-verify-release (EVR), which addresses the challenges of providing a strict upper bound for privacy parameter in DP compositions by converting an *estimate* of privacy parameter into a formal guarantee. The EVR paradigm first estimates the privacy parameter of a mechanism, then verifies whether it meets this guarantee, and finally releases the query output based on the verification result. The core component of the EVR is privacy verification. We develop a randomized privacy verifier using Monte Carlo (MC) technique. Furthermore, we propose an MC-based DP accountant that outperforms existing DP accounting techniques in terms of accuracy and efficiency. Our empirical evaluation shows the newly proposed EVR paradigm improves the utility-privacy tradeoff for privacy-preserving machine learning.

1 Introduction

The concern for privacy is a major obstacle to deploying machine learning (ML) applications. In response, ML algorithms with differential privacy (DP) guarantees have been proposed and developed. For privacy-preserving ML algorithms, DP mechanisms are often repeatedly applied to private training data. For instance, when training deep learning models using DP-SGD (Abadi et al., 2016), it is often necessary to execute Subsampled Gaussian mechanisms on the private training data thousands of times.

A main challenge in machine learning with differential privacy is *privacy accounting*, i.e., measuring the privacy loss of the composition of DP mechanisms. A privacy accountant takes a list of mechanisms, and returns the privacy parameter (ϵ and δ) for the composition of those mechanisms. Usually, a privacy accountant is given a target ϵ and finds the *smallest achievable* δ such that the composed mechanism \mathcal{M} is (ϵ, δ) -DP. We use $\delta_{\mathcal{M}}(\epsilon)$ to denote the smallest achievable δ given ϵ , which is often referred to as the *optimal privacy curve* in the literature.

Training deep learning models with DP-SGD is essentially the *adaptive composition* for thousands of Subsampled Gaussian Mechanisms. Moment Accountant (MA) is a pioneer solution for privacy loss calculation in differentially private deep learning (Abadi et al., 2016). However, MA does not provide the optimal $\delta_{\mathcal{M}}(\epsilon)$ in general (Zhu et al., 2022). This motivates the development of more advanced privacy accounting techniques that outperforms MA. Two major lines of such works are based on Fast Fourier Transform (FFT) (e.g., (Gopi et al., 2021) and Central Limit Theorem (CLT) (Bu et al., 2020; Wang et al., 2022a). Both techniques can provide an *estimate* as well as an upper

bound for $\delta_{\mathcal{M}}(\varepsilon)$ though bounding the worst-case estimation error. In practice, **only the upper bounds for $\delta_{\mathcal{M}}(\varepsilon)$ can be used**, as differential privacy is a strict guarantee.

Motivation: estimates can be more accurate than upper bounds.

The motivation for this paper stems from the limitations of current privacy accounting techniques in providing upper bounds for $\delta_{\mathcal{M}}(\varepsilon)$. Despite outperforming MA, both FFT- and CLT-based methods can provide ineffective bounds in certain regimes. We demonstrate such limitations in Figure 1 using the composition of Gaussian mechanisms. For FFT-based technique (Gopi et al., 2021), we can see that although it outperforms MA for most of the regimes, the upper bounds (blue dashed curve) are worse than that of MA when $\delta < 10^{-10}$ due to computational limitations (see Gopi et al. (2021)’s Appendix A for detail).¹ The CLT-based techniques (e.g., (Wang et al., 2022a)) also produce sub-optimal upper bounds (red dashed curve) for the entire range of δ . This is primarily due to the small number of mechanisms used ($k = 1200$), which does not meet the requirements for CLT bounds to converge (similar phenomenon observed in Wang et al. (2022a)). On the other hand, we can see that the *estimates* of $\delta_{\mathcal{M}}(\varepsilon)$ from both FFT and CLT-based techniques, which estimate the parameters rather than providing an upper bound, are in fact very close to the ground truth (the three curves overlapped in Figure 1). However, as we mentioned earlier, these accurate estimations cannot be used in practice, as we cannot prove that they do not underestimate $\delta_{\mathcal{M}}(\varepsilon)$. The dilemma raises an important question: *can we develop new techniques that allow us to use privacy parameter estimates instead of strict upper bounds in privacy accounting?*

This paper gives a positive answer to it. Our contributions are summarized as follows.

Estimate-Verify-Release (EVR): a DP paradigm that converts privacy parameter estimate into a formal guarantee. We develop a new DP paradigm called *Estimate-Verify-Release* which augments a mechanism with a formal privacy guarantee based on its privacy parameter estimates. The basic idea of EVR is to verify whether the mechanism satisfies the estimated DP guarantee, and release the mechanism’s output based on the verification result. The core component of the EVR paradigm is **privacy verification**. A DP verifier can be randomized and imperfect, suffering from both false positives (accept an underestimation) and false negatives (reject an overestimation). We show that EVR’s privacy guarantee can be achieved when privacy verification has a low false negative rate.

A Monte Carlo-based DP Verifier. We then develop a privacy verification approach for the EVR paradigm based on Monte Carlo (MC) technique. We further improve this paradigm by constructing an advanced verifier using Importance Sampling, which significantly reduces the sample complexity required to achieve a low false positive rate (hence making EVR more efficient). Additionally, we

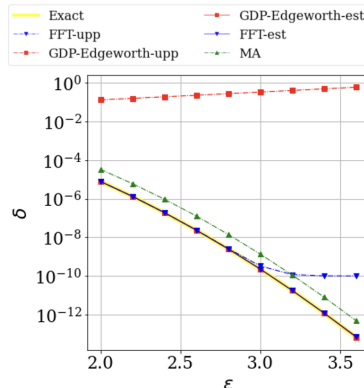

Figure 1: Results of estimating/bounding $\delta_{\mathcal{M}}(\varepsilon)$ for the composition of 1200 Gaussian mechanisms with $\sigma = 70$. ‘-upp’ means upper bound and ‘-est’ means estimate. Curves of ‘Exact’, ‘FFT-est’, and ‘CLT-est’ are overlapped.

¹One may wonder whether we care about the regime where $\delta < 10^{-10}$. Here, we give two reasons why it is important to develop privacy accounting techniques that can work with such tiny δ : (1) δ is interpreted as an upper bound on the probability of catastrophic failure (e.g., the entire dataset being published) and needs to be “cryptographically small”, i.e., $\delta < n^{-\omega(1)}$ (Dwork et al., 2014; Vadhan, 2017). (2) Even if we follow the common (but questionable) rule of thumb of $\delta < n^{-1}$ or $n^{-1.1}$, the dataset size n is already at billion level for modern datasets, e.g., JFT-3B (Zhai et al., 2022) or LAION-5B (Schuhmann et al., 2022).

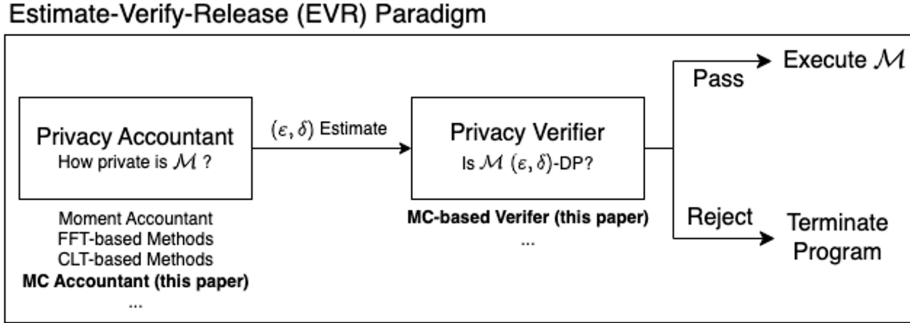

Figure 2: An overview of our EVR paradigm. EVR achieves privacy guarantee based on the estimated (ϵ, δ) , provided by a privacy accountant. Compared with the original mechanism, the EVR has an extra failure mode that does not output anything when the estimated (ϵ, δ) is rejected. We show that the MC-based verifier we proposed can achieve negligible failure probability in Section 4.4.

present techniques to ensure that MC-based verifier also achieves a low false negative rate, making the EVR and the original mechanism indistinguishable (having similar utility) when the privacy parameter estimates are accurate.

A Monte Carlo-based DP Accountant. We further propose a new MC-based approach for DP accounting, which we call the *Monte Carlo (MC) accountant*. It utilizes similar MC techniques as in privacy verification. We show that the MC accountant achieves several advantages over existing FFT and CLT-based methods. In particular, we demonstrate that MC accountant is particularly efficient for *online privacy accounting*, a more realistic scenario for privacy practitioners where one wants to be able to update the estimate on the privacy loss whenever executing a new mechanism.

Figure 2 gives an overview of the proposed EVR paradigm as well as this paper’s contribution.

2 Privacy Accounting: a Mean Estimation/Bounding Problem

In this section, we review relevant concepts and introduce privacy accounting as a mean estimation/bounding problem.

Symbols and notations. We use $D, D' \in \cup_{n \in \mathbb{N}} \mathcal{X}^n$ to denote two datasets with an unspecified size. We call two datasets D and D' *adjacent* (denoted as $D \sim D'$) if we can construct one by adding/removing one data point from the other. We use P, Q to denote random variables. We also overload the notation and denote $P(\cdot), Q(\cdot)$ the density function of P, Q .

Differential privacy and its equivalent characterizations. Having established the notations, we can now proceed to formally define differential privacy.

Definition 1 (Differential Privacy (Dwork et al., 2006)). *For $\epsilon, \delta \geq 0$, a randomized algorithm $\mathcal{M} : \text{MultiSets}(\mathcal{X}) \rightarrow \mathcal{Y}$ is (ϵ, δ) -differentially private if for every pair of adjacent datasets $D, D' \in \text{MultiSets}(\mathcal{X})$, we have:*

$$\forall E \subseteq \mathcal{Y} \Pr[\mathcal{M}(D) \in E] \leq e^\epsilon \cdot \Pr[\mathcal{M}(D') \in E] + \delta$$

where the randomness is over the coin flips of algorithm \mathcal{M} .

One can alternatively define differential privacy in terms of the maximum possible divergence between the output distribution of any pair of $\mathcal{M}(D)$ and $\mathcal{M}(D')$.

Lemma 2 (Barthe & Olmedo (2013)). A mechanism \mathcal{M} is (ε, δ) -DP iff $\sup_{D \sim D'} \mathbb{E}_{e^\varepsilon}(\mathcal{M}(D) \| \mathcal{M}(D')) \leq \delta$, where $\mathbb{E}_\gamma(P \| Q) := \mathbb{E}_{o \sim Q}[(\frac{P(o)}{Q(o)} - \gamma)_+]$ and $(a)_+ := \max(a, 0)$.

\mathbb{E}_γ is usually referred as *Hockey-Stick* (HS) Divergence in the literature. For every mechanism \mathcal{M} and every $\varepsilon \geq 0$, there exists a smallest δ such that \mathcal{M} is (ε, δ) -DP. Following the literature (Zhu et al., 2022; Alghamdi et al., 2022), we formalize such a δ as a function of ε .

Definition 3 (Optimal Privacy Curve). The optimal privacy curve of a mechanism \mathcal{M} is the function $\delta_{\mathcal{M}} : \mathbb{R}^+ \rightarrow [0, 1]$ s.t. $\delta_{\mathcal{M}}(\varepsilon) := \sup_{D \sim D'} \mathbb{E}_{e^\varepsilon}(\mathcal{M}(D) \| \mathcal{M}(D'))$.

Dominating Distribution Pair and Privacy Loss Random Variable (PRV). It is computationally infeasible to find $\delta_{\mathcal{M}}(\varepsilon)$ by computing $\mathbb{E}_{e^\varepsilon}(\mathcal{M}(D) \| \mathcal{M}(D'))$ for all pairs of adjacent dataset D and D' . A mainstream strategy in the literature is to find a pair of distributions (P, Q) that dominates all $(\mathcal{M}(D), \mathcal{M}(D'))$ in terms of the Hockey-Stick divergence. This results in the introduction of *dominating distribution pair* and *privacy loss random variable* (PRV).

Definition 4 (Zhu et al. (2022)). A pair of distributions (P, Q) is a pair of dominating distributions for \mathcal{M} under adjacent relation \sim if **for all** $\gamma \geq 0$, $\sup_{D \sim D'} \mathbb{E}_\gamma(\mathcal{M}(D) \| \mathcal{M}(D')) \leq \mathbb{E}_\gamma(P \| Q)$. If equality is achieved **for all** $\gamma \geq 0$, then we say (P, Q) is a pair of tightly dominating distributions for \mathcal{M} . Furthermore, we call $Y := \log\left(\frac{P(o)}{Q(o)}\right)$, $o \sim P$ the privacy loss random variable (PRV) of \mathcal{M} associated with dominating distribution pair (P, Q) .

Zhu et al. (2022) shows that all mechanisms have a pair of tightly dominating distributions. Hence, we can alternatively characterize the optimal privacy curve as $\delta_{\mathcal{M}}(\varepsilon) = \mathbb{E}_{e^\varepsilon}(P \| Q)$ for the tightly dominating pair (P, Q) , and we have $\delta_{\mathcal{M}}(\varepsilon) \leq \mathbb{E}_{e^\varepsilon}(P \| Q)$ if (P, Q) is a dominating pair that is not necessarily tight. The importance of the concept of PRV comes from the fact that we can write $\mathbb{E}_{e^\varepsilon}(P \| Q)$ as an expectation over it: $\mathbb{E}_{e^\varepsilon}(P \| Q) = \mathbb{E}_Y \left[(1 - e^{\varepsilon - Y})_+ \right]$. Thus, one can bound $\delta_{\mathcal{M}}(\varepsilon)$ by first identifying \mathcal{M} 's dominating pair distributions as well as the associated PRV Y , and then computing this expectation. Such a formulation allows us to bound $\delta_{\mathcal{M}}(\varepsilon)$ without enumerating over all adjacent D and D' . For notation convenience, we denote

$$\delta_Y(\varepsilon) := \mathbb{E}_Y \left[(1 - e^{\varepsilon - Y})_+ \right] \tag{1}$$

Clearly, $\delta_{\mathcal{M}} \leq \delta_Y$. If (P, Q) is a tightly dominating pair for \mathcal{M} , then $\delta_{\mathcal{M}} = \delta_Y$.

Privacy Accounting as a Mean Estimation/Bounding Problem. Privacy accounting aims to estimate and bound the optimal privacy curve $\delta_{\mathcal{M}}(\varepsilon)$ for adaptively composed mechanism $\mathcal{M} = \mathcal{M}_1 \circ \dots \circ \mathcal{M}_k(D)$. The *adaptive composition* of two mechanisms \mathcal{M}_1 and \mathcal{M}_2 is defined as $\mathcal{M}_1 \circ \mathcal{M}_2(D) := (\mathcal{M}_1(D), \mathcal{M}_2(D, \mathcal{M}_1(D)))$, in which \mathcal{M}_2 can access both the dataset and the output of \mathcal{M}_1 . Most of the practical privacy accounting techniques are based on the concept of PRV, centered on the following result.

