26 Abstract

27 A comprehensive characterization of the human body resistome (sets of antibiotic resistance genes (ARGs)) is yet to be done and paramount for addressing the antibiotic 28 microbial resistance threat. Here, we study the resistome of 771 samples from five 29 major body parts (skin, nares, vagina, gut and oral cavity) of healthy subjects from the 30 31 Human Microbiome Project and addressed the potential dispersion of ARGs in pristine environments. A total of 28,731 ARGs belonging to 344 different ARG types were 32 found in the HMP proteome dataset $(n=9.1 \times 10^7 \text{ proteins analyzed})$. Our study reveals a 33 34 distinct resistome profile (ARG type and abundance) between body sites and high interindividual variability. Nares had the highest ARG load (~5.4 genes/genome) followed 35 by the oral cavity, while the gut showed one of the highest ARG richness (shared with 36 37 nares) but the lowest abundance (≈ 1.3 genes/genome). Fluroquinolone resistance genes were the most abundant in the human body, followed by macrolide-lincosamide-38 streptogramin (MLS) or tetracycline. Most of the ARGs belonged to common bacterial 39 commensals and multidrug resistance trait was predominant in the nares and vagina. 40 41 Our data also provide hope, since the spread of common ARG from the human body to pristine environments (n=271 samples; 77 Gb of sequencing data and 2.1×10^8 proteins 42 analyzed) thus far remains very unlikely (only one case found in an autochthonous 43 44 bacterium from a pristine environment). These findings broaden our understanding of ARG in the context of the human microbiome and the One-Health Initiative of WHO 45 46 uniting human host-microbes and environments as a whole.

47

48

49 Importance

50 The current antibiotic resistance crisis affects our health and wealth at a global scale and by 2050 predictions estimate 10 million deaths attributed to antibiotic resistance 51 worldwide. Remarkably, a comprehensive analysis of ARG diversity and prevalence in 52 different human body sites is yet to be done. Undoubtedly, our body and human built-53 environment have antibiotic resistant bacteria than can also be transported to other 54 environments. Hence, the analysis of Human Microbiome Project dataset provides us 55 not only the opportunity to explore in detail the ARGs diversity and prevalence in 56 57 different parts of our body but also to provide some insights into the dispersion of ARGs from human to natural populations inhabiting pristine environments. Thus, our 58 59 data would help to stablish a baseline in ARG surveillance protocols to asses further 60 changes in antibiotic resistances in our society.

A manuscript submitted to mSystems

66 Introduction

67 Since the discovery of antibiotics, human and animal health has profoundly changed.

68 Undoubtedly, antibiotics have not only saved millions of lives but also have

69 transformed modern medicine (Ventola, 2015; Centers for Disease Control and

70 Prevention, 2019). Nevertheless, antibiotic overuse, incorrect prescription, extensive use

of antibiotics in agriculture and farming and the low availability of new antibiotics have

12 led to a major antibiotic resistance crisis, wherein bacterial pathogens are becoming

resistant to available antibiotics (Ventola, 2015). In the US, it has been estimated that

antibiotic-resistant organisms cause 2.8 million infections and 35,900 deaths each year

75 (Centers for Disease Control and Prevention, 2019). This not only is a health issue but

also affects food security and requires significant financial investment. For instance, it

has been estimated that in 2017, the annual treatment of six multidrug-resistant bacteria

costs approximately \$4.6 billion to the US healthcare system (Nelson *et al.*, 2021). By

2050, predictions estimate that over 10 million deaths and a total cost of \approx 100 trillion

80 USD will be attributed to antibiotic resistance worldwide (Brogan and Mossialos, 2016;

O'Neill, 2016), and recently, the WHO estimated that in 10 years, antimicrobial

resistance could force up to 24 million people into extreme poverty (IACG, 2019).

Antibiotic resistance is a natural process in which bacteria become resistant to 83 antibiotics using different mechanisms, which are classified as phenotypic resistance 84 (due to physiological changes and nonhereditary) or acquired (when antibiotic 85 resistance is genetically gained) (Olivares et al., 2013). Different antibiotic resistance 86 genes (ARGs) that confer resistance to antibiotics could be acquired due to mutations in 87 the bacterial genome or through horizontal gene transfer (HGT). The transference of 88 89 ARGs could be mediated by bacteria, viruses, plasmids or even vesicles (Emamalipour et al., 2020). Among the possible antibiotic classifications, the most common are the 90 ones based on their chemical structure (drug classes, e.g., tetracycline, beta-lactams, 91 aminoglycosides...), mode of action (determined by the antibiotic target, mainly 92 proteins, cell membrane and nucleic acids) and spectrum of activity (from narrow to 93 broad) (Wright, 2010; Etebu and Arikekpar, 2016; Reygaert, 2018). 94

The occurrence of antibiotic resistance has increased and accelerated since antibiotics
are constantly present in the environment, derived from anthropogenic sources such as
wastewater treatment plants, hospitals or domestic use (Rodriguez-Mozaz *et al.*, 2020).
Another cause of this increase is the dispersion of resistant bacteria from hot spots, such

A manuscript submitted to mSystems

| 99 a | as wastewater treatment | plants (from our own | n human microbiome) and built |
|------|-------------------------|----------------------|-------------------------------|
|------|-------------------------|----------------------|-------------------------------|

100 environments (i.e., microorganisms found in human-constructed environments) (Baron

101 *et al.*, 2018; Centers for Disease Control and Prevention, 2019), which continuously

102 disseminates our microbes and thus parts of their genetic content.

103 The human microbiome project (HMP) (Methé et al., 2012), an interdisciplinary effort, was developed with the objective of characterizing the human microbiome. For this 104 105 purpose, samples from different major body parts of healthy humans were obtained and 106 sequenced, producing one of the largest resources for the study of the human 107 microbiome (Huttenhower et al., 2012). To the best of our knowledge, comprehensive analysis and cross-comparison of the human resistome from all human body parts 108 109 studied within the HMP have not been performed, but to date, some valuable but separate and non-interconnected studies have been performed for the oral cavity and the 110 111 skin (Carr et al., 2020; Li et al., 2021). Addressing the abundance and diversity of ARGs as a whole in all human body parts has enormous potential to broaden our 112 knowledge on the dispersion of ARGs from human bacteria within different microbial 113

114 populations in nature.

115 Thus, here, in the context of antibiotic resistance-related health concerns, in addition to analyzing in detail the antibiotic resistance genes present in the HMP-studied body sites, 116 117 we studied the potential spread of ARGs from the human body to different types of pristine environments. These environments are supposed to be undisturbed and not 118 affected by anthropic actions. While many places, such as caves or polar environments 119 120 with no apparent and visible human activity, are often perceived as pristine environments, human activity unfortunately leaves an indirect ever-increasing footprint. 121 122 Here, we use some of these pristine environments as a model to address and estimate the potential "mobility" of common human ARGs found in the human body to better 123 124 assess the global impact of antibiotic resistance in our ecosystems, in line with the One 125 Health concept (i.e., human health and animal health are interdependent and bound to 126 ecosystems) (Atlas, 2012). Pristine environments are commonly used as "reporter 127 ecosystems" to monitor pollution and climate change and, in our case, specifically to 128 measure how deep the potential impact of the spread of antibiotic resistance is.

129

A manuscript submitted to mSystems

131 Results

132 Comprehensive metagenomic characterization of the human resistome

- 133 The HMP (Huttenhower *et al.*, 2012) aimed to characterize the diversity and metabolic
- 134 potential of the microbiomes of healthy human subjects from different body sites. In
- this study, we analyzed the resistome (i.e., pool of antibiotic resistance genes) of these
- body parts, examining a total of 771 HMP samples from the oral cavity, skin, nares,
- 137 vagina and gut (Suppl. Table 1 and 2). Detection of ARGs was performed using amino
- acid sequence similarity searching against the following reference ARG databases (see
- methods for details): CARD 3.0.3 (Jia et al., 2017), RESFAMS (Gibson et al., 2015)
- and ARG_ANNOT (Gupta *et al.*, 2014). ARGs with an e-value $\leq 10^{-5}$, amino acid
- identity \ge 90% and bit score \ge 70 were considered *bona fide* ARG hits.
- 142 From all the detected HMP proteins (9.17E+07), a total of 28,731 ARG hits were found,
- representing between 0.02 and 0.08% of the relative abundance of HMP proteins
- depending on the body site analyzed (Suppl. Table 2). Overall, nearly all analyzed
- samples (99%) from the different human body sites showed at least one ARG. The
- 146 exceptions were some specific HMP samples from the nares ($\approx 14\%$ of nares samples),
- skin (4.25% of skin samples) and vagina (45% of vagina samples), in which no ARG
- 148 was detected (Suppl. Table 2).
- 149 On average, tetracycline resistance genes were the most abundant antibiotic resistance
- 150 genes in the HMP dataset (Fig. 1A and B), followed by MLS or fluoroquinolone
- resistance genes, the ranks of which were dependent on the analyzed body site.
- 152 Tetracycline resistance genes were the most abundant ARGs in vagina (53.4%) and gut
- 153 (40.52%), whereas their abundance decreased in oral cavity, skin and nares (26.02, 9.03
- and 10.45%), where the most dominant antibiotic resistance genes were, respectively,
- 155 fluoroquinolone (30%), multidrug (18.22%) and beta-lactamase resistance genes
- 156 ($\approx 20\%$) (Fig. 1A). In gut samples, the second most abundant resistance genes were the
- 157 ones conferring resistance against beta-lactamases (as in skin), while in the vagina, the
- second most abundant were multidrug resistance genes (19.37%). Aminocoumarin
- resistance genes were only found in the gut, while peptide antibiotic resistance genes
- 160 were found in all body parts analyzed and they were more frequent in skin and nares
- 161 (representing a 6-fold increase compared with the relative abundance of this antibiotic
- 162 class resistance gene in the rest of the body).

A manuscript submitted to mSystems

All samples from the oral cavity (hard palate, buccal mucosa, saliva, subgingival and 163 164 supragingival plaque, attached/keratinized gingivae, tongue dorsum, throat and palatine tonsils) showed a similar pattern of resistance to the different antibiotic classes with 165 minor variations (Fig. 1B; Suppl. Fig. 1). Separated from the oral cavity, the skin and 166 167 nares showed similar dominant antibiotic resistance genes grouped by drug classes 168 (fluoroquinolone, multidrug, macrolide-lincosamide-streptogramin (MLS) and betalactamase resistance), although the ARG in nares displayed resistance to 14 different 169 drug classes, while ARG present in skin displayed resistance to 10 different drug 170 171 classes. The bacteria from the vagina had resistance against 8 antibiotic classes, being the lowest number of the 5 body parts compared in this study (the top three ARG ranked 172 were tetracycline, fluoroquinolone and MLS resistance genes). Remarkably, nares and 173 174 gut showed resistance to the highest number of antibiotic classes (14 out of the 16 175 different classes found in this study).

As shown in Fig. 1C, the body part that had the highest abundance of ARGs per

assembled mega-base pair (Mb) was the nares (1.86±2.32 ARGs/Mb), followed by the

skin (1.22±1.42 ARGs/Mb) and oral cavity (0.90±0.88 ARGs/Mb) (Fig. 1C). It is worth

noting that the gut (0.34±0.33 ARGs/Mb) had the lowest amount of ARGs per Mb

among all the analyzed body parts (Fig. 1C). The Welch test employed to compare the

abundance of different body parts showed statistically significant differences (P-

value ≤ 0.05) between almost all body parts but not between the skin and nares (Fig. 1C).