Lemma 5 (Zhu et al. (2022)). Let (P_j, Q_j) be a pair of tightly dominating distributions for mechanism \mathcal{M}_j for $j \in \{1, \dots, k\}$. Then $(P_1 \times \dots \times P_k, Q_1 \times \dots \times Q_k)$ is a pair of dominating distributions for $\mathcal{M} = \mathcal{M}_1 \circ \dots \circ \mathcal{M}_k$, where \times denotes the product distribution. Furthermore, the associated privacy loss random variable $Y = \sum_{i=1}^k Y_i$ where Y_i is the PRV associated with (P_i, Q_i) .

Lemma 5 suggests that privacy accounting for DP composition can be cast into a *mean estimation/bounding problem* where one aims to approximate or bound the expectation in (1) when $Y = \sum_{i=1}^k Y_i$. Note that while Lemma 5 does not guarantee a pair of tightly dominating distributions

for the adaptive composition, it cannot be improved in general, as noted in Dong et al. (2019). Hence, all the current privacy accounting techniques work on δ_Y instead of $\delta_{\mathcal{M}}$, as Lemma 5 is tight even for non-adaptive composition. Following the prior works, in this paper, we only consider the practical scenarios where Lemma 5 is tight for the simplicity of presentation. That is, we assume $\delta_Y = \delta_{\mathcal{M}}$ unless otherwise specified.

Most of the existing privacy accounting techniques can be described as different techniques for such a mean estimation problem. **Example-1: FFT-based methods.** This line of works (e.g., Gopi et al. (2021)) discretizes the domain of each Y_i and use Fast Fourier Transform (FFT) to speed up the approximation of $\delta_Y(\varepsilon)$. The upper bound is derived through the worst-case error bound for the approximation. **Example-2: CLT-based methods.** Bu et al. (2020); Wang et al. (2022a) use CLT to approximate the distribution of $Y = \sum_{i=1}^k Y_i$ as Gaussian distribution. They then use CLT’s finite-sample approximation guarantee to derive the upper bound for $\delta_Y(\varepsilon)$.

3 Estimate-Verify-Release

As mentioned earlier, upper bounds for $\delta_Y(\varepsilon)$ are the only valid options for privacy accounting techniques. However, as we have demonstrated in Figure 1, both FFT- and CLT-based methods can provide overly conservative upper bounds in certain regimes. On the other hand, their *estimates* for $\delta_Y(\varepsilon)$ can be very close to the ground truth even though there is no provable guarantee. Therefore, it is highly desirable to develop new techniques that enable the use of privacy parameter estimates instead of overly conservative upper bounds in privacy accounting.

We tackle the problem by introducing a new paradigm for constructing DP mechanisms, which we call Estimate-Verify-Release (EVR). The key component of the EVR is a new concept called differential privacy verifier (DP verifier) introduced in Section 3.1. The full EVR paradigm is then presented in Section 3.2, where the DP verifier is utilized as a building block to guarantee privacy.

3.1 Differential Privacy Verifier

We first formalize the notion of *differential privacy verifier*, the central element of the EVR paradigm. In informal terms, a DP verifier is an algorithm that attempts to verify whether a mechanism satisfies a specific level of differential privacy.

Definition 6 (Differential Privacy Verifier). *We say a differentially private verifier $DPV(\cdot)$ is an algorithm that takes the description of a mechanism \mathcal{M} and proposed privacy parameter $(\varepsilon, \delta^{\text{est}})$ as input, and returns $\mathbf{True} \leftarrow DPV(\mathcal{M}, \varepsilon, \delta^{\text{est}})$ if the algorithm believes \mathcal{M} is $(\varepsilon, \delta^{\text{est}})$ -DP (i.e., $\delta^{\text{est}} \geq \delta_Y(\varepsilon)$ where Y is the PRV of \mathcal{M}), and returns \mathbf{False} otherwise.*

We establish a relaxed notion of false positive (FP) and false negative (FN) rate for DP verifiers. The traditional FP rate is the probability for DPV to accept $(\varepsilon, \delta^{\text{est}})$ when $\delta^{\text{est}} < \delta_Y(\varepsilon)$. However, δ^{est} is still a good estimate for $\delta_Y(\varepsilon)$ by being a small (e.g., <10%) underestimate. Hence, we introduce a smoothing factor $\tau \in (0, 1]$ where δ^{est} is considered as “should be rejected” only when $\delta^{\text{est}} \leq \tau \delta_Y(\varepsilon)$. Similar reasoning can be made for FN. This leads to the relaxed notions for FP and FN rate:

Definition 7. *We say a DPV’s τ -relaxed false positive rate at $(\varepsilon, \delta^{\text{est}})$ is*

$$\text{FP}_{DPV}(\varepsilon, \delta^{\text{est}}; \tau) := \sup_{\mathcal{M}: \delta^{\text{est}} < \tau \delta_Y(\varepsilon)} \Pr_{DPV} [DPV(\mathcal{M}, \varepsilon, \delta^{\text{est}}) = \mathbf{True}]$$

Algorithm 1 Estimate-Verify-Release (EVR) Framework

- 1: **Input:** \mathcal{M} : mechanism. D : dataset. $(\varepsilon, \delta^{\text{est}})$: an estimated privacy parameter for \mathcal{M} .
 - 2: **if** $\text{DPV}(\mathcal{M}, \varepsilon, \delta^{\text{est}})$ outputs **True** **then** Execute $\mathcal{M}(D)$.
 - 3: **else** Print \perp .
-

We say a DPV 's ρ -relaxed false negative rate at $(\varepsilon, \delta^{\text{est}})$ is

$$\text{FN}_{\text{DPV}}(\varepsilon, \delta^{\text{est}}; \rho) := \sup_{\mathcal{M}: \delta^{\text{est}} > \rho \delta_Y(\varepsilon)} \Pr_{\text{DPV}} [\text{DPV}(\mathcal{M}, \varepsilon, \delta^{\text{est}}) = \text{False}]$$

While we are the first to formalize the concept of a DP verifier, several heuristics have tried to perform DP verification, forming a line of work called *auditing differential privacy* (Jagielski et al., 2020; Nasr et al., 2021; Lu et al., 2022). Specifically, these techniques can verify a claimed privacy parameter by computing a lower bound for the actual privacy parameter, and comparing that with the claimed privacy parameter. The input description of mechanism \mathcal{M} for DPV , in this case, is a black-box oracle $\mathcal{M}(\cdot)$, where the DPV makes multiple queries to $\mathcal{M}(\cdot)$ and estimates the actual privacy leakage. Privacy auditing techniques can achieve 100% accuracy when $\delta^{\text{est}} > \delta_Y(\varepsilon)$ (or 0 ρ -FN rate for any $\rho \leq 1$), as the computed lower bound is guaranteed to be smaller than δ^{est} . However, when δ^{est} lies between $\delta_Y(\varepsilon)$ and the computed lower bound, the DP verification will be wrong. Moreover, such techniques do not have a guarantee for the lower bound's tightness.

Privacy Verification with DP Accountant. For a composed mechanism $\mathcal{M} = \mathcal{M}_1 \circ \dots \circ \mathcal{M}_k$, a DP verifier can be easily implemented using any existing privacy accounting techniques. That is, one can execute DP accountant to obtain an estimate or upper bound $(\varepsilon, \hat{\delta})$ of the actual privacy parameter. If $\delta^{\text{est}} < \hat{\delta}$, then the proposed privacy level is rejected as it is more private than what the DP accountant tells; otherwise, the test is passed. The input description of a mechanism \mathcal{M} , in this case, can differ depending on the DP accounting method. For the Advanced Composition Theorem (Dwork et al., 2010), the input description is simply the $(\varepsilon_i, \delta_i)$ privacy guarantee of each individual mechanism \mathcal{M}_i . For Moment Accountant (Abadi et al., 2016), the input description is the upper bound of the moment-generating function (MGF) of the privacy loss random variable for each individual mechanism. For FFT and CLT-based methods, the input description is the cumulative distribution functions (CDF) of the dominating distribution pair of each individual \mathcal{M}_i .

3.2 EVR: Ensuring Estimated Privacy with DP Verifier

We now present the full paradigm of EVR. As suggested by the name, it contains three steps: **(1) Estimate:** A privacy parameter $(\varepsilon, \delta^{\text{est}})$ for \mathcal{M} is estimated, e.g., based on a privacy auditing or accounting technique. **(2) Verify:** A DP verifier DPV is used for validating whether mechanism \mathcal{M} satisfies $(\varepsilon, \delta^{\text{est}})$ -DP guarantee. **(3) Release:** If DP verification test is passed, we can execute \mathcal{M} as usual; otherwise, the program is terminated immediately. The procedure is summarized in Algorithm 1.

Given an estimated privacy parameter $(\varepsilon, \delta^{\text{est}})$, we have the following privacy guarantee for the EVR paradigm.

Theorem 8. *Algorithm 1 is $(\varepsilon, \delta^{\text{est}}/\tau)$ -DP for any $\tau > 0$ if $\text{FP}_{\text{DPV}}(\varepsilon, \delta^{\text{est}}; \tau) \leq \delta^{\text{est}}/\tau$.*

We defer the proof to Appendix B. The implication of this result is that, for any *estimate* of the privacy parameter, one can safely use it as a DPV with a bounded false positive rate would enforce differential privacy. However, this is not enough: an overly conservative DPV that satisfies 0 FP rate

but rejects everything would not be useful. When δ^{est} is accurate, we hope the DPV can also achieve a small *false negative rate* so that the output distributions of EVR and \mathcal{M} are indistinguishable. We discuss the instantiation of DPV in Section 4.

Connection to the Propose-Test-Release (PTR) paradigm (Dwork & Lei, 2009). PTR is a classic differential privacy paradigm introduced over a decade ago by Dwork & Lei (2009), and is being generalized in Redberg et al. (2022); Wang et al. (2022b). At a high level, PTR checks if releasing the query answer is safe with a certain amount of randomness (in a private way). If the test is passed, the query answer is released; otherwise, the program is terminated. PTR shares a similar underlying philosophy with our EVR paradigm. However, they are fundamentally different in terms of implementation. The verification step in EVR is completely independent of the dataset. In contrast, the test step in PTR measures the privacy risks for the mechanism \mathcal{M} on a specific dataset D , which means that the test itself may cause additional privacy leakage. One way to think about the difference is that EVR asks “whether \mathcal{M} is private”, while PTR asks “whether $\mathcal{M}(D)$ is private”.

4 Monte Carlo Verifier of Differential Privacy

As we can see from Section 3.2, a DP verifier (DPV) that achieves a small false positive rate is the central element for the EVR framework. In the meanwhile, it is also important that DPV has a low false negative rate in order to maintain the good utility of the EVR when the privacy parameter estimate is accurate. In this section, we present an instantiation of DPV based on the Monte Carlo technique which achieves both goals.

We consider the scenario where we are able to obtain a dominating distribution pair (and thus the PRV) for each individual mechanism \mathcal{M}_i . This applies to most of the commonly used privacy mechanisms such as the Gaussian, Subsampled Gaussian, and Laplace Mechanisms. This is also the assumption for most of the advanced privacy accounting techniques (including FFT- and CLT-based methods).

4.1 DPV through an MC Estimator for $\delta_Y(\varepsilon)$

Recall that most of the recently proposed DP accountants are essentially different techniques for estimating the expectation

$$\delta_{Y=\sum_{i=1}^k Y_i}(\varepsilon) = \mathbb{E}_Y \left[\left(1 - e^{\varepsilon - Y}\right)_+ \right]$$

where each Y_i is the privacy loss random variable $Y_i = \log \left(\frac{P_i(t)}{Q_i(t)} \right)$ for $t \sim P_i$, and (P_i, Q_i) is a pair of dominating distribution for individual mechanism \mathcal{M}_i . In the following text, we denote the product distribution $\mathbf{P} := P_1 \times \dots \times P_k$ and $\mathbf{Q} := Q_1 \times \dots \times Q_k$. Recall from Lemma 5 that (\mathbf{P}, \mathbf{Q}) is a pair of dominating distributions for the composed mechanism \mathcal{M} . For notation simplicity, we denote a vector $\mathbf{t} := (t^{(1)}, \dots, t^{(k)})$.

Monte Carlo (MC) technique is arguably one of the most natural and widely used techniques for approximating expectations. Since $\delta_Y(\varepsilon)$ is an expectation in terms of the PRV Y , one can apply MC-based technique to estimate it. Given an MC estimator for $\delta_Y(\varepsilon)$, we construct a DPV($\mathcal{M}, \varepsilon, \delta^{\text{est}}$) as shown in Algorithm 2 (instantiated by the Simple MC estimator introduced in Section 4.2). Specifically, we first obtain an estimate $\hat{\delta}$ from an MC estimator for $\delta_Y(\varepsilon)$. The estimate δ^{est} passes

Algorithm 2 DPV($\mathcal{M}, \varepsilon, \delta^{\text{est}}$) with Simple MC Estimator and Offset Parameter Δ .

- 1: Obtain i.i.d. samples $\{\mathbf{t}_i\}_{i=1}^m$ from \mathbf{P} .
 - 2: Compute $\hat{\delta} = \frac{1}{m} \sum_{i=1}^m (1 - e^{\varepsilon - y_i})_+$ with PRV samples $y_i = \log \left(\frac{\mathbf{P}(\mathbf{t}_i)}{\mathbf{Q}(\mathbf{t}_i)} \right)$, $i = 1 \dots m$.
 - 3: **if** $\hat{\delta} < \frac{\delta^{\text{est}}}{\tau} - \Delta$ **then** return **True**.
 - 4: **else** return **False**.
-

the test if $\hat{\delta} < \frac{\delta^{\text{est}}}{\tau} - \Delta$, and fails otherwise. The parameter $\Delta \geq 0$ here is an offset that controls the τ -relaxed false positive rate. We defer the discussion on how to set Δ in Section 4.4.

In the following contents, we first present two constructions of MC estimators for $\delta_Y(\varepsilon)$ in Section 4.2. We then discuss the condition for which our MC-based DPV achieves a certain target FP rate in Section 4.3. Finally, we discuss the utility guarantee for the MC-based DPV in Section 4.4.

4.2 Constructing MC Estimator for $\delta_Y(\varepsilon)$

In this section, we first present a simple MC estimator that applies to any mechanisms where we can derive and sample from the dominating distribution pairs. Given the importance of Poisson Subsampled Gaussian mechanism for privacy-preserving machine learning, we further design a more advanced and specialized MC estimator for it based on the importance sampling technique.