183 No significant differences were found between male and female subjects in any of the

body sites analyzed (Suppl. Fig. 2). According to recent estimates of the average

genome size (AGS) of human microbes from different body parts of HMP datasets

186 (Nayfach and Pollard, 2015), in general, the correlation of ARGs and the AGS indicated

that the number of ARGs per bacterial genome ranged from 1.3 in stool (AGS=3.9 Mb)

188 to 3 in nares (AGS \approx 2.5 Mb).

189 Characterization of dominant antibiotic resistance genes in the human body

190 In this section, beyond the above-described diversity and abundance of antibiotic

191 resistance gene classes in the HMP dataset, we sought to study in detail the pool of

192 different types of ARGs and the identity of antibiotic-resistant microbes harboring these

193 ARGs. Within each of the antibiotic classes, different types of ARGs are described in

databases (2404 in CARD (Jia et al., 2017), 2038 in ARG_ANNOT (Gupta et al.,

195 2014), and 3169 in RESFAMS (Gibson *et al.*, 2015)). In addition, based on the

A manuscript submitted to mSystems

antibiotic mechanism of action (Reygaert, 2018), five types of antibiotics are defined: 196 antibiotics that 1) inhibit cell wall synthesis (e.g., beta-lactams), 2) depolarize the cell 197 membrane (e.g., lipopeptides), 3) target nucleic acid synthesis (e.g., quinolones), 4) 198 inhibit metabolic pathways (e.g., sulfonamides) and 5) affect protein synthesis (e.g., 199 200 MLS antibiotics or tetracyclines) (Reygaert, 2018). Therefore, ARGs could provide protection against one specific antibiotic or different types of antibiotics. 201 202 In the HMP datasets, after comparison with all three of the above ARG databases, a total of 344 different type of ARGs were found in all the analyzed samples (Suppl. 203 204 Table 3 and 4). The gut samples had 198 different ARGs, the highest number and 205 diversity among the analyzed body sites, while the lowest ARG diversity was found in 206 the vagina (46) (Suppl. Table 4). The most abundant type of ARG in the oral cavity was 207 patB, which provides resistance to fluoroquinolones via antibiotic efflux (ARO:

208 3000025). The *fmtC* gene was the predominant ARG in the nares and skin, while *tetO*

209 was the most common ARG in the gut and in the vagina, the most frequent gene was

tetM (Suppl. Table 4).

211 Regarding the identification of the most common antibiotic resistant (AR) bacteria in

HMP datasets (Fig. 2) based on the best-hit score, as expected, the results differed

among body parts. The oral cavity had 326 different species harboring ARGs, followed

by the gut (257 different species). The skin showed the lowest number of different

species with ARGs (a total of 52) (Fig. 2). *Streptococcus mitis* was the most abundant

AR bacterium in the oral cavity. In the gut, the most abundant AR bacterium was

217 Escherichia coli, while in nares and skin, Staphylococcus was the predominant AR

218 bacterium (*Staphylococcus aureus* in nares and *Staphylococcus epidermis* in skin).

219 Finally, *Gardnerella vaginalis* was the most abundant resistant species in the vagina. S.

220 aureus, E. coli and Bacteroides fragilis were the most abundant AR bacteria found in all

body sites (Fig. 2). Remarkably, from the total ARG hits found in the HMP (n=28,731),

only one example detected in the oral cavity was detected with high confidence in a

viral genome fragment of a human herpesvirus carrying APH(4)-Ia; this ARG was an

aminoglycoside phosphotransferase that inactivates aminoglycosides (human subject

225 765560005, buccal mucosa, Suppl. Table 5).

A manuscript submitted to mSystems

The increasing multiantibiotic-resistant bacteria (MRBs) are a major threat to human 227 health. We next attempted to identify genome fragments (i.e. contigs) having two or 228 more ARGs which provide insights into multiple-antibiotic resistance (MR) bacteria in 229 HMP datasets. For this purpose, we applied the criteria for the detection of more than 230 231 one ARG in the same assembled genome fragment, conferring resistance to at least two different antibiotics classes in each of the analyzed HMP samples. The percentage of 232 metagenomic samples from the HMP with the presence of MR was between $\approx 25\%$ (oral 233 cavity) and 6% (vagina). Twenty-one percent of the analyzed gut samples had >1 contig 234 235 conferring multi-antibiotic resistance potential, whereas in the skin, the percentage was 19%, and in nares, 15% of the samples showed MR (Fig. 3A). The MR frequency 236 changed depending on the studied group. Vagina samples showed the highest multi-237 antibiotic resistance-related contig frequency, with a large difference among vaginal 238 239 samples (0.42±0.27 MRB/assembled Mb). The skin, oral cavity and gut had the lowest frequency of MR (Fig. 3B). 240

The most abundant MR species in each body site were the same in all cases and werealso detected as the most predominant resistant bacteria (Fig. 3C). The MR profile was

243 different depending on the sampling site. In the vagina there was only one MR species

whereas in skin, there were only 2 main species carrying more than one ARG, while the

245 gut had 23 MR species, with the highest number of different MR found in all body sites.

246 None of the MRB species were found in all the body parts. In fact, 6 species

247 (Bacteroides sp. 4_1_36, Bacteroides fragilis, Enterococcus faecium, Staphylococcus

248 aureus, Staphylococcus epidermidis, Streptococcus mitis) out of the 33 MRBs found

were in two or three different parts of the body, while the rest were only body site

250 specific (Suppl. Fig. 3).

251 When all of the above ARGs detected in healthy humans were clustered ($\geq 90\%$ amino

acid identity) to study a highly conserved core of shared ARGs, it was observed that

there were 3 common ARGs in all the body parts. One, MFS-type efflux protein

254 (msrD), was related to resistance to macrolides. The other 2 genes were related to

- ribosomal resistance against tetracycline (*tetO* and *tetQ*) associated with conjugative
- 256 plasmids or transposons. In feces, *tetO* was found not only in bacteria belonging to the

257 phylum Firmicutes (*Clostridiales bacterium VE202-13*; Ga0104838_1543581) but also

- in bacteria of the phylum Actinobacteria (*Trueperella pyogenes MS249*;
- 259 Ga0111491_10662371).

A manuscript submitted to mSystems

260 Detection of Human Microbiome Project ARGs in pristine environments

- 261 Resistomes and ARGs dispersion from hot spots such as wastewater plants or hospitals
- to downstream aquatic environments have been extensively studied and characterized
- 263 (Rowe et al., 2017; Ju et al., 2018; Khan et al., 2019). Although the presence of ARGs
- in environments with low or scarce human intervention has been explored (Van
- Goethem *et al.*, 2018; Naidoo *et al.*, 2020), to the best of our knowledge, it has never
- 266 been explored whether common ARGs from HMP datasets are present in autochthonous
- 267 bacteria from different pristine environments.
- 268 To determine the presence of ARGs from the HMP in pristine environments (Fig. 4;
- polar, desert, cave, hot spring, and submarine volcano environments; Suppl. Table 6)
- 270 with no *a priori* anthropogenic influence, proteins from 271 different pristine
- environments (i.e. metagenomic datasets) were screened to search for ARGs detected in
- the analyzed HMP samples. Only those proteins with identity $\ge 90\%$, with bit-score ≥ 70
- and belonging to genomic scaffolds with at least 4 proteins were considered for further
- analysis. It is important to remark that if an ARG from the HMP dataset is detected in a
- 275 genome fragment from a pristine environment, two different hypothesis could be
- 276 considered: this detected ARG in pristine environments was 1) an allochthon HMP gene
- 277 dispersed from anthropic areas that was acquired by autochthonous bacteria inhabiting
- the pristine environment, or 2) this ARG in pristine environments is actually the result
- of contamination during sample manipulation, collection or post-processing (e.g., DNA
- 280 contaminant fragments in reagents from kits, DNA sequencing and other
- 281 metagenomics-related experiments) and thus is not truly present in these pristine
- environments.

In the 271 analyzed samples from pristine environments (a total of 77 Gb of sequencing

information and 2.1E+08 analyzed proteins), we detected a total of 9 ARGs from HMP

dataset. Only one of those ARGs were found in a genome fragment of a putative

- autochthonous bacterium from the family *Rhodobacteraceae* recovered in a submarine
- volcano (Fig. 4; Suppl. Table 7; a chloramphenicol acetyltransferase gene 100% amino
- acid identical with the HMP gene dataset). The rest and great majority of detected
- ARGs in pristine environments were simply exogenous contaminant present in these
- 290 metagenomes from manipulation or laboratory reagents. For instance, it is obvious that
- 291 Escherichia coli should not be detected in hot springs. However, we indeed found

A manuscript submitted to mSystems

ARGs in *E. coli* genome fragments in the corresponding hot spring metagenomes (Fig.

- 293 4, bottom right panel).
- 294 Discussion

The human resistome has received increased attention in recent years due to its impact 295 296 in our society. Usually, resistome studies focus their attention on one body site, usually 297 studying the gut (Hu et al., 2013; Palleja et al., 2018) or, more recently, the skin (Li et 298 al., 2021). To our knowledge, only one study has compared resistome traits from the gut with different parts of the oral cavity, examined via different protocols (Carr et al., 299 300 2020). In our study, the advantage of using only HMP samples that were subjected to 301 standardized procedures was the elimination of biases and variability introduced by 302 contrasting procedures from different surveys (Huttenhower et al., 2012). Here, in our 303 study, we found that the most abundant ARGs in the HMP resistome provided 304 resistance against fluoroquinolone, MLS and tetracycline resistance genes, followed by multidrug resistance genes and beta-lactamases. Members of these antibiotic classes 305 306 were among the most commonly prescribed oral antibiotics in 2010 (Hicks et al., 2013), 307 right before the samples were obtained, which shows a plausible relation between the 308 consumed antibiotics and the detected resistance in American subjects, even though we cannot rule out the influence of antibiotics consumed through the food (Salyers et al., 309 310 2004). A human gut study from Chinese, Spanish and Danish subjects showed that more than 75% of the ARGs were tetracycline resistance genes, MLS resistance genes and 311 beta-lactamases (Hu et al., 2013). This was consistent with our data since these three 312 313 antibiotic classes accounted for 61% of the relative abundance found in our study with HMP samples (Van Boeckel et al., 2014). The characterization of resistomes from 314 315 metagenomic data can also be performed from unassembled data (Arango-Argoty et al., 2018; Maestre-Carballa et al., 2019). Here, the analysis from unassembled data (Suppl. 316 317 Fig. 5; Suppl. Table 8) showed that major ARGs grouped by drug classes relative 318 abundance was similar to the one obtained with assembled data shown in Fig. 1. Even 319 though, we cannot rule out that the normalized abundances (no. of ARG per Mb) could 320 be biased by the metagenomic assembly step or by the very short lengths of Illumina 321 DNA reads and the predicted amino acid sequences obtained from the HMP datasets 322 (Suppl. Fig. 6).

A manuscript submitted to mSystems

The different physiological conditions, bacteria-host interactions, and average genome 324 size (AGS) (Nayfach and Pollard, 2015) present in each body part could be important 325 326 factors contributing to the differences in ARG abundance, which were statistically significant for different paired body parts analyzed, except in the skin-nares pair (Fig. 327 1C). In addition, the well-known inter-individual variability in the human microbiome 328 was also observed here for ARG abundance. The highest ARG abundance was found in 329 the nares, a body entrance for microorganisms carried by air, which could include 330 pathogenic bacteria such as Legionella or Mycobacterium species. Airborne bacteria 331 could also carry ARGs (Li et al., 2018); therefore, antibiotic resistance genes could first 332 arrive at the nares. It has been calculated that we inhale 7 m^3 of air and 10^4 - 10^6 bacterial 333 cells per cubic meter of air per day (Kumpitsch et al., 2019) albeit the quantity varies 334 depending on different factors, such as geography, weather, micro-niches and air 335 pollution (Li et al., 2018; Kumpitsch et al., 2019; Zhang et al., 2019). In addition, 336 seasonal variation in bacterial species in the nares environment has been observed 337 338 (Camarinha-Silva et al., 2012). However, considering that bacteria present on the nares surface, in contrast to gut or oral bacteria, are not typically in "direct contact" with 339 340 antibiotics, it is certainly surprising that the nares microbiome maintains the highest rate of ARG abundance, and more intriguing are the mechanisms used to acquire and fix 341 these ARGs. 342