Simple Monte Carlo Estimator. One can easily sample from Y by sampling $\mathbf{t} \sim \mathbf{P}$ and output $\log \left(\frac{\mathbf{P}(\mathbf{t})}{\mathbf{Q}(\mathbf{t})} \right)$. Hence, a straightforward algorithm for estimating (1) is the Simple Monte Carlo (SMC) algorithm, which directly samples from the privacy random variable Y . We formally define it in the following.

Definition 9 (Simple Monte Carlo Estimator). We denote $\hat{\delta}_{\text{MC}}^m(\varepsilon)$ as the random variable of SMC estimator for $\delta_Y(\varepsilon)$ with m samples, i.e.,

$$\hat{\delta}_{\text{MC}}^m(\varepsilon) := \frac{1}{m} \sum_{i=1}^m (1 - e^{\varepsilon - y_i})_+$$

for y_1, \dots, y_m i.i.d. sampled from Y .

Importance Sampling Estimator for Poisson Subsampled Gaussian (Overview). As $\delta_Y(\varepsilon)$ is usually a tiny value (10^{-5} or even cryptographically small), it is likely that by naive sampling from Y , almost all of the samples in $\{(1 - e^{\varepsilon - y_i})_+\}_{i=1}^m$ are just 0s! That is, the i.i.d. samples $\{y_i\}_{i=1}^m$ from Y can rarely exceed ε . To further improve the sample efficiency, one can potentially use more advanced MC techniques such as Importance Sampling or MCMC. However, these advanced tools usually require additional distributional information about Y and thus need to be developed case-by-case.

Poisson Subsampled Gaussian mechanism is the main workhorse behind the famous DPSGD algorithm (Abadi et al., 2016). Given its important role in privacy-preserving ML, we derive an advanced MC estimator for it based on the Importance Sampling technique. Importance Sampling (IS) is a classic method for rare event simulation. It samples from an alternative distribution instead of the distribution of the quantity of interest, and a weighting factor is then used for correcting the difference between the two distributions. The specific design of alternative distribution is complicated and notation-heavy, and we defer the technical details to Appendix C. At a high level, we construct the alternative sampling distribution based on the *exponential tilting* technique, and we derive the

optimal tilting parameter such that the corresponding IS estimator approximately achieves the smallest variance. Similar to Definition 9, we use $\widehat{\delta}_{\text{IS}}^m$ to denote the random variable of importance sampling estimator with m samples.

4.3 Bounding FP Rate

We now discuss the FP guarantee for the DPV instantiated by $\widehat{\delta}_{\text{MC}}^m$ and $\widehat{\delta}_{\text{IS}}^m$ we developed in the last section. Since both estimators are unbiased, by Law of Large Number, both $\widehat{\delta}_{\text{MC}}^m$ and $\widehat{\delta}_{\text{IS}}^m$ converge to $\delta_Y(\varepsilon)$ almost surely as $m \rightarrow \infty$, which leads a DPV with perfect accuracy. Of course, m cannot go to ∞ in practice. In the following, we derive the required amount of samples m for ensuring that τ -relaxed false positive rate is smaller than δ^{est}/τ for $\widehat{\delta}_{\text{MC}}^m$ and $\widehat{\delta}_{\text{IS}}^m$. We use $\widehat{\delta}_{\text{MC}}$ (or $\widehat{\delta}_{\text{IS}}$) as an abbreviation for $\widehat{\delta}_{\text{MC}}^1$ (or $\widehat{\delta}_{\text{IS}}^1$), the random variable for a single draw of sampling. We state the theorem for $\widehat{\delta}_{\text{MC}}^m$, and the same result for $\widehat{\delta}_{\text{IS}}^m$ can be obtained by simply replacing $\widehat{\delta}_{\text{MC}}$ with $\widehat{\delta}_{\text{IS}}$. We use FP_{MC} to denote the FP rate for DPV implemented by SMC estimator.

Theorem 10. *Suppose $\mathbb{E}\left[\left(\widehat{\delta}_{\text{MC}}\right)^2\right] \leq \nu$. DPV instantiated by $\widehat{\delta}_{\text{MC}}^m$ has bounded τ -relaxed false positive rate $\text{FP}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \tau) \leq \delta^{\text{est}}/\tau$ with $m \geq \frac{2\nu}{\Delta^2} \log(\tau/\delta^{\text{est}})$.*

The proof is based on Bennett’s inequality and is deferred to Appendix D. This result suggests that, to improve the computational efficiency of MC-based DPV (i.e., tighten the number of required samples), it is important to bound the second moment of $\widehat{\delta}_{\text{MC}}$ (or $\widehat{\delta}_{\text{IS}}$) as tight as possible, which we are going to discuss next.

Bounding the Second-Moment of MC Estimators (Overview). For paper readability, we defer the notation-heavy results and derivation of the upper bounds for $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]$ and $\mathbb{E}[(\widehat{\delta}_{\text{IS}})^2]$ to Appendix E. Our high-level idea for bounding $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]$ is through the RDP guarantee for the composed mechanism \mathcal{M} . This is a natural idea since converting RDP to upper bounds for $\delta_Y(\varepsilon)$ – the first moment of $\widehat{\delta}_{\text{MC}}$ – is a well-studied problem (Mironov, 2017; Canonne et al., 2020; Asoodeh et al., 2021). Bounding $\mathbb{E}[(\widehat{\delta}_{\text{IS}})^2]$ is highly technically involved. We also note that if tighter second-moment bounds are derived in future work, one can simply plug in the bound to Theorem 10 to further improve sample complexity of the MC-based verifiers.

4.4 Guaranteeing Utility

Overall picture so far. Given the proposed privacy parameter $(\varepsilon, \delta^{\text{est}})$, a tolerable degree of underestimation τ , and an offset parameter Δ , one can now compute the number of samples m required for the MC-based DPV such that τ -relaxed FP rate to be $\leq \delta^{\text{est}}/\tau$ based on the results from Section 4.3 and Appendix E. We have not yet discussed the selection of the hyperparameter Δ . An appropriate Δ is important for the utility of MC-based DPV. That is, when δ^{est} is not too smaller than $\delta_Y(\varepsilon)$, the probability of being rejected by DPV should stay negligible. If we set $\Delta \rightarrow \infty$, the DPV simply rejects everything, which achieves 0 FP rate (and with $m = 0$) but is not useful at all!

Formally, the utility of a DPV is quantified by the ρ -relaxed false negative (FN) rate (Definition 7). While one may be able to bound the FN rate through concentration inequalities, a more convenient way is to pick an appropriate Δ such that FN_{DPV} is *approximately* smaller than FP_{DPV} . After all, FP_{DPV} already has to be a small value $\leq \delta^{\text{est}}/\tau$ for privacy guarantee. The result is stated informally in the following (holds for both $\widehat{\delta}_{\text{MC}}$ and $\widehat{\delta}_{\text{IS}}$), and the technically involved derivation is deferred to Appendix F.

Theorem 11 (Informal). *When $\Delta = 0.4(1/\tau - 1/\rho)\delta^{\text{est}}$, we have*

$$\text{FN}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \rho) \lesssim \text{FP}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \tau) \quad (2)$$

Therefore, by setting $\Delta = 0.4(1/\tau - 1/\rho)\delta^{\text{est}}$, one can ensure that $\text{FN}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \rho)$ is also (approximately) upper bounded by $\Theta(\delta^{\text{est}}/\tau)$. Moreover, in Appendix, we empirically show that the FP rate is actually a very conservative bound for the FN rate. Both τ and ρ are selected based on the tradeoff between privacy, utility, and efficiency.

5 Monte Carlo Accountant of Differential Privacy

The Monte Carlo estimators $\widehat{\delta}_{\text{MC}}$ and $\widehat{\delta}_{\text{IS}}$ described in Section 4.2 are used for implementing DP verifiers. One may already realize that the same estimators can also be utilized to directly implement a DP accountant which *estimates* $\delta_Y(\varepsilon)$. It is important to note that with the EVR paradigm, DP accountants are no longer required to derive a strict upper bound for $\delta_Y(\varepsilon)$. We refer to the technique of estimating $\delta_Y(\varepsilon)$ using the MC estimators as *Monte Carlo accountant*.

Finding ε for a given δ . It is straightforward to implement MC accountant when we fix ε and compute for $\delta_Y(\varepsilon)$. In practice, privacy practitioners often want to do the inverse: finding ε for a given δ , which we denote as $\varepsilon_Y(\delta)$. Similar to the existing privacy accounting methods, we use binary search to find $\varepsilon_Y(\delta)$. Specifically, after generating PRV samples $\{y_i\}_{i=1}^m$, we simply need to find the ε such that $\frac{1}{m} \sum_{i=1}^m (1 - e^{\varepsilon - y_i})_+ = \delta$. We do **not** need to generate new PRV samples for different ε we evaluate during the binary search, and hence the additional binary search step is computationally efficient.

Algorithm 3 MC Accountant for $\varepsilon_Y(\delta)$.

- 1: Obtain PRV samples $\{y_i\}_{i=1}^m$ with either Simple MC or Importance Sampling.
 - 2: Binary search ε such that $\frac{1}{m} \sum_{i=1}^m (1 - e^{\varepsilon - y_i})_+ = \delta$.
 - 3: Return ε .
-

Number of Samples for MC Accountant. Compared with the number of samples required for achieving the FP guarantee in Section 4.3, one may be able to use much fewer samples to obtain a decent estimate for $\delta_Y(\varepsilon)$, as the sample complexity bound derived based on concentration inequality may be conservative. Many existing empirical methods for guiding the number of samples in MC simulation have been developed (e.g., Wald confidence interval) and can be applied to the setting of MC accountants.

Compared with the FFT-based and CLT-based methods, MC accountant exhibits the following strength:

(1) Accurate $\delta_Y(\varepsilon)$ estimation in all regimes. As we mentioned earlier, the state-of-the-art FFT-based method (Gopi et al., 2021) fails to provide meaningful bounds due to computational limitations when the true value of $\delta_Y(\varepsilon)$ is small. In contrast, the simplicity of the MC accountant allows us to accurately estimate $\delta_Y(\varepsilon)$ in all regimes.

(2) Short clock runtime & Easy GPU acceleration. MC-based techniques are well-suited for parallel computing and GPU acceleration due to their nature of repeated sampling. One can easily utilize PyTorch’s CUDA functionality (e.g., `torch.randn(size=(k,m)).cuda()*sigma+mu`) to significantly boost the computational efficiency for sampling from common distributions such as

Figure 3: Privacy analysis and runtime of the EVR paradigm. The settings are the same as Figure 1. For (a), when $\tau > 0.9$, the curves are indistinguishable from ‘Exact’. For fair comparison, we set $\rho = (1 + \tau)/2$ and set Δ according to Theorem 11, which ensures EVR’s failure probability is negligible ($O(\delta)$). For (b), the runtime is estimated on an NVIDIA A100-SXM4-80GB GPU.

Gaussian. In Appendix G, we show that when using one NVIDIA A100-SXM4-80GB GPU, the execution time of sampling Gaussian mixture $(1 - q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$ can be improved by 10^3 times compared with CPU-only scenario.

(3) Efficient online privacy accounting. When training ML models with DP-SGD or its variants, a privacy practitioner usually wants to compute a running privacy leakage for *every* training iteration, and pick the checkpoint with the best utility-privacy tradeoff. This involves estimating $\delta_{Y^{(i)}}(\epsilon)$ for every $i = 1, \dots, k$, where $Y^{(i)} := \sum_{j=1}^i Y_j$. We refer to such a scenario as *online privacy accounting*². MC accountant is especially efficient for online privacy accounting. When estimating $\delta_{Y^{(i)}}(\epsilon)$, one can re-use the samples previously drawn from Y_1, \dots, Y_{i-1} that were used for estimating privacy loss at earlier iterations.

These advantages are justified empirically in Section 6 and Appendix G.

6 Numerical Experiments

In this section, we conduct numerical experiments to illustrate (1) EVR paradigm with MC verifiers enables a tighter privacy analysis, and (2) MC accountant achieves state-of-the-art performance in privacy parameter estimation.

6.1 EVR vs Upper Bound

To illustrate the advantage of the EVR paradigm compared with directly using a strict upper bound for privacy parameters, we take the current state-of-the-art DP accountant, the FFT-based method from Gopi et al. (2021) as the example.

EVR provides a tighter privacy guarantee. Recall that in Figure 1, FFT-based method provides vacuous bound when the ground-truth $\delta_Y(\epsilon) < 10^{-10}$. Under the same hyperparameter setting, Figure 3 (a) shows the privacy bound of the EVR paradigm where the δ^{est} are FFT’s estimates. We use the Importance Sampling estimator $\hat{\delta}_{\text{IS}}$ for DP verification. We experiment with different values of τ . A higher value of τ leads to tighter privacy guarantee but longer runtime. For fair comparison, the EVR’s output distribution needs to be almost indistinguishable from the original mechanism. We set $\rho = (1 + \tau)/2$ and set Δ according to the heuristic from Theorem

²Note that this is different from the scenario of privacy odometer (Rogers et al., 2016), as here the privacy parameter of the next individual mechanism is not adaptively chosen.

11. This guarantees that, as long as the estimate of δ^{est} from FFT is not a big underestimation (i.e., $\delta^{\text{est}} \geq \rho\delta_Y(\varepsilon)$), the failure probability of the EVR paradigm is negligible ($< O(\delta_Y(\varepsilon))$). The ‘FFT-EVR’ curve in Figure 3 (a) is essentially the ‘FFT-est’ curve in Figure 1 scaled up by $1/\tau$. As we can see, EVR provides a significantly better privacy analysis in the regime where the ‘FFT-upp’ is unmeaningful ($\delta < 10^{-10}$).

EVR incurs little extra runtime. In Figure 3 (b), we plot the runtime of the Importance Sampling verifier in Figure 3 (b) for different $\tau \geq 0.9$. Note that for $\tau > 0.9$, the privacy curves are indistinguishable from ‘Exact’ in Figure 3 (a). The runtime of EVR is determined by the number of samples required to achieve the target τ -relaxed FP rate from Theorem 10. Smaller τ leads to faster DP verification. As we can see, even when $\tau = 0.99$, the runtime of DP verification in the EVR is < 2 minutes. This is attributable to the advanced IS estimator and GPU acceleration.

EVR provides better privacy-utility tradeoff for Privacy-preserving ML. To further illustrate the advantage of the EVR paradigm in real applications, we show the privacy-utility tradeoff curve when finetuning on CIFAR100 dataset with full batch DP gradient descent (DP-GD). As shown in Figure 4, EVR paradigm provides a better test accuracy for any privacy budget ε compared with the traditional upper bound method. When $\tau = 0.95$, the runtime for privacy verification is $< 10^{-10}$ seconds for all ε , which is negligible. We provide additional results for DP-SGD in Appendix G.