343

As shown in this study, the numbers of ARGs per assembled Mb in the gut was lower 344 345 than that in the other body parts, but the ARG richness was greater. This observation is 346 consistent with the results of Carr et al. (2020), who compared oral and fecal samples. 347 Even though the abundance was measured with other parameters (reads per kilobase of read per million (RPKM) and coverage greater than 90%), the ARG abundance in stool 348 349 was smaller than that in oral samples from China, the USA and Fiji but not western 350 Europe (Carr et al., 2020). Carr et al. (2020) hypothesized that different niches in the 351 oral cavity, such as the dorsum of the tongue, could aid the deposition of debris and 352 microbes or even the formation of biofilms, which are structures that favor HGT between different species (Giaouris et al., 2015). 353

A manuscript submitted to mSystems

| 355 | Regarding the bacterial species with antibiotic resistance, consistent with other studies, |
|-----|--|
| 356 | we found that commensals such as Staphylococcus aureus and Staphylococcus |
| 357 | epidermidis in skin were the top 10 AR bacteria (Li et al., 2021). Further, some of them, |
| 358 | such as S. aureus, were multidrug-resistant bacteria, with a total of 4 ARGs in nares |
| 359 | (arlS, arlR, dha-2, mprF) conferring resistance to 3 different antibiotic classes |
| 360 | (fluoroquinolone, beta-lactam and cationic antibiotics). Additionally, as expected, |
| 361 | methicillin-resistant S. aureus (MRSA), which is listed among the CDC's Antibiotic |
| 362 | Resistance Threats in the United States (Centers for Disease Control and Prevention, |
| 363 | 2019), was present naturally in nares from different subjects. Another species found in |
| 364 | oral HMP samples listed in the AR Threats report was Streptococcus pneumoniae. |

365

366 Remarkably, our data give hope, since the dispersion of ARGs detected in the HMP 367 dataset to pristine environments is extremely infrequent and anecdotical, with only one ARG in an autochthonous bacterium among dozens of millions of analyzed genes. 368 369 Therefore, even using more relaxed thresholds, it can be considered as a rara avis event. As shown in Fig. 4, nearly all detected ARGs from pristine environments actually 370 371 belonged to laboratory contaminants or exogenous bacteria that were not obviously found in these habitats (e.g., E. coli in hot springs). Sometimes, a general metagenomic 372 373 analysis could mislead the interpretation of the data if sequencing and genomic 374 assembled data is not carefully inspected. Our study exemplifies very well this bias since an initial ARG search detection indeed discovered a certain number of ARGs, but 375 376 later on, it was demonstrated that they were clearly not naturally present in these pristine environments. 377

378

379 Finally, it is important to discuss potential caveats and biases of our study. Here, we 380 have used sequence similarity-based searches with strict conservative thresholds for 381 detecting ARGs in metagenomics datasets to avoid false positives. Only hits with amino acid identity \geq 90% and bit-score \geq 70 against ARGs deposited in curated reference 382 antibiotic resistance databases were considered. This methodology has been widely used 383 in previous publications (Van Goethem et al., 2018; Chng et al., 2020; Lira et al., 384 2020). Obviously, unknown ARGs yet to be discovered and therefore not present in 385 386 reference ARG databases cannot be detected using our methodology. Likewise,

A manuscript submitted to mSystems

probably our approach has ruled out some actual ARGs present in samples that display 387 388 a score similarity below our thresholds (i.e. false negatives). However, it is worth-389 noting, as highlighted in previous studies using our methodologies, that more rigorous 390 thresholds are clearly preferred. It is very interesting to read the discussion on how 391 using less strict thresholds when detecting ARGs in viruses can profoundly mislead data 392 interpretation (Enault *et al.*, 2017)). This is even more important when analyzing datasets from pristine environments since a conservative approach is preferable over 393 using riskier thresholds. Even though we have used strict thresholds to detect only bona 394 395 fide ARGs, it may be noted that some genes could "scape" this filter. For instance, some housekeeping genes (constitutive genes required for basic cellular functions) only 396 require one or few mutations to conferring antibiotic resistance (e.g. rplS, gyrA, parY). 397 For instance, the mutant version of the housekeeping gene gyrA found in common 398 399 antibiotic resistance databases used in this study, typically display a very short motif 400 called "QRDR" that is responsible for quinolone resistance (Avalos et al., 2015; Jia et 401 al., 2017). However, in our search in HMP datasets, despite having high similarity and above our thresholds, the great majority of detected gyrA proteins in HMP did not have 402 403 this motif (Suppl. Fig. 4) and therefore was totally unclear whether they confer 404 antibiotic resistance. Similar cases were found for other housekeeping genes, even when 405 they displayed high sequence similarity. Thus, to avoid including false positives that would overestimate ARG abundance, housekeeping gene hits were ruled out from our 406 407 analysis.

408

409 Overall, our study provides a comprehensive analysis of the human microbiome 410 resistomes from different body sites studied by the HMP consortium, providing valuable biological insights that can serve as baseline for further studies and be thus 411 412 integrated into AMR surveillance protocols to determine the fate of the diversity and 413 abundance of ARGs in the long term. Our data also show that the level and impact of 414 ARGs spreading and selection pressure to fix these alleles in non-anthropogenic areas is 415 negligible. However, it is in our hands, as a society, to control these selection pressures 416 and, if possible, reverse and ameliorate the impact of ARGs in nature.

417 Experimental Procedures

418 *Sample collection*

- 419 A total of 751 shotgun-sequenced samples from 15 different parts of the body from
- 420 healthy American adults belonging to the Human Microbiome Project (HMP)
- 421 (Huttenhower *et al.*, 2012) were retrieved from JGI-IMG/ER (Chen *et al.*, 2021) (Suppl.
- 422 Table 1). Not all HMP assembled data present at JGI-IMG/ER was accessible, thus only
- 423 the available metagenomes were included in this study. The data were organized in 5
- 424 groups: Skin (retro-auricular crease), Nares, Gut, Vagina (posterior-fornix, mid vagina
- 425 and vagina introitus), and oral cavity (hard palate, buccal mucosa, saliva, subgingival
- 426 plaque, attached gingivae, tongue dorsum, throat, palatine tonsils, and supragingival
- 427 plaque).
- 428 20 metagenomes belonging to left and right retro-auricular crease that could not be
- 429 found in JGI-IMG were downloaded from the HMP page
- 430 (https://www.hmpdacc.org/HMASM/) and included with the rest of HMP samples
- 431 (Suppl. Table 1).
- 432 Proteins of 271 metagenomes from pristine environments (or environments with no or
- 433 little human presence) were downloaded from JGI-IMG, and they were organized in 5
- 434 groups: Arid deserts (65), submarine volcanoes (66), hot springs (68), polar
- environments (57) and caves (15) yielding a total of 76 Gb (Suppl. Table 6).
- 436 Environments associated to a host (e.g., tubeworms) were also discarded.
- 437 *HMP resistome in silico analysis*
- 438 Proteins from 751 samples of the HMP were retrieved from de JGI-IMG/ER (Chen et
- 439 *al.*, 2021). In addition, 20 assembled metagenomes were downloaded directly from the
- 440 HMP official page since they were not available in JGI. ORF of the genomic sequences
- 441 downloaded from HMP were predicted with prodigal 2.6.3 (Hyatt *et al.*, 2010).
- 442 Then, all obtained proteins were compared using BLASTp 2.8.1+ with the following
- 443 antibiotic resistance protein databases: CARD 3.0.3 (Jia et al., 2017), ARG-ANNOT
- 444 (Gupta et al., 2014) and RESFAMS (Gibson et al., 2015). Aiming to identify only
- high-confidence ARG, only those ARG with e-value $\leq 10^{-5}$, amino acid identity $\geq 90\%$
- and bit-score \geq 70 with the mentioned ARG databases were considered as hits, thus,
- being more conservative than other accepted thresholds (bit-score \geq 70) (Enault *et al.*,
- 448 2017).

A manuscript submitted to mSystems

449 The ARG were grouped, following CARD 3.0.3 annotation (Jia *et al.*, 2017), according

450 to the drug class their confer resistance to. The taxonomic affiliation was extracted from

451 the annotation found in JGI/IMG-ER (Chen *et al.*, 2021). To compare the obtained

452 results, hits were normalized by the assembled Megabase pair (Mb).

453 Multiresistant contigs were manually curated, and only those with at least 2 different

454 ARG conferring resistance to at least two different drug classes were included in the

analysis. The abundance of metagenomes with multiresistant contigs was calculated by

456 dividing the number of metagenomes with at least one multiresistant contig by the total

457 number of metagenomes studied. The frequency of multiresistant species only in

458 metagenomes with more than one multiresistant bacteria was done by dividing the

459 number of multiresistant by the total number of contigs.

The presence of common ARGs in all the analysed parts of the body was performed

using CD-HIT (90% identity) (Fu *et al.*, 2012) which was used to cluster all the ARGsfound in the HMP.

463 For studying the effect of our threshold in housekeeping genes that requires few

464 mutations to become resistant, gyrA proteins from the HMP dataset that were

465 considered as ARG by our analysis were extracted and aligned against the gyrA

466 fluroquinolone resistant gene deposited in CARD (Jia et al., 2017) from Mycobacterium

467 *tuberculosis* (>gb|CCP42728.1|+|Mycobacterium tuberculosis gyrA conferring

468 resistance to fluoroquinolones [Mycobacterium tuberculosis H37Rv]) and $gyrA^{R}$

469 obtained from RESFAMS (Gibson *et al.*, 2015) (NC_002952_2859949_p01) from

470 Staphylococcus. The alignment was performed with MUSCLE available in Geneious

471 9.1.3.

472

473 *HMP antibiotic resistance genes in pristine environments*

To determine the presence of ARG from the HMP in pristine environments with

475 presumptive low or none human presence, the ARGs obtained from the human samples

were compared with the proteins from the chosen metagenomes using BLASTp 2.8.1+.

477 Only those hits with an amino acid identity $\ge 90\%$, a bit-score ≥ 70 and e-value $\le 10^{-5}$

478 were considered. The taxonomic annotation was retrieved from JGI-IMG/ER only for

those scaffolds with at least 4 proteins to ensure the detection of HMP ARGs in

A manuscript submitted to mSystems

- 480 autochthonous bacteria (3 out of, at least, 4 proteins should be from the autochthonous
- 481 bacteria). All the hits were manually curated to avoid false positives, especially those
- 482 produced by housekeeping genes. Those belonging to taxons that could not be
- 483 associated with a specific environment were discarded.
- 484 Alignments were performed using the software geneious 9.1.3.
- 485 Comparison between ARGs present in assembled and raw data was performed
- analysing paired unassembled and assembled metagenomes from 5 gut samples from
- different subjects (Subjects ID: 159005010, 159247771, 159369152, 763961826 and
- 488 246515023; Suppl. Table 7) and from five buccal mucosa samples from 5 different
- 489 subjects (Subjects ID: 370425937, 764325968, 604812005, 246515023 and 809635352;
- 490 Suppl. Table 7). ARG in assembled data were detected with blastp as mentioned above.
- 491 ARGs detection in raw data was performed with two different strategies: DeepARG
- 492 (Arango-Argoty et al., 2018), a machine learning algorithm that detects ARGs and
- 493 normalises it by the number of 16S rRNA gene (90% identity, e-value $\leq 10^{-10}$), and
- 494 comparing the reads with blastx against the antibiotic resistance databases CARD (Jia et
- 495 *al.*, 2017), ARG-ANNOT (Gupta *et al.*, 2014) and RESFAMS (Gibson *et al.*, 2015) (e-
- 496 value $\leq 10^{-5}$, amino acid identity $\geq 90\%$ and bit-score ≥ 70) and normalised by the

497 unassembled Mb.