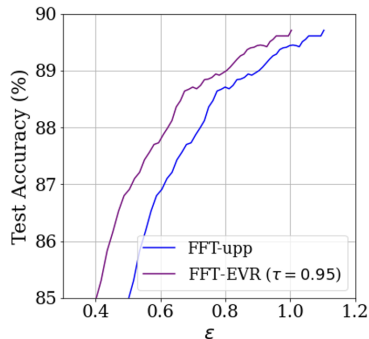

Figure 4: Utility-privacy tradeoff curve for fine-tuning ImageNet-pretrained BEiT (Bao et al., 2021) on CIFAR100 when $\delta = 10^{-5}$. We follow the training procedure from Panda et al. (2022).

6.2 MC Accountant

We conduct numerical experiments to evaluate the MC Accountant proposed in Section 5. We focus on privacy accounting for the composition of Poisson Subsampled Gaussian mechanisms, the algorithm behind the famous DP-SGD algorithm (Abadi et al., 2016). The mechanism is specified by the noise magnitude σ and subsampling rate q .

Settings. We consider two practical scenarios of privacy accounting: **(1) Offline accounting** which aims at estimating $\delta_{Y^{(k)}}(\varepsilon)$, and **(2) Online accounting** which aims at estimating $\delta_{Y^{(i)}}(\varepsilon)$ for all $i = 1, \dots, k$. For space constraint, we only show the results of online accounting here, and defer the results for offline accounting to Appendix G.

Metric: Relative Error. To easily and fairly evaluate the performance of privacy parameter estimation, we compute the *almost exact* (yet computationally expensive) privacy parameters as the ground-truth value through numerical integration. The ground-truth value allows us to compute the *relative error* of an estimate of privacy leakage. That is, if the corresponding ground-truth of an estimate $\hat{\delta}$ is δ , then the relative error $r_{\text{err}} = |\hat{\delta} - \delta|/\delta$.

For MC accountant, we use the IS estimator described in Section 4.2. For baselines, in addition to the FFT-based and CLT-based method we mentioned earlier, we also examine AFA (Zhu et al., 2022) and GDP accountant (Bu et al., 2020). For a fair comparison, we adjust the number of samples for MC accountant so that **the runtime of MC accountant and FFT is comparable**. Detailed settings for both MC accountant and the baselines are provided in Appendix G.

MC Accountant is both more accurate and efficient for online accounting. Figure 5 (a)

shows the online accounting results for $(\sigma, \delta, q) = (1.0, 10^{-9}, 10^{-3})$. As we can see, MC accountant outperforms all of the baselines in estimating $\varepsilon_Y(\delta)$. Figure 5 (b) shows that MC accountant is around 5 times faster than FFT, the baseline with the best performance in (a). This demonstrates that MC accountant is *both* accurate and efficient in online accounting scenarios.

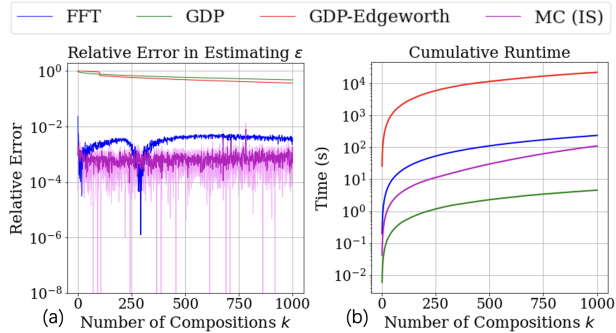

Figure 5: Experiment for Composing Subsampled Gaussian Mechanisms in the Online Setting. (a) Compares the relative error in approximating $k \mapsto \varepsilon_Y(\delta)$. The error bar for MC accountant is the variance taken over 5 independent runs. Note that the y-axis is in the log scale. (b) Compares the cumulative runtime for online privacy accounting. We were not able to run AFA (Zhu et al., 2022) as it does not terminate in 24 hours.

7 Conclusion and Future Works

This paper addresses an important obstacle faced by many existing privacy accounting techniques where deriving the provable upper bound for privacy leakage is hard. We developed a new DP paradigm called estimate-verify-release (EVR) which enables the safe use of privacy parameter estimate. The core of the EVR paradigm is privacy verification, and we presented a randomized DP verifier based on Monte Carlo (MC) technique, which achieves high verification accuracy. We further proposed an MC-based DP accountant, which exhibits several advantages over the existing privacy accounting techniques.

Currently, our MC-based DP verifier and accountant require known and efficiently samplable dominating pairs for the individual mechanism. The derivation of dominating pairs, however, is usually non-trivial. Moreover, one may need to optimize the MC estimator for δ_Y for different kinds of mechanisms case-by-case. Removing these requirements is interesting future work.

A Extended Related Work

Early privacy accounting techniques such as Advanced Composition Theorem (Dwork et al., 2010) only make use of the privacy parameters of the individual mechanisms, which bounds $\delta_{\mathcal{M}}(\varepsilon)$ in terms of the privacy parameter $(\varepsilon_i, \delta_i)$ for each $\mathcal{M}_i, i = 1, \dots, k$. The optimal bound for $\delta_{\mathcal{M}}(\varepsilon)$ under this condition has been derived (Kairouz et al., 2015; Murtagh & Vadhan, 2016). However, the computation of the optimal bound is #P-hard in general. Bounding $\delta_{\mathcal{M}}(\varepsilon)$ only in terms of $(\varepsilon_i, \delta_i)$ is often sub-optimal for many commonly used mechanisms (Murtagh & Vadhan, 2016). This disadvantage has spurred many recent advances in privacy accounting by making use of more statistical information from the specific mechanisms to be composed (Abadi et al., 2016; Mironov, 2017; Koskela et al., 2020; Bu et al., 2020; Koskela & Honkela, 2021; Koskela et al., 2021; Gopi et al., 2021; Zhu et al., 2022; Ghazi et al., 2022; Doroshenko et al., 2022; Wang et al., 2022a; Alghamdi et al., 2022). All of these works can be described as approximating the expectation in (1) when $Y = \sum_{i=1}^k Y_i$. For instance, the line of Koskela et al. (2020); Bu et al. (2020); Koskela & Honkela (2021); Koskela et al. (2021); Gopi et al. (2021); Ghazi et al. (2022); Doroshenko et al. (2022) discretizes the domain of each Y_i and use Fast Fourier Transform (FFT) in order to speed up the approximation of $\delta_Y(\varepsilon)$. Zhu et al. (2022) tracks the characteristic function of the privacy loss random variables for the composed mechanism and still requires discretization when the mechanisms do not have closed-form characteristic functions. The line of Bu et al. (2020); Wang et al. (2022a) uses Central Limit Theorem (CLT) to approximate the distribution of $Y = \sum_{i=1}^k Y_i$ as Gaussian distribution and uses the finite-sample bound to derive the strict upper bound for $\delta_Y(\varepsilon)$. We also note that Mahloujifar et al. (2022) also use Monte Carlo approaches to calculate optimal membership inference bounds. They use a similar Simple MC estimator as the one in Section 4.2. Although their Monte Carlo approach is similar, their error analysis only works for large values of δ ($\delta \approx 0.5$) as they use sub-optimal concentration bounds.

B Proofs for Privacy

Theorem 8. *Algorithm 1 is $(\varepsilon, \delta^{\text{est}}/\tau)$ -DP for any $\tau > 0$ if $\text{FP}_{\text{DPV}}(\varepsilon, \delta^{\text{est}}; \tau) \leq \delta^{\text{est}}/\tau$.*

Proof. For any mechanism \mathcal{M} , we denote A as the event that $\delta^{\text{est}} \geq \tau\delta_Y(\varepsilon)$, and indicator variable $B = I[\text{DPV}(\mathcal{M}, \varepsilon, \delta^{\text{est}}; \tau) = \text{True}]$. Note that event A implies \mathcal{M} is $(\delta^{\text{est}}/\tau)$ -DP.

Thus, we know that

$$\Pr[B = 1|\bar{A}] \leq \text{FP}_{\text{DPV}}(\varepsilon, \delta^{\text{est}}; \tau) \quad (3)$$

For notation simplicity, we also denote $p_{\text{fp}} := \Pr[B = 1|\bar{A}]$, and $p_{\text{tp}} := \Pr[B = 1|A]$.

For any possible event S ,

$$\begin{aligned} & \Pr_{\mathcal{M}^{\text{aug}}}[\mathcal{M}^{\text{aug}}(D) \in S] \\ &= \Pr_{\mathcal{M}}[\mathcal{M}(D) \in S|B = 1] \Pr[B = 1] + I[\perp \in S] \Pr[B = 0] \\ &= \Pr_{\mathcal{M}}[\mathcal{M}(D) \in S|B = 1, A] \Pr[B = 1|A] I[A] + \Pr_{\mathcal{M}}[\mathcal{M}(D) \in S|B = 1, \bar{A}] \Pr[B = 1|\bar{A}] I[\bar{A}] \\ &\quad + I[\perp \in S] \Pr[B = 0] \\ &\leq \left(e^\varepsilon \Pr_{\mathcal{M}}[\mathcal{M}(D') \in S|B = 1, A] + \frac{\delta^{\text{est}}}{\tau} \right) \Pr[B = 1|A] I[A] + \Pr_{\mathcal{M}}[\mathcal{M}(D) \in S|B = 1, \bar{A}] \Pr[B = 1|\bar{A}] I[\bar{A}] \\ &\quad + I[\perp \in S] \Pr[B = 0] \\ &\leq \left(e^\varepsilon \Pr_{\mathcal{M}}[\mathcal{M}(D') \in S|B = 1, A] + \frac{\delta^{\text{est}}}{\tau} \right) p_{\text{tp}} I[A] + p_{\text{fp}} I[\bar{A}] + I[\perp \in S] \Pr[B = 0] \\ &\leq e^\varepsilon \left(\Pr_{\mathcal{M}}[\mathcal{M}(D') \in S|B = 1, A] p_{\text{tp}} I[A] + \Pr_{\mathcal{M}}[\mathcal{M}(D') \in S|B = 1, \bar{A}] p_{\text{fp}} I[\bar{A}] + I[\perp \in S] \Pr[B = 0] \right) \\ &\quad + \frac{\delta^{\text{est}}}{\tau} p_{\text{tp}} I[A] + p_{\text{fp}} I[\bar{A}] \\ &\leq e^\varepsilon \Pr_{\mathcal{M}^{\text{aug}}}[\mathcal{M}^{\text{aug}}(D') \in S] + \max\left(\frac{\delta^{\text{est}} p_{\text{tp}}}{\tau}, p_{\text{fp}}\right) \end{aligned}$$

Therefore, \mathcal{M}^{aug} is $(\varepsilon, \max(\frac{\delta^{\text{est}} p_{\text{tp}}}{\tau}, p_{\text{fp}}))$ -DP. By assumption of $p_{\text{fp}} \leq \text{FP}_{\text{DPV}}(\varepsilon, \delta^{\text{est}}; \tau) \leq \delta^{\text{est}}/\tau$, we reach the conclusion. \square

C Importance Sampling via Exponential Tilting

Notation Review. Recall that most of the recently proposed DP accountants are essentially different techniques for estimating the expectation

$$\delta_{Y=\sum_{i=1}^k Y_i}(\varepsilon) = \mathbb{E}_Y \left[(1 - e^{\varepsilon - Y})_+ \right]$$

where each Y_i is the privacy loss random variable $Y_i = \log \left(\frac{P_i(t)}{Q_i(t)} \right)$ for $t \sim P_i$, and (P_i, Q_i) is a pair of dominating distribution for individual mechanism \mathcal{M}_i . In the following text, we denote the product distribution $\mathbf{P} := P_1 \times \dots \times P_k$ and $\mathbf{Q} := Q_1 \times \dots \times Q_k$. Recall from Lemma 5 that (\mathbf{P}, \mathbf{Q}) is a pair of dominating distributions for the composed mechanism \mathcal{M} . For notation simplicity, we denote a vector $\mathbf{t} := (t^{(1)}, \dots, t^{(k)})$. We slightly abuse the notation and write $y(\mathbf{t}; P, Q) := \log \left(\frac{P(\mathbf{t})}{Q(\mathbf{t})} \right)$. Note that $y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) = \sum_{i=1}^k y(t^{(i)}; P_i, Q_i)$. When the context is clear, we omit the dominating pairs and simply write $y(\mathbf{t})$.

C.1 Importance Sampling for the Composition of Poisson Subsampled Gaussian Mechanisms

Importance Sampling (IS) is a classic method for rare event simulation. It samples from an alternative distribution instead of the distribution of the quantity of interest, and a weighting factor is then used for correcting the difference between the two distributions. Specifically, we can re-write the expression for $\delta_Y(\varepsilon)$ as follows:

$$\begin{aligned} \delta_Y(\varepsilon) &= \mathbb{E}_Y \left[(1 - e^{\varepsilon - Y})_+ \right] \\ &= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+ \right] \\ &= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}'} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+ \frac{\mathbf{P}(\mathbf{t})}{\mathbf{P}'(\mathbf{t})} \right] \end{aligned} \quad (4)$$

where \mathbf{P}' is the alternative distribution up to the user's choice. From Equation (4), one can construct an unbiased importance sampling estimator for $\delta_Y(\varepsilon)$ by sampling from \mathbf{P}' . In this section, we develop a \mathbf{P}' for estimating $\delta_Y(\varepsilon)$ when composing *identically distributed Poisson subsampled Gaussian mechanisms*, which is arguably the most important DP mechanism nowadays due to its application in differentially private stochastic gradient descent.

Exponential tilting is a common way to construct alternative sampling distribution for IS. The exponential tilting of a distribution P is defined as

$$P_\theta(t) := \frac{e^{\theta t}}{M_P(\theta)} P(t)$$

where $M_P(\theta) := \mathbb{E}_{t \sim P}[e^{\theta t}]$ is the moment generating function for P . Such a transformation is especially convenient for distributions from the exponential family. For example, for normal distribution $\mathcal{N}(\mu, \sigma^2)$, the tilted distribution is $\mathcal{N}(\mu + \theta\sigma^2, \sigma^2)$, which is easy to sample from.

Without the loss of generality, we consider Poisson Subsampled Gaussian mechanism with sensitivity 1, noise variance σ^2 , and subsampling rate q . Recall from Gopi et al. (2021) that the dominating pair in this case is $Q := \mathcal{N}(0, \sigma^2)$ and $P := (1 - q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$. For notation simplicity, we denote $P_0 := \mathcal{N}(1, \sigma^2)$, and thus $P = (1 - q)Q + qP_0$. Since each individual mechanism is the

same, $\mathbf{P} = P \times \dots \times P$ and $\mathbf{Q} = Q \times \dots \times Q$. The exponential tilting of P with parameter θ is $P_\theta := (1 - q)\mathcal{N}(\theta\sigma^2, \sigma^2) + q\mathcal{N}(1 + \theta\sigma^2, \sigma^2)$. We propose the following importance sampling estimator for $\delta_Y(\varepsilon)$ based on exponential tilting.

Definition 12 (Importance Sampling Estimator for Subsampled Gaussian Composition). *Let the alternative distribution*

$$\mathbf{P}' := \mathbf{P}_\theta = (P, \dots, \underbrace{P_\theta}_{i\text{th dim}}, \dots, P), \quad i \sim \text{Unif}([k])$$

with $\theta = 1/2 + \sigma^2 \log\left(\frac{\exp(\varepsilon) - (1 - q)}{q}\right)$. Given a random draw $\mathbf{t} \sim \mathbf{P}_\theta$, an unbiased sample for $\delta_Y(\varepsilon)$ is $(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})})_+ \left(\frac{1}{k} \sum_{i=1}^k \frac{P_\theta(t_i)}{P(t_i)}\right)^{-1}$. We denote $\widehat{\delta}_{\text{IS}, \theta}^m(\varepsilon)$ as the random variable of the corresponding importance sampling estimator with m samples.

We defer the formal justification of the choice of θ to Appendix C.2. We first give the intuition for why we choose such an alternative distribution \mathbf{P}_θ .

Intuition for the alternative distribution \mathbf{P}_θ . It is well-known that the variance of the importance sampling estimator is minimized when the alternative distribution

$$\mathbf{P}'(\mathbf{t}) \propto \left(1 - e^{\varepsilon - y(\mathbf{t})}\right)_+ \mathbf{P}(\mathbf{t})$$

The distribution of each privacy loss random variable $y(t; P, Q), t \sim P$ is light-tailed, which means that for the rare event where $y(\mathbf{t}) = \sum_{i=1}^k y(t^{(i)}) > \varepsilon$, it is most likely that there is only *one* outlier t^* among all $\{t^{(i)}\}_{i=1}^k$ such that $y(t^*)$ is large (which means that $y(\mathbf{t})$ is also large), and all the rest of $y(t^{(i)})$ s are small. Hence, a reasonable alternative distribution can just tilt the distribution of a randomly picked $t^{(i)}$, and leave the rest of $k - 1$ distributions to stay the same. Moreover, θ is selected to *approximately* minimize the variance of $\widehat{\delta}_{\text{IS}, \theta}$ (detailed in Appendix C.2). An intuitive way to see it is that $y(\theta) = \varepsilon$, which significantly improves the probability where $y(\mathbf{t}) \geq \varepsilon$ while also accounting for the fact that $P(t)$ decays exponentially fast as t increases.

We also empirically verify the advantage of the IS estimator over the SMC estimator. The orange curve in Figure 6 (a) shows the empirical estimate of $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$ which quantifies the variance of $\widehat{\delta}_{\text{IS}, \theta}$. Note that $\theta = 0$ corresponds to the case of $\widehat{\delta}_{\text{MC}}$. As we can see, $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$ drops quickly as θ increases, and eventually converges. We can also see that the θ selected by our heuristic in Definition 12 (marked as red ‘*’) approximately corresponds to the lowest point of $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$. This validates our theoretical justification for the selection of θ .

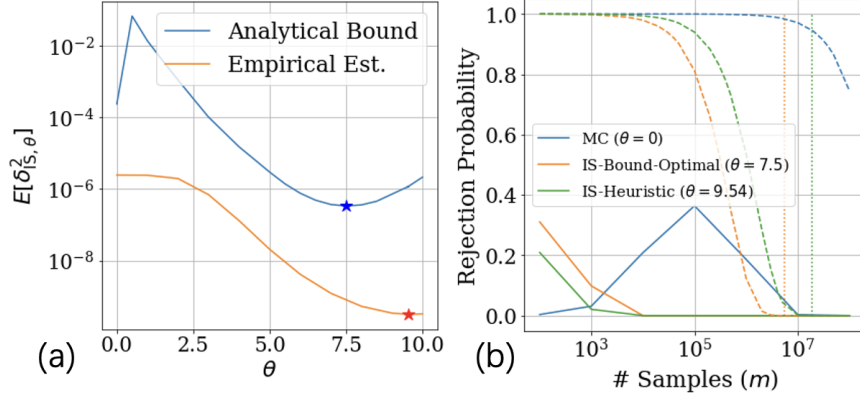

Figure 6: We examine the properties of MC-based DP verifiers for Poisson Subsampled mechanism. We set $q = 10^{-3}, \sigma = 0.6, \varepsilon = 1.5, k = 100$. $\delta_Y(\varepsilon) \approx 7.7 \times 10^{-6}$ in this case. **(a)** Plot for the upper bound and empirical estimate of $\mathbb{E}[\widehat{\delta}_{\text{MC}}^2]$ and $\mathbb{E}[\widehat{\delta}_{\text{IS},\theta}^2]$. The upper bounds are computed by Corollary 16 (for $\mathbb{E}[\widehat{\delta}_{\text{MC}}^2]$) and Theorem 17 (for $\mathbb{E}[\widehat{\delta}_{\text{IS},\theta}^2]$). Note that $\theta = 0$ corresponds to $\widehat{\delta}_{\text{MC}}$. The red star indicates the second moment for the value of θ selected by our heuristic in Definition 12. The blue star indicates the θ that minimizes the analytical bound. **(b)** Empirical estimate of the rejection probability $\Pr[\widehat{\delta}_{\text{IS},\theta}^m > \delta^{\text{est}}/\tau - \Delta]$ scaled with the number of samples m . We set $\delta^{\text{est}} = 0.8\delta_Y(\varepsilon), \tau = 10^{-5}/\delta^{\text{est}}$, and we set Δ following the heuristic proposed in Section 4.4.

C.2 Justification of the Heuristic of Choosing Exponential Tilting Parameter θ

The variance of the IS estimator proposed in Definition 12 is given by

$$\begin{aligned}
& \mathbb{E}_{\mathbf{t} \sim \mathbf{P}_\theta} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{\mathbf{P}(\mathbf{t})}{\mathbf{P}_\theta(\mathbf{t})} \right)^2 \right] \\
&= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{\mathbf{P}(\mathbf{t})}{\mathbf{P}_\theta(\mathbf{t})} \right)^2 \right] \\
&= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{k} \sum_{i=1}^k \frac{P_\theta(t_i)}{P(t_i)} \right)^{-1} \right] \\
&= k M_P(\theta) \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right)^2 \right]
\end{aligned}$$

Let $S(\theta) := k M_P(\theta) \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right)^2 \right]$. We aim to find θ that minimizes $S(\theta)$.

Note that

$$M_P(\theta) = (1 - q) e^{\frac{1}{2}\sigma^2\theta^2} + q e^{\theta + \frac{1}{2}\sigma^2\theta^2} \quad (5)$$

To simplify the notation, let $b(\mathbf{t}) := \left(1 - e^{\varepsilon - y(\mathbf{t})} \right)_+^2 \prod_{i=1}^k P_0(t_i)$.

$$\frac{\partial}{\partial \theta} S(\theta) = \left[(1-q)e^{\frac{1}{2}\sigma^2\theta^2}(\sigma^2\theta) + qe^{\theta+\frac{1}{2}\sigma^2\theta^2}(1+\sigma^2\theta) \right] \int \dots \int b(\mathbf{t}) \left(\sum_{i=1}^k e^{\theta t_i} \right)^{-1} dt \quad (6)$$

$$- \left[(1-q)e^{\frac{1}{2}\sigma^2\theta^2} + qe^{\theta+\frac{1}{2}\sigma^2\theta^2} \right] \int \dots \int b(\mathbf{t}) \frac{\sum_{i=1}^k e^{\theta t_i t_i}}{\left(\sum_{i=1}^k e^{\theta t_i} \right)^2} dt \quad (7)$$

By setting $\frac{\partial}{\partial \theta} S(\theta) = 0$ and simplify the expression, we have

$$\frac{(1-q+qe^\theta)(\sigma^2\theta) + qe^\theta}{1-q+qe^\theta} = \frac{\int \dots \int b(\mathbf{t}) \frac{\sum_{i=1}^k e^{\theta t_i t_i}}{\left(\sum_{i=1}^k e^{\theta t_i} \right)^2} dt}{\int \dots \int b(\mathbf{t}) \left(\sum_{i=1}^k e^{\theta t_i} \right)^{-1} dt} \quad (8)$$

As we mentioned earlier, $b(\mathbf{t}) > 0$ only when $y(\mathbf{t}) = \sum_{i=1}^k y(t^{(i)}) > \varepsilon$, and for such an event it is most likely that there is only *one outlier* t^* among all $\{t^{(i)}\}_{i=1}^k$ such that $y(t^*) \approx \varepsilon$, and all the rest of $y(t^{(i)}) \approx 0$. Therefore, a simple but surprisingly effective approximation for the RHS of (8) is

$$\frac{\int \dots \int b(\mathbf{t}) \frac{\sum_{i=1}^k e^{\theta t_i t_i}}{\left(\sum_{i=1}^k e^{\theta t_i} \right)^2} dt}{\int \dots \int b(\mathbf{t}) \left(\sum_{i=1}^k e^{\theta t_i} \right)^{-1} dt} \approx \frac{b(t)e^{-\theta t}}{b(t)e^{-\theta t}} = t \quad (9)$$

for t s.t. $y(t) = \varepsilon$. This leads to an approximate solution

$$\theta^* = \frac{1}{2\sigma^2} + \log((\exp(\varepsilon) - (1-q))/q) \quad (10)$$

D Sample Complexity for Achieving Target False Positive Rate

To derive the sample complexity for achieving a DP verifier with a target false positive rate, we use Bennett's inequality.

Theorem 13 (Bennett's inequality). *Let X_1, \dots, X_n be independent real-valued random variables with finite variance such that $X_i \leq b$ for some $b > 0$ almost surely for all $1 \leq i \leq n$. Let $\nu \geq \sum_{i=1}^n \mathbb{E}[X_i^2]$. For any $t > 0$, we have*

$$\Pr \left[\sum_{i=1}^n X_i - \mathbb{E}[X_i] \geq t \right] \leq \exp \left(-\frac{\nu}{b^2} h \left(\frac{bt}{\nu} \right) \right) \quad (11)$$

where $h(x) = (1+x) \log(1+x) - x$ for $x > 0$.

Theorem 10. *Suppose $\mathbb{E} \left[\left(\widehat{\delta}_{\text{MC}} \right)^2 \right] \leq \nu$. DPV instantiated by $\widehat{\delta}_{\text{MC}}^m$ has bounded τ -relaxed false positive rate $\text{FP}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \tau) \leq \delta^{\text{est}}/\tau$ with $m \geq \frac{2\nu}{\Delta^2} \log(\tau/\delta^{\text{est}})$.*

Proof. For any \mathcal{M} s.t. $\delta^{\text{est}} < \tau\delta_Y(\varepsilon)$, we have

$$\begin{aligned} \Pr \left[\widehat{\delta}_{\text{MC}}^m(\varepsilon; Y) < \delta^{\text{est}}/\tau - \Delta \right] &\leq \Pr \left[\widehat{\delta}_{\text{MC}}^m(\varepsilon; Y) < \delta_Y(\varepsilon) - \Delta \right] \\ &= \Pr \left[\frac{1}{m} \sum_{i=1}^m (\widehat{\delta}_{\text{MC}}^{(i)} - \delta_Y(\varepsilon)) < -\Delta \right] \\ &= \Pr \left[\sum_{i=1}^m (\delta_Y(\varepsilon) - \widehat{\delta}_{\text{MC}}^{(i)}) > m\Delta \right] \end{aligned} \quad (12)$$

Since $\widehat{\delta}_{\text{MC}} \in [-1, 0]$, the condition in Bennett's inequality is satisfied with $b \rightarrow 0^+$. Hence, (12) can be upper bounded by

$$\begin{aligned} (12) &\leq \lim_{b \rightarrow 0^+} \exp \left(-\frac{m\nu}{b^2} h \left(\frac{b\Delta}{\nu} \right) \right) \\ &= \exp \left(-\frac{m\Delta^2}{2\nu} \right) \end{aligned}$$

By setting $\exp \left(-\frac{m\Delta^2}{2\nu} \right) \leq \delta^{\text{est}}/\tau$, we have

$$m \geq \frac{2\nu}{\Delta^2} \log(\tau/\delta^{\text{est}})$$

□

E Proofs for Moment Bound

E.1 Overview

A good upper bound for $\mathbb{E}\left[\left(\widehat{\delta}_{\text{MC}}\right)^2\right]$ (or $\mathbb{E}\left[\left(\widehat{\delta}_{\text{IS}}\right)^2\right]$) is important for the computational efficiency of MC-based DPV, as suggested by Theorem 10.

We upper bound the higher moment of $\widehat{\delta}_{\text{MC}}$ through the RDP guarantee for the composed mechanism \mathcal{M} . This is a natural idea since converting RDP to upper bounds for $\delta_Y(\varepsilon)$ – the first moment of $\widehat{\delta}_{\text{MC}}$ – is a well-studied problem (Mironov, 2017; Canonne et al., 2020; Asoodeh et al., 2021). Recall that the RDP guarantee for \mathcal{M} is equivalent to a bound for $M_Y(\lambda) := \mathbb{E}[e^{\lambda Y}]$ for \mathcal{M} 's privacy loss random variable Y for any $\lambda \geq 0$.

Lemma 14 (RDP-MGF conversion). *If a mechanism \mathcal{M} is $(\alpha, \varepsilon_{\text{R}}(\alpha))$ -RDP, then $M_Y(\lambda) \leq \exp(\lambda \varepsilon_{\text{R}}(\lambda + 1))$.*

We convert an upper bound for $M_Y(\cdot)$ into the following guarantee for the higher moment of $\widehat{\delta}_{\text{MC}} = (1 - e^{\varepsilon - Y})_+$.

Theorem 15. *For any $u \geq 1$, we have*

$$\mathbb{E}[(\widehat{\delta}_{\text{MC}})^u] = \mathbb{E}[(1 - e^{\varepsilon - Y})_+^u] \leq \min_{\lambda \geq 0} M_Y(\lambda) e^{-\varepsilon \lambda} \frac{u^u \lambda^\lambda}{(u + \lambda)^{u + \lambda}}$$

The proof is deferred to Appendix E.2. The basic idea is to find the smallest constant c such that $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^u] \leq c M_Y(\lambda)$. By setting $u = 1$, our result recovers the RDP-DP conversion from Canonne et al. (2020). By setting $u = 2$, we obtain the desired bound for $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]$.