- 498
- 499 *Statistical analysis*
- 500 One-way ANOVA was performed to compare the ARG abundance (ARG/Mb) in each501 body site between samples from women and men.
- 502 Comparison between ARGs hits/Mb was performed with Welch test and pairwise.t.test
- 503 in R (R Core Team, 2014). P-value ≤ 0.05 was considered as significant in all the
- statistical test performed.
- 505 PcoA analysis was performed calculating the distance matrix using the Euclidean
- distance and plotted with ggplot (Wickham, 2016). For the different sites of the body it
- 507 was studied the relative abundance of each ARG categorized by antibiotic class
- 508 resistance.

673 Figures and Figure Legends

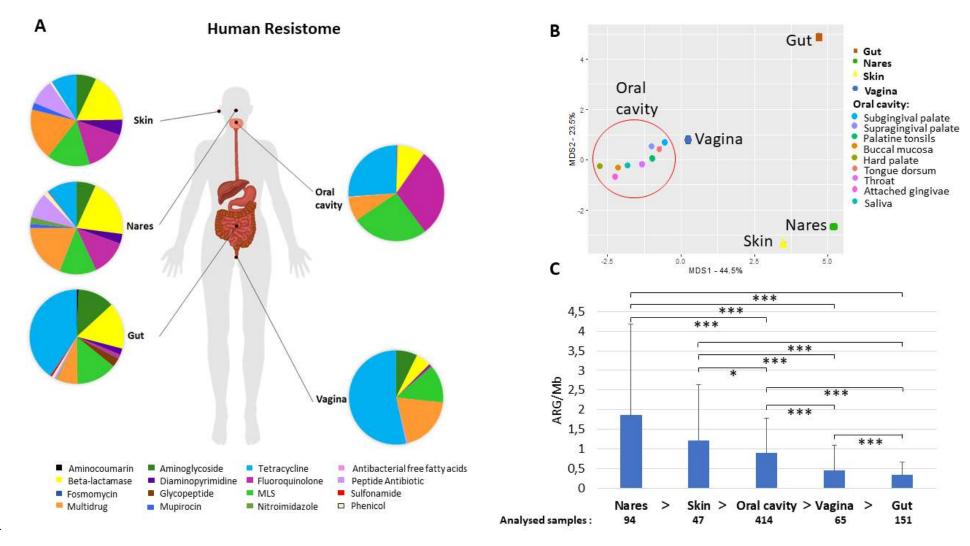

Fig. 1. Human Resistome. Human atlas of the ARGs grouped by drug class their confer resistance to present in different body parts. The body 675 groups studied were the gut, the skin (retroauricular crease), vagina (posterior-fornix, mid vagina and vagina intraotus), the nares and the oral 676 cavity (hard palate, buccal mucosa, saliva, subgingival plaque, attached gingivae, tongue dorsum, throat, palatine tonsils, and supragingival 677 plaque) (A). PCoA analysis of the different body sites distributed according to their relative abundance of AR to different drug classes (B). The 678 samples included in the group oral cavity (hard palate, buccal mucosa, saliva, subgingival plaque, attached gingivae, tongue dorsum, throat, 679 palatine tonsils, and supragingival plaque -shaped as a circle-) gathered together and separately from nares, skin and gut samples. Abundance of 680 antibiotic resistance genes calculated as ARGs hits per assembled Mb and number of samples included in each body group (C). Welch test was 681 performed to compare ARG abundances between different body sites. All paired samples showed statistically significant differences but the 682 nares and the skin. P-values (P) considerer as significant were indicated with an asterisk: $P \le 0.05^{*}$, $P \le 0.01^{**}$, $P \le 0.001^{***}$. 683

Fig. 2. Main antibiotic resistant bacteria in HMP dataset. Relative abundance of the most abundant resistant bacteria. Top five bacteria were chosen in each body part and then the graphic was completed with the relative frequency of all the chosen bacteria in all body parts. Circle sizes were different to determine the relative abundance of each species and colours were used to differentiate the body parts (red-oral cavity, browngut, skin-yellow,green-nares,blue-vagina). At the bottom of the graphic the number of different species that carried ARGs is shown.