Corollary 16. $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2] \leq \min_{\lambda \geq 0} M_Y(\lambda) e^{-\varepsilon \lambda} \frac{4\lambda^\lambda}{(\lambda + 2)^{\lambda + 2}}$.

Corollary 16 applies to any mechanisms where the RDP guarantee is available, which covers a wide range of commonly used mechanisms such as (Subsampled) Gaussian or Laplace mechanism. We also note that one may be able to further tighten the above bound similar to the optimal RDP-DP conversion in Asoodeh et al. (2021). We leave this as an interesting future work.

Next, we derive the upper bound for $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$ for Poisson Subsampled Gaussian mechanism.

Theorem 17. *For any positive integer λ , and for any $a, b \geq 1$ s.t. $1/a + 1/b = 1$, we have $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2] \leq k M_P(\theta) \left(\mathbb{E}[\widehat{\delta}_{\text{MC}}^{2a}]\right)^{1/a} \cdot \left(b \theta e^{-\lambda \varepsilon} \int [r(\lambda, x)]^k e^{-b \theta x} dx\right)^{1/b}$ where $r(\lambda, x)$ is an upper bound for $\Pr_{t \sim \mathcal{P}}[\max_i t_i \leq x, y(\mathbf{t}) \geq \varepsilon]$ detailed in Appendix E.3.*

The proof is based on applying Hölder's inequality to the expression of $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$, and then bound the part where θ is involved: $\mathbb{E}_{\mathbf{t} \sim \mathcal{P}} \left[\left(\frac{1}{k} \sum_{i=1}^k \frac{P_\theta(t_i)}{P(t_i)} \right)^{-1} \right]$. We can bound $\mathbb{E}[\widehat{\delta}_{\text{MC}}^{2a}]$ through Theorem 15.

Figure 6 (a) shows the analytical bound from Corollary 16 and Theorem 17 compared with empirically estimated $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]$ and $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$. As we can see, the analytical bound for $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2]$ for relatively large θ is much smaller than the bound for $\mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]$ (i.e., $\theta = 0$ in the plot). Moreover, we find that the θ which minimizes the analytical bound (the blue ‘*’) is *close* to the θ selected by our heuristic (the red ‘*’). For computational efficiency, one may prefer to use θ that minimizes the analytical bound. However, the heuristically selected θ is still useful when one simply wants to estimate $\delta_Y(\varepsilon)$ and does not require the formal, analytical guarantee for the false positive rate. We see such a

scenario when we introduce the MC accountant in Section 5. We also note that such a discrepancy (and the gap between the analytical bound and empirical estimate) is due to the use of Hölder's inequality in bounding $\mathbb{E}[(\widehat{\boldsymbol{\delta}}_{\text{IS},\theta})^2]$. Further tightening the bound for $\mathbb{E}[(\widehat{\boldsymbol{\delta}}_{\text{IS},\theta})^2]$ is important for future work.

E.2 Moment Bound for Simple Monte Carlo Estimator

Theorem 15. *For any $u \geq 1$, we have*

$$\mathbb{E}[(\widehat{\boldsymbol{\delta}}_{\text{MC}})^u] = \mathbb{E}[(1 - e^{\varepsilon-Y})_+^u] \leq \min_{\lambda \geq 0} M_Y(\lambda) e^{-\varepsilon\lambda} \frac{u^u \lambda^\lambda}{(u + \lambda)^{u+\lambda}}$$

Proof.

$$\mathbb{E}[(1 - e^{\varepsilon-Y})_+^u] = \int (1 - e^{\varepsilon-x})_+^u P(x) dx \quad (13)$$

$$= M_Y(\lambda) \int (1 - e^{\varepsilon-x})_+^u e^{-\lambda x} \frac{P(x) e^{\lambda x}}{\mathbb{E}[e^{\lambda Y}]} dx \quad (14)$$

$$= M_Y(\lambda) \mathbb{E}_{x \sim P_\theta} [(1 - e^{\varepsilon-x})_+^u e^{-\lambda x}] \quad (15)$$

$$= M_Y(\lambda) e^{-\lambda \varepsilon} \mathbb{E}_{x \sim P_\theta} [(1 - e^{\varepsilon-x})_+^u e^{(\varepsilon-x)\lambda}] \quad (16)$$

where $P_\lambda(x) := \frac{P(x) e^{\lambda x}}{\mathbb{E}[e^{\lambda Y}]}$ is the exponential tilting of P . Define $f(x, \lambda) := (1 - e^{-x})_+^u e^{-x\lambda}$. When $x \leq 0$, $f(x, \lambda) = 0$. When $x > 0$, the derivative of f with respect to x is

$$\frac{\partial f(x, \lambda)}{\partial x} = e^{-x\lambda} (1 - e^{-x})^{u-1} [e^{-x}(u + \lambda) - \lambda] \quad (17)$$

It is easy to see that the maximum of $f(x, \lambda)$ is achieved at $x^* = \log\left(\frac{u+\lambda}{\lambda}\right)$, and we have

$$\max_x f(x, \lambda) = \left(\frac{u}{u + \lambda}\right)^u \left(\frac{\lambda}{u + \lambda}\right)^\lambda \quad (18)$$

$$= \frac{u^u \lambda^\lambda}{(u + \lambda)^{u+\lambda}} \quad (19)$$

Overall, we have

$$\mathbb{E}[(1 - e^{\varepsilon-Y})_+^u] \leq M_Y(\lambda) e^{-\varepsilon\lambda} \frac{u^u \lambda^\lambda}{(u + \lambda)^{u+\lambda}} \quad (20)$$

□

E.3 Moment Bound for Importance Sampling Estimator

Theorem 18. *For any $\theta \geq 1/\sigma^2$, we have*

$$\mathbb{E}[(\widehat{\boldsymbol{\delta}}_{\text{IS},\theta})^2] \leq M_P(\theta) \left[\frac{1}{k} \left(\frac{\varepsilon}{q} + k \right) \right]^{-\theta\sigma^2} e^{-\theta/2} \mathbb{E}[(\widehat{\boldsymbol{\delta}}_{\text{MC}})^2]$$

Proof.

$$\mathbb{E}_{\mathbf{t} \sim P_\theta} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{\mathbf{P}(\mathbf{t})}{P_\theta(\mathbf{t})}\right)^2 \right] \quad (21)$$

$$= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{\mathbf{P}(\mathbf{t})}{P_\theta(\mathbf{t})}\right) \right] \quad (22)$$

$$= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{1}{k} \sum_{i=1}^k \frac{P_\theta(t_i)}{P(t_i)}\right)^{-1} \right] \quad (23)$$

$$= M_P(\theta) \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{k}{\sum_{i=1}^k e^{\theta t_i}}\right) \right] \quad (24)$$

Note that

$$\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{k}{\sum_{i=1}^k e^{\theta t_i}}\right) \right] \quad (25)$$

$$= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})}\right)_+^2 \left(\frac{k}{\sum_{i=1}^k e^{\theta t_i}}\right) I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \quad (26)$$

Lemma 19. *When $y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) = \sum_{i=1}^k \log(1 - q + qe^{(2t_i - 1)/(2\sigma^2)}) \geq \varepsilon$ and $\theta\sigma^2 \geq 1$, we have*

$$\sum_{i=1}^k e^{\theta t_i} \geq k \left[\frac{1}{k} \left(\frac{\varepsilon}{k} + k\right) e^{1/(2\sigma^2)} \right]^{\theta\sigma^2} \quad (27)$$

Proof. Since $\log(1 + x) \leq x$, we have

$$\varepsilon \leq \sum_{i=1}^k \log(1 - q + qe^{(2t_i - 1)/(2\sigma^2)}) \quad (28)$$

$$\leq \sum_{i=1}^k q \left(e^{(2t_i - 1)/(2\sigma^2)} - 1 \right) \quad (29)$$

Hence,

$$\sum_{i=1}^k e^{t_i/\sigma^2} \geq \left(\frac{\varepsilon}{q} + k\right) e^{1/(2\sigma^2)} \quad (30)$$

Hence,

$$\begin{aligned}
\sum_{i=1}^k e^{t_i \theta} &= \sum_{i=1}^k \left(e^{t_i / \sigma^2} \right)^{\theta \sigma^2} = k \left[\frac{1}{k} \sum_{i=1}^k \left(e^{t_i / \sigma^2} \right)^{\theta \sigma^2} \right] \\
&\geq k \left[\frac{1}{k} \sum_{i=1}^k \left(e^{t_i / \sigma^2} \right) \right]^{\theta \sigma^2} \\
&\geq k \left[\frac{1}{k} \left(\frac{\varepsilon}{q} + k \right) e^{1/(2\sigma^2)} \right]^{\theta \sigma^2} \\
&= k \left[\frac{1}{k} \left(\frac{\varepsilon}{q} + k \right) \right]^{\theta \sigma^2} e^{\theta/2}
\end{aligned}$$

where the first inequality is due to Jensen's inequality. \square

By Lemma 19, we have

$$\begin{aligned}
(24) &\leq M_P(\theta) \frac{1}{\left[\frac{1}{k} \left(\frac{\varepsilon}{q} + k \right) \right]^{\theta \sigma^2} e^{\theta/2}} \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \right] \\
&= M_P(\theta) \left[\frac{1}{k} \left(\frac{\varepsilon}{q} + k \right) \right]^{-\theta \sigma^2} e^{-\theta/2} \mathbb{E}[(\widehat{\delta}_{\text{MC}})^2]
\end{aligned}$$

which concludes the proof. \square

Theorem 20. For any positive integer λ , we have

$$\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2] \leq k M_P(\theta) \theta e^{-\lambda \varepsilon} \int [r(\lambda, x)]^k e^{-\theta x} dx \quad (31)$$

where $r(\lambda, x)$ is an upper bound for the MGF of privacy loss random variable of truncated Gaussian mixture $P|_{\leq x}$.

Proof. Similar to Theorem 18, the goal is to bound

$$k M_P(\theta) \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right) \right]$$

Note that

$$\begin{aligned}
&\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right) \right] \\
&= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right) I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \\
&\leq \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\frac{1}{\sum_{i=1}^k e^{\theta t_i}} I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \\
&\leq \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\frac{1}{e^{\theta t_{\max}}} I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \quad (32)
\end{aligned}$$

where $t_{\max} := \max_i t_i$.

Further note that

$$\begin{aligned}
(32) &= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[e^{-\theta t_{\max}} I[y(\mathbf{t}) \geq \varepsilon] \right] \\
&= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[e^{-\theta t_{\max}} |y(\mathbf{t}) \geq \varepsilon \right] \Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon] \\
&= \left(\int e^{-\theta x} d \Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x] \right) \Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon] \\
&= - \left(\int \Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x | y(\mathbf{t}) \geq \varepsilon] d e^{-\theta x} \right) \Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon] \tag{33}
\end{aligned}$$

$$= \theta \int \Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x, y(\mathbf{t}) \geq \varepsilon] e^{-\theta x} dx \tag{34}$$

where (33) is obtained through integration by parts.

Now, as we can see from (34), the question reduces to bound $\Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x, y(\mathbf{t}) \geq \varepsilon]$ for any $x \in \mathbb{R}$. It might be easier to write

$$\Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x, y(\mathbf{t}) \geq \varepsilon] = \Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon | t_{\max} \leq x] \Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x]$$

and we know that

$$\Pr_{\mathbf{t} \sim \mathbf{P}} [t_{\max} \leq x] = \left(\Pr_{t \sim P} [t \leq x] \right)^k \tag{35}$$

$$= \left((1 - q)\Phi(x; 0, \sigma^2) + q\Phi(x; 1, \sigma^2) \right)^k \tag{36}$$

as all t_i s are i.i.d. random samples from P , where $\Phi(\cdot; \mu, \sigma^2)$ is the CDF of Gaussian distribution with mean μ and variance σ^2 .

It remains to bound the conditional probability $\Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon | t_{\max} \leq x]$, it may be easier to see it in this way:

$$\begin{aligned}
&\Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon | t_{\max} \leq x] \\
&= \Pr_{\mathbf{t} \sim \mathbf{P}} [y(\mathbf{t}) \geq \varepsilon | t_1 \leq x, \dots, t_k \leq x] \\
&= \Pr_{\mathbf{t} \sim \mathbf{P}} \left[\sum_{i=1}^k y(t_i) \geq \varepsilon | y(t_1) \leq y(x), \dots, y(t_k) \leq y(x) \right] \\
&\leq \frac{\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[e^{\lambda \sum_{i=1}^k y(t_i)} \geq e^{\lambda \varepsilon} | y(t_1) \leq y(x), \dots, y(t_k) \leq y(x) \right]}{e^{\lambda \varepsilon}}
\end{aligned}$$

where the last step is due to Chernoff bound which holds for any $\lambda > 0$. Now we only need to bound the moment generating function for $y(t) = \log(1 - q + qe^{\frac{2t-1}{2\sigma^2}})$, $t \sim P|_{\leq x}$, where $P|_{\leq x}$ is the truncated distribution of P . We note that this is equivalent to bounding the Rényi divergence for truncated Gaussian mixture distribution.

Recall that $P = (1 - q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$. For any λ that is a positive integer, we have

$$\begin{aligned} & \mathbb{E}_{t \sim P} \left[e^{\lambda y(t)} I[t \leq x] \right] \\ &= \frac{1}{\sqrt{2\pi}\sigma} \left[(1 - q) \int_{-\infty}^x \left(1 - q + qe^{\frac{2t-1}{2\sigma^2}} \right)^\lambda e^{-\frac{t^2}{2\sigma^2}} dt + q \int_{-\infty}^x \left(1 - q + qe^{\frac{2t-1}{2\sigma^2}} \right)^\lambda e^{-\frac{(t-1)^2}{2\sigma^2}} dt \right] \\ &= \frac{1}{2} \left(qe^{-\frac{1}{2\sigma^2}} \right)^\lambda \sum_{i=0}^{\lambda} \binom{\lambda}{i} \tilde{q}^i \left[(1 - q) e^{\frac{(\lambda-i)^2}{2\sigma^2}} \left(\operatorname{erf} \left(\frac{x - (\lambda - i)}{\sqrt{2}\sigma} \right) + 1 \right) + q e^{\frac{(\lambda-i+1)^2}{2\sigma^2}} \left(\operatorname{erf} \left(\frac{x - (\lambda - i + 1)}{\sqrt{2}\sigma} \right) + 1 \right) \right] \end{aligned} \quad (37)$$

where $\tilde{q} := \frac{(1-q)\exp(1/(2\sigma^2))}{q}$. Note that the above expression can be efficiently computed. Denote the above results as $r(\lambda, x) := (37)$. Hence

$$\mathbb{E}_{t \sim P} \left[e^{\lambda y(t)} | t \leq x \right] = \frac{r(\lambda, x)}{\Pr_{t \sim P}[t \leq x]} \quad (38)$$

Now we have

$$\begin{aligned} \Pr_{t \sim P} [y(\mathbf{t}) \geq \varepsilon | t_{\max} \leq x] &\leq \frac{\mathbb{E}_{t \sim P} \left[e^{\lambda \sum_{i=1}^k y(t_i)} \geq e^{\lambda \varepsilon} | t_{\max} \leq x \right]}{e^{\lambda \varepsilon}} \\ &= \frac{[r(\lambda, x)]^k}{e^{\lambda \varepsilon} (\Pr_{t \sim P}[t \leq x])^k} \end{aligned}$$

Plugging this bound into (34), we have

$$\begin{aligned} (32) &= \theta \int \Pr_{t \sim P} [t_{\max} \leq x, y(\mathbf{t}) \geq \varepsilon] e^{-\theta x} dx \\ &\leq \theta e^{-\lambda \varepsilon} \int [r(\lambda, x)]^k e^{-\theta x} dx \end{aligned}$$

which leads to the final conclusion. \square

Remark 21. In practice, we can further improve the bound by moving the minimum operation inside the integral:

$$\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2] \leq kM_P(\theta)\theta e^{-\lambda \varepsilon} \int \left[\min_{\lambda} r(\lambda, x) \right]^k e^{-\theta x} dx \quad (39)$$

Of course, this bound will be less efficient to compute.

Theorem 17. For any positive integer λ , and for any $a, b \geq 1$ s.t. $1/a + 1/b = 1$, we have $\mathbb{E}[(\widehat{\delta}_{\text{IS}, \theta})^2] \leq kM_P(\theta) \left(\mathbb{E}[\widehat{\delta}_{\text{MC}}^{2a}] \right)^{1/a} \cdot \left(b\theta e^{-\lambda \varepsilon} \int [r(\lambda, x)]^k e^{-b\theta x} dx \right)^{1/b}$ where $r(\lambda, x)$ is an upper bound for $\Pr_{t \sim P}[\max_i t_i \leq x, y(\mathbf{t}) \geq \varepsilon]$ detailed in Appendix E.3.

Proof. Note that Theorem 18 and Theorem 20 can both be viewed as two special cases of Hölder's inequality: for any $a, b \geq 1$ s.t. $\frac{1}{a} + \frac{1}{b} = 1$, we have

$$\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right) \right] \quad (40)$$

$$= \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^2 \left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right) I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \quad (41)$$

$$\leq \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^{2a} \right]^{1/a} \mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right)^b I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right]^{1/b} \quad (42)$$

Theorem 18 corresponds to the case where $a = 1$, and Theorem 20 corresponds to the case where $b = 1$. We can actually tune the parameters a and b to see if we can obtain any better bounds, as we have

$$\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(1 - e^{\varepsilon - y(\mathbf{t}; \mathbf{P}, \mathbf{Q})} \right)_+^{2a} \right] \leq \mathbb{E}[\widehat{\delta}_{\text{MC}}^{2a}] \quad (43)$$

and

$$\mathbb{E}_{\mathbf{t} \sim \mathbf{P}} \left[\left(\frac{1}{\sum_{i=1}^k e^{\theta t_i}} \right)^b I[y(\mathbf{t}; \mathbf{P}, \mathbf{Q}) \geq \varepsilon] \right] \leq b\theta e^{-\lambda\varepsilon} \int [r(\lambda, x)]^k e^{-b\theta x} dx \quad (44)$$

Simply combining the above inequalities leads to the final conclusion.

□

F Proofs for Utility

F.1 Overview

While one may be able to bound the false negative rate through similar techniques that we bound the false positive rate, i.e., applying the concentration inequalities, the guarantee may be loose. As a formal, strict guarantee for FN_{DPV} is not required, we provide a convenient heuristic of picking an appropriate Δ such that FN_{DPV} is *approximately* smaller than FP_{DPV} .

For any mechanism \mathcal{M} such that $\delta^{\text{est}} > \rho\delta_Y(\varepsilon)$, we have

$$\begin{aligned} & \Pr_{\text{DPV}} [\text{DPV}(\mathcal{M}, \varepsilon, \delta^{\text{est}}) = \text{False}] \\ &= \Pr [\widehat{\delta}_{\text{MC}}^m > \delta^{\text{est}}/\tau - \Delta] \\ &= \Pr [\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) > \delta^{\text{est}}/\tau - \delta_Y(\varepsilon) - \Delta] \\ &\leq \Pr [\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) > ((1/\tau - 1/\rho)\delta^{\text{est}} - \Delta)] \end{aligned}$$

and in the meantime, if $\delta^{\text{est}} < \tau\delta_Y(\varepsilon)$, we have

$$\Pr [\widehat{\delta}_{\text{MC}}^m < \delta^{\text{est}}/\tau - \Delta] \leq \Pr [\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) < -\Delta]$$

Our main idea is to find Δ such that

$$\begin{aligned} & \Pr [\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) > ((1/\tau - 1/\rho)\delta^{\text{est}} - \Delta)] \\ &\lesssim \Pr [\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) < -\Delta] \end{aligned}$$

In this way, we know that $\text{FN}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \rho)$ is upper bounded by $\Theta(\delta^{\text{est}}/\tau)$ for the same amount of samples we discussed in Section 4.3.

Observe that $\widehat{\delta}_{\text{MC}}$ (or $\widehat{\delta}_{\text{IS},\theta}$ with a not too large θ) is typically a highly asymmetric distribution with a significant probability of being zero, and the probability density decreases monotonically for higher values. Under such conditions, we prove the following results:

Theorem 22 (Informal). *When $m \geq \frac{2\nu}{\Delta^2} \log(\tau/\delta^{\text{est}})$, we have*

$$\Pr[\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) < -\Delta] \gtrsim \Pr[\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) > \frac{3}{2}\Delta]$$

The proof is deferred to Appendix F.2. Therefore, by setting $\Delta = 0.4(1/\tau - 1/\rho)\delta^{\text{est}}$, one can ensure that $\text{FN}_{\text{MC}}(\varepsilon, \delta^{\text{est}}; \rho)$ is also (approximately) upper bounded by $\Theta(\delta^{\text{est}}/\tau)$. We empirically verify the effectiveness of such a heuristic by estimating the actual false negative rate. As we can see from Figure 6 (b), the dashed curve is much higher than the two solid curves, which means that the false negative rate is a very conservative bound.

F.2 Technical Details

In this section, we provide theoretical justification for the heuristic of setting $\Delta = 0.4(1/\tau - 1/\rho)\delta^{\text{est}}$.

For notation convenience, throughout this section, we talk about $\widehat{\delta}_{\text{MC}}$, but the same argument also applies to $\widehat{\delta}_{\text{IS},\theta}$ with a not too large θ , unless otherwise specified. We use $\widehat{\delta}_{\text{MC}}(x)$ to denote the density of $\widehat{\delta}_{\text{MC}}$ at x . Note that $\widehat{\delta}_{\text{MC}}(0) = \infty$.

We make the following assumption about the distribution of $\widehat{\delta}_{\text{MC}}$.

Assumption 23. $\Pr[\widehat{\delta}_{\text{MC}} = 0] \geq 1/2$.

While intuitive, this assumption is hard to analyze for the case of Subsampled Gaussian mechanism. Therefore, we instead provide a condition for which the assumption holds for Pure Gaussian mechanism.

Lemma 24. Fix ε, σ . When $k/(2\sigma^2) \leq \varepsilon$, Assumption 23 holds.

Proof. The PRV for the composition of k Gaussian mechanism is $\mathcal{N}(\frac{k}{2\sigma^2}, \frac{k}{\sigma^2})$.

$$\Pr[(1 - e^{\varepsilon - Y})_+ = 0] = \Pr[Y \leq \varepsilon]$$

which is clearly $\geq 1/2$ when $k/(2\sigma^2) \leq \varepsilon$. □

We also empirically verify this assumption for Subsampled Gaussian mechanism as in Figure 7. As we can see, the θ selected by our heuristic (the red star) has $\Pr[\widehat{\delta}_{\text{IS},\theta} = 0] \approx 1/2$ which matches our principle of selecting θ . The θ minimizes the analytical bound (**which we are going to use in practice**) achieves $\Pr[\widehat{\delta}_{\text{IS},\theta} = 0] \approx 0.88 \gg 0.5$.

Figure 7: We empirically estimate $\Pr[\widehat{\delta}_{\text{IS},\theta} = 0]$ for the case of Poisson Subsampled Gaussian mechanism. We set $q = 10^{-3}, \sigma = 0.6, \varepsilon = 1.5, k = 100$. $\delta_Y(\varepsilon) \approx 7.7 \times 10^{-6}$ in this case. The red star indicates the second moment for the value of θ selected by our heuristic in Definition 12. The blue star indicates the θ that minimizes the analytical bound.

Our goal is to show that $\Pr[\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) < -\Delta^*] \gtrsim \Pr[\widehat{\delta}_{\text{MC}}^m - \delta_Y(\varepsilon) > \Delta^*]$ for large m . For notation

simplicity, we denote $\delta := \mathbb{E}[\widehat{\delta}_{\text{MC}}] = \delta_Y(\varepsilon)$ in the remaining of the section. We also denote

$$\begin{aligned} p_0 &:= \Pr[\widehat{\delta}_{\text{MC}} = 0] \\ p_{(0,1)} &:= \Pr[0 < \widehat{\delta}_{\text{MC}} < \delta] \\ p_{(1,2)} &:= \Pr[\delta \leq \widehat{\delta}_{\text{MC}} \leq 2\delta] \\ p_{(2,\infty)} &:= \Pr[\widehat{\delta}_{\text{MC}} \geq 2\delta] \end{aligned}$$

Note that $p_0 + p_{(0,1)} + p_{(1,2)} + p_{(2,\infty)} = 1$. We also write $\widehat{\delta}_{\text{MC}}|_{(a,b)}$ and $\widehat{\delta}_{\text{MC}}|_{[a,b]}$ to indicate the truncated distribution of $\widehat{\delta}_{\text{MC}}$ on (a, b) and $[a, b)$, respectively.

We first construct an alternative random variable $\widetilde{\delta}_{\text{MC}}$ with the following distribution:

$$\widetilde{\delta}_{\text{MC}} = \begin{cases} 2\delta - x & \text{for } x \sim \widehat{\delta}_{\text{MC}}|_{\geq 2\delta} & \text{w.p. } p_{(2,\infty)} \\ x & \text{for } x \sim \widehat{\delta}_{\text{MC}}|_{(0,\delta)} & \text{w.p. } p_{(0,1)} \\ 2\delta - x & \text{for } x \sim \widehat{\delta}_{\text{MC}}|_{(0,\delta)} & \text{w.p. } p_{(0,1)} \\ x & \text{for } x \sim \widehat{\delta}_{\text{MC}}|_{\geq 2\delta} & \text{w.p. } p_{(2,\infty)} \\ \delta & & \text{w.p. } 1 - 2(p_{(0,1)} + p_{(2,\infty)}) \end{cases} \quad (45)$$

This is a valid probability due to Assumption 23, as $p_{(0,1)} + p_{(2,\infty)} \leq 1 - p_0 \leq 1/2$. The distribution of $\widetilde{\delta}_{\text{MC}}$ is illustrated in Figure 8. Note that $\widetilde{\delta}_{\text{MC}}$ is a symmetric distribution with $\mathbb{E}[\widetilde{\delta}_{\text{MC}}] = \delta$.

Figure 8: Illustration for the density function of $\widetilde{\delta}_{\text{MC}}$ (black curve indicates the density curve for $\widehat{\delta}_{\text{MC}}$, and red curve indicates the density curve for $\widehat{\delta}_{\text{IS},\theta}$).

Similar to the notation of $\widehat{\delta}_{\text{MC}}^m$, we write $\widetilde{\delta}_{\text{MC}}^m := \frac{1}{m} \sum_{i=1}^m \widetilde{\delta}_{\text{MC}}^{(i)}$. We show an asymmetry result for $\widetilde{\delta}_{\text{MC}}^m$ in terms of δ .

Lemma 25. For any $\Delta^* \in \mathbb{R}$, we have

$$\Pr[\tilde{\delta}_{\text{MC}}^m - \delta < -\Delta^*] \geq \Pr[\tilde{\delta}_{\text{MC}}^m - \delta > \Delta^*] \quad (46)$$

Proof. Note that the above argument holds trivially when $m = 0, 1$. For $m \geq 2$, we use the induction argument. Suppose we have

$$\Pr[\tilde{\delta}_{\text{MC}}^{m-1} - \delta < -\Delta^*] \geq \Pr[\tilde{\delta}_{\text{MC}}^{m-1} - \delta > \Delta^*] \quad (47)$$

for any $\Delta^* \in \mathbb{R}$. That is,

$$\Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta < -(m-1)\Delta^*\right] \geq \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta > (m-1)\Delta^*\right] \quad (48)$$

for any $\Delta^* \in \mathbb{R}$.

$$\begin{aligned} \Pr[\tilde{\delta}_{\text{MC}}^m - \delta < -\Delta^*] &= \Pr\left[\sum_{i=1}^m \tilde{\delta}_{\text{MC}}^{(i)} - m\delta < -m\Delta^*\right] \\ &= \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta + \tilde{\delta}_{\text{MC}}^{(m)} - \delta < -m\Delta^*\right] \\ &= \int \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta < -m\Delta^* - x\right] \Pr[\tilde{\delta}_{\text{MC}}^{(m)} - \delta = x] dx \\ &\geq \int \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta > m\Delta^* + x\right] \Pr[\tilde{\delta}_{\text{MC}}^{(m)} - \delta = x] dx \\ &= \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta - (\tilde{\delta}_{\text{MC}}^{(m)} - \delta) > m\Delta^*\right] \\ &= \int \Pr\left[x - (\tilde{\delta}_{\text{MC}}^{(m)} - \delta) > m\Delta^*\right] \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta = x\right] dx \\ &= \int \Pr\left[\tilde{\delta}_{\text{MC}}^{(m)} - \delta < -m\Delta^* + x\right] \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta = x\right] dx \\ &\geq \int \Pr\left[\tilde{\delta}_{\text{MC}}^{(m)} - \delta > m\Delta^* - x\right] \Pr\left[\sum_{i=1}^{m-1} \tilde{\delta}_{\text{MC}}^{(i)} - (m-1)\delta = x\right] dx \\ &= \left[\sum_{i=1}^m \tilde{\delta}_{\text{MC}}^{(i)} - m\delta > m\Delta^*\right] \\ &= \left[\tilde{\delta}_{\text{MC}}^m - \delta > \Delta^*\right] \end{aligned}$$

where the two inequalities are due to the induction assumption. \square

Now we come back and analyze $\widehat{\delta}_{\text{MC}}^m$ by using Lemma 25.

$$\begin{aligned}
& \Pr \left[\widehat{\delta}_{\text{MC}}^m - \delta \leq -\Delta^* \right] \\
&= \Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m + \widetilde{\delta}_{\text{MC}}^m - \delta \leq -\Delta^* \right] \\
&\geq \Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m + \widetilde{\delta}_{\text{MC}}^m - \delta \leq -\Delta^* \mid \widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \\
&\geq \Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \delta \leq -\Delta^* - c \right] \\
&\geq \Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + c \right]
\end{aligned}$$

Similarly,

$$\begin{aligned}
& \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + c \right] \\
&= \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \widehat{\delta}_{\text{MC}}^m + \widehat{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + c \right] \\
&\geq \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \widehat{\delta}_{\text{MC}}^m \geq -c \right] \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \widehat{\delta}_{\text{MC}}^m + \widehat{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + c \mid \widetilde{\delta}_{\text{MC}}^m - \widehat{\delta}_{\text{MC}}^m \geq -c \right] \\
&\geq \Pr \left[\widetilde{\delta}_{\text{MC}}^m - \widehat{\delta}_{\text{MC}}^m \geq -c \right] \Pr \left[\widehat{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + 2c \right]
\end{aligned}$$

Overall, we have

$$\Pr \left[\widehat{\delta}_{\text{MC}}^m - \delta \leq -\Delta^* \right] \geq \left(\Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \right)^2 \Pr \left[\widehat{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + 2c \right] \quad (49)$$

for any $\Delta^* \in \mathbb{R}$. Note that the above argument does not require $\widehat{\delta}_{\text{MC}}^m$ and $\widetilde{\delta}_{\text{MC}}^m$ to be correlated. To maximize $\Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right]$, we can sample $\widetilde{\delta}_{\text{MC}}^m$ for a given $\widehat{\delta}_{\text{MC}}^m$ as follows: for each $\widehat{\delta}_{\text{MC}}^{(i)}$,

1. If $\widehat{\delta}_{\text{MC}}^{(i)} > 0$, then let $\widetilde{\delta}_{\text{MC}}^{(i)} = \widehat{\delta}_{\text{MC}}^{(i)}$.
2. If $\widehat{\delta}_{\text{MC}}^{(i)} = 0$, then with probability $p_{(2,\infty)}/p_0$, output $2\delta - x$ for $x \sim \widehat{\delta}_{\text{MC}}|_{(2,\infty)}$; with probability $p_{(0,1)}/p_0$ output $2\delta - x$ for $x \sim \widehat{\delta}_{\text{MC}}|_{(0,1)}$; with probability $1 - (p_{(0,1)} + p_{(2,\infty)})/p_0$ output δ .

Denote the random variable $\delta_{\text{diff}} := \widehat{\delta}_{\text{MC}} - \widetilde{\delta}_{\text{MC}}$. It is not hard to see that $\mathbb{E}[\delta_{\text{diff}}^2] \leq \mathbb{E}[\widehat{\delta}_{\text{MC}}^2] + \delta^2 \leq 2\mathbb{E}[\widehat{\delta}_{\text{MC}}^2]$. By Bennett's inequality, with $m \geq \frac{2\nu}{\Delta^2} \log(\tau/\delta^{\text{est}})$, we have

$$\Pr \left[\widehat{\delta}_{\text{MC}}^m - \widetilde{\delta}_{\text{MC}}^m \leq c \right] \gtrsim 1 - \frac{\tau}{\delta^{\text{est}}} \exp \left(-\frac{c^2}{\Delta^2} \right) \quad (50)$$

$$= 1 - O \left(\frac{\tau}{\delta^{\text{est}}} \right) \quad (51)$$

if we set $c = O(\Delta)$. Let $c = \frac{1}{4}\Delta$, then by setting $-\Delta^* = -\Delta$ and $\Delta^* + 2c = (1/\tau - 1/\rho) \delta^{\text{est}} - \Delta$, we have $\Delta = 0.4(1/\tau - 1/\rho) \delta^{\text{est}}$.

To summarize, when we set Δ with the heuristic, we have

$$\Pr \left[\widehat{\delta}_{\text{MC}}^m - \delta \geq \Delta^* + 2c \right] \lesssim \frac{\tau/\delta^{\text{est}}}{\left(1 - O\left(\frac{\tau}{\delta^{\text{est}}}\right)\right)^2} \quad (52)$$

$$\approx \tau/\delta^{\text{est}} \quad (53)$$

G Experiment Settings & Additional Results

G.1 GPU Acceleration for MC Sampling

MC-based techniques are well-suited for parallel computing and GPU acceleration due to their nature of repeated sampling. One can easily utilize PyTorch’s CUDA functionality, e.g.,

```
torch.randn(size=(k,m)).cuda()*sigma+mu
```

, to significantly boost the computational efficiency. Figure 9 (a) shows that when using a NVIDIA A100-SXM4-80GB GPU, the execution time of sampling Gaussian mixture $((1 - q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2))$ can be improved by 10^3 times compared with CPU-only scenario. Figure 9 (b) shows the predicted runtime for different target false positive rate for $k = 1000$. We vary σ and set the target false positive rate as the smallest $s \times 10^{-r}$ that is greater than $\delta_Y(\varepsilon)$, where $s \in \{1, 5\}$ and r is positive integer. We set $\delta^{\text{est}} = 0.8\delta_Y(\varepsilon)$, and τ, ρ, Δ are set as the heuristics introduced in the previous sections. The runtime is predicted by the number of required samples for the given false positive rate. As we can see, even when we target at 10^{-10} false positive rate (which means that $\Delta \approx 10^{-10}$), the clock time is still acceptable (around 3 hours).

Figure 9: The execution time of sampling Gaussian mixture $((1 - q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2))$ when only using CPU and when using a NVIDIA A100-SXM4-80GB GPU.

G.2 Experiment for Evaluating EVR Paradigm

G.2.1 Settings

For Figure 1 & Figure 3, the FFT-based method has hyperparameter being set as $\varepsilon_{\text{error}} = 10^{-3}, \delta_{\text{error}} = 10^{-10}$. For the GDP-Edgeworth accountant, we use the second-order expansion and uniform bound, following Wang et al. (2022a).

For Figure 4 (as well as Figure 11), the BEiT (Bao et al., 2021) is first self-supervised pretrained on ImageNet-1k and then trained finetuned on ImageNet-21k, following the state-of-the-art approach in Panda et al. (2022). For DP-GD training, we set σ as 28.914, clipping norm as 1, learning rate as 2, and we train for at most 60 iterations, and we only finetune the last layer on CIFAR-100.

G.2.2 Additional Results

$k \rightarrow \varepsilon_{Y^{(k)}}(\delta)$ curve. We show additional results for a more common setting in privacy-preserving machine learning where one set a target δ and try to find $\varepsilon_{Y^{(k)}}(\delta)$ for different k , the number of individual mechanisms in the composition. We use $Y^{(k)}$ to stress that the PRV Y is for the composition of k mechanisms. Such a scenario can happen when one wants to find the optimal stopping iteration for training a differentially private neural network.

Figure 10 shows such a result for Poisson Subsampled Gaussian where we set subsampling rate 0.01, $\sigma = 2$, and $\delta = 10^{-5}$. We set $\varepsilon_{\text{error}} = 10^{-1}, \delta_{\text{error}} = 10^{-10}$ for the FFT method. The estimate in this case is obtained by fixing $\delta^{\text{est}} = \tau\delta$ and find the corresponding estimate for ε through FFT-based method (Gopi et al., 2021). As we can see, the EVR paradigm achieves a much tighter privacy analysis compared with the upper bound derived by FFT-based method. The runtime of privacy verification in this case is < 15 minutes for all k s.

Figure 10: $k \rightarrow \varepsilon_{Y^{(k)}}(\delta)$ curve for Poisson Subsampled Gaussian mechanism for subsampling rate 0.01, $\sigma = 2$, and $\delta = 10^{-5}$. When running on an NVIDIA A100-SXM4-80GB GPU, the runtime of privacy verification is < 15 minutes.

Privacy-Utility Tradeoff. We show additional results for the privacy-utility tradeoff curve when finetuning ImageNet-pretrained BEiT on CIFAR100 dataset with DP stochastic gradient descent (DP-SGD). For DP-SGD training, we set σ as 5.971, clipping norm as 1, learning rate as 0.2, momentum as 0.9, batch size as 4096, and we train for at most 360 iterations (30 epochs). We only finetune the last layer on CIFAR-100.

As shown in Figure 11 (a), the EVR paradigm provides a better utility-privacy tradeoff compared with the traditional upper bound method. In Figure 11 (b), we show the runtime of DP verification when $\rho = (1 + \tau)/2$ and we set Δ according to Theorem 11 (which ensures EVR’s failure probability is negligible). The runtime is estimated on an NVIDIA A100-SXM4-80GB GPU. As we can see, it only takes a few minutes for privacy verification, which is short compared with hours of model training.

Figure 11: (a) Utility-privacy tradeoff curve for fine-tuning ImageNet-pretrained BEiT (Bao et al., 2021) on CIFAR100 when $\delta = 10^{-12}$ with DPSGD. We follow the training hyperparameters from Panda et al. (2022). (b) Runtime of privacy verification in the EVR paradigm. For fair comparison, we set $\rho = (1 + \tau)/2$ and set Δ according to Theorem 11, which ensures EVR’s failure probability is negligible. For (b), the runtime is estimated on an NVIDIA A100-SXM4-80GB GPU.

G.3 Experiment for Evaluating MC Accountant

G.3.1 Settings

Evaluation Protocol. We use $Y^{(k)}$ to stress that the PRV Y is for the composition of k Poisson Subsampled Gaussian mechanisms. For the offline setting, we make the following two kinds of plots: **(1)** the relative error in approximating $\varepsilon \mapsto \delta_{Y^{(k)}}(\varepsilon)$ (for fixed k), and **(2)** the relative error in $k \mapsto \varepsilon_Y(\delta)$ (for fixed δ), where $\varepsilon_Y(\delta)$ is the inverse of $\delta_{Y^{(k)}}(\varepsilon)$ from **(1)**. For the online setting, we make the following two kinds of plots: **(1)** the relative error in approximating $k \mapsto \varepsilon_{Y^{(k)}}(\delta)$ (for fixed δ), and **(2)** $k \mapsto$ cumulative time for privacy accounting until k th iteration.

MC Accountant. We use the importance sampling technique with the tilting parameter being set according to the heuristic described in Definition 12.

Baselines. We compare MC against the following state-of-the-art DP accountants with the following settings:

- The state-of-the-art FFT-based approach (Gopi et al., 2021). The setting of $\varepsilon_{\text{error}}$ and δ_{error} is specified in the next section.
- CLT-based GDP accountant (Bu et al., 2020).
- GDP-Edgeworth accountant with second-order expansion since it is the one used in Wang et al. (2022a) and uniform bound.
- The Analytical Fourier Accountant based on characteristic function (Zhu et al., 2022), with double quadrature approximation as this is the practical method recommended in the original paper.

G.3.2 Additional Results for Offline Accounting

In this experiment, we set the number of samples for MC accountant as 10^7 , and the parameter for FFT-based method as $\varepsilon_{\text{error}} = 10^{-3}$, $\delta_{\text{error}} = 10^{-10}$. The parameters are controlled so that the MC accountant is faster than FFT-based method, as shown in Table 1. Figure 12 (a) shows the offline accounting results for $\varepsilon \mapsto \delta_{Y^{(k)}}(\varepsilon)$ when we set $(\sigma, q, k) = (0.5, 10^{-3}, 1000)$. As we can see, the performance of MC accountant is comparable with the state-of-the-art FFT method. In Figure 13 (a), we decrease q to 10^{-5} . Compared against baselines, MC approximations are significantly more accurate for larger ε , compared with the FFT accountant. Figure 12 (b) shows the offline accounting results for $k \mapsto \varepsilon_Y(\delta)$ when we set $(\sigma, q, \delta) = (0.5, 10^{-3}, 10^{-5})$. Similarly, MC accountant performs comparably as FFT accountant. However, when we decrease q to 10^{-5} and δ to 10^{-14} , MC accountant significantly outperforms FFT accountant. This illustrates that MC accountant performs well in all regimes, and is especially more favorable when the true value of $\delta_Y(\varepsilon)$ is tiny.

Table 1: Runtime for $k = 1000$.

AFA	GDP	GDP-E	FFT	MC-IS
18.63	4.1×10^{-4}	1.50	3.01	2.31

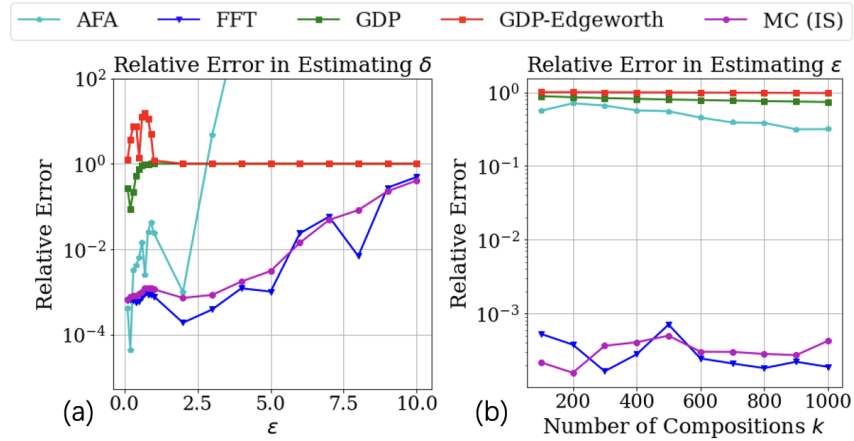

Figure 12: Experiment for Composing Subsampled Gaussian Mechanisms: (a) Compares the relative error in approximating $\varepsilon \mapsto \delta_{\mathcal{Y}^{(k)}}(\varepsilon)$ where we set $\sigma = 0.5, k = 1000, q = 10^{-3}$. (b) Compares the relative error in $k \mapsto \varepsilon_{\mathcal{Y}}(\delta)$ where we set $\sigma = 0.5, \delta = 10^{-5}, q = 10^{-3}$.

Figure 13: Experiment for Composing Subsampled Gaussian Mechanisms: (a) Compares the relative error in approximating $\varepsilon \mapsto \delta_{\mathcal{Y}^{(k)}}(\varepsilon)$ where we set $\sigma = 0.5, k = 100, q = 10^{-5}$. (b) Compares the relative error in $k \mapsto \varepsilon_{\mathcal{Y}}(\delta)$ where we set $\sigma = 0.5, \delta = 10^{-14}, q = 10^{-5}$.