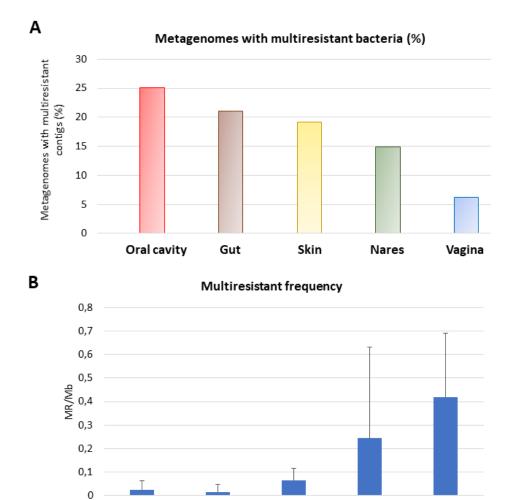

Oral cavity

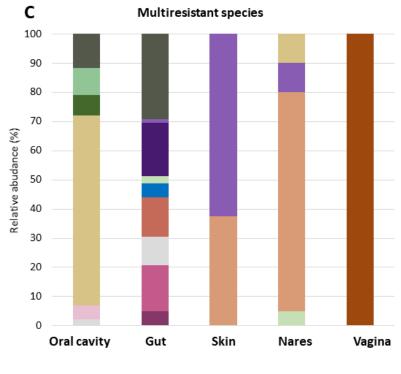

Gut

Skin

Nares

Vagina

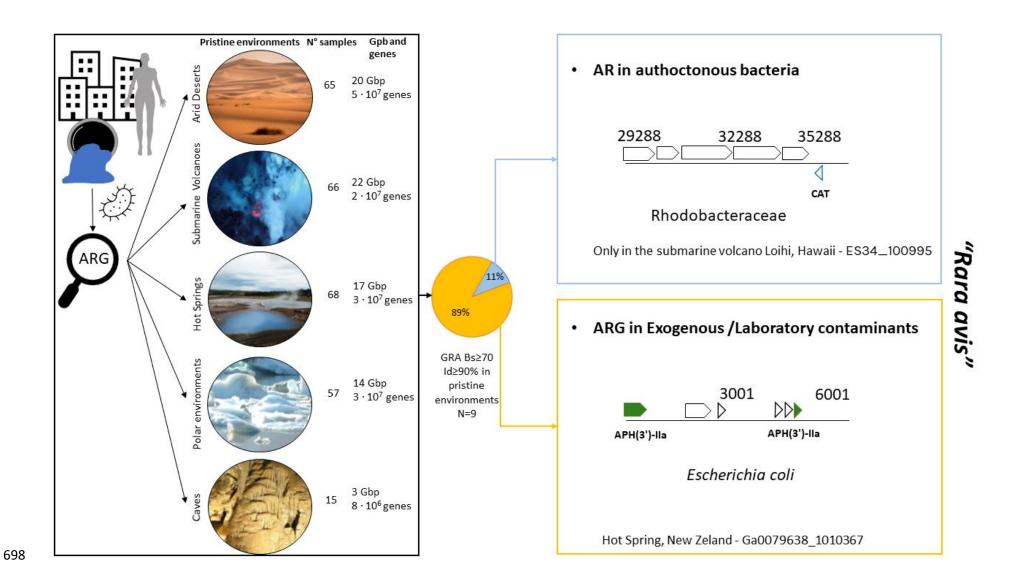

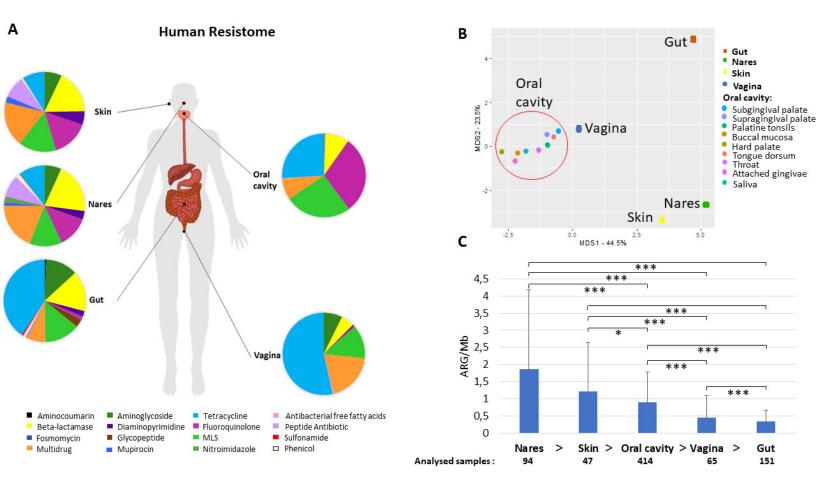

- Bacteroides dorei
 Bacteroides sp. 4_1_36
 Bacteroides ovatus
 Escherichia coli
 Neisseria cinerea
 Staphylococcus epidermidis
 Streptococcus pneumoniae
 Other
- Bacteroides salyersiae
- Bacteroides sp. 20_3
- Enterococcus faecicum
- Gardnerella vaginalis
- Staphylococcus aureus
- Streptococcus mitis
- Streptococcus sanguinis

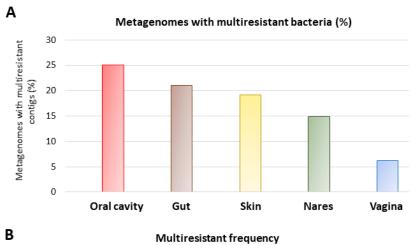

Fig. 3. Multiresistance in the human body. Those assembled genome fragments (i.e. contigs) that had more than one ARG conferring resistance to at least 2 different antibiotic families were considered as multiresistant (MR). Percentage of metagenomes with multiresistant contigs compared with all the metagenomes studied from the same HMP sample (A). Study of the multiresistant contigs frequency in metagenomes with at least one multiresistant contig (B), to compare the different samples, the number of multiresistant contigs was divided by the assembled Mb. Standard deviation is shown in the graphic. Relative abundance of the most abundant MR (C). Only MR whose relative abundance was, at least in one body site, equal or greater than 5% were represented.

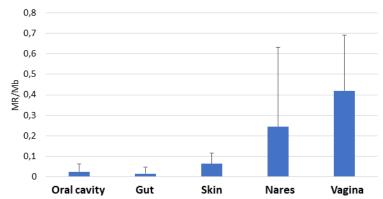

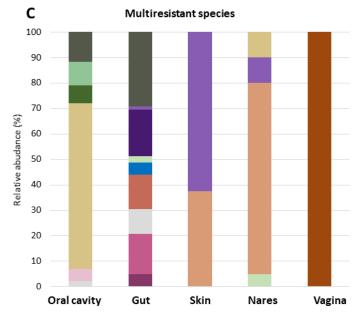

- **Fig. 4.** Detection of ARGs from Human Microbiome Project dataset in pristine environments (arid deserts (n=65), submarine volcanoes (n=66),
- hot springs (n=68), polar environment (n=57) and caves (n=15)). Only 9 ARGs were found in pristine environments according to our criteria (see
- methods and results). The only case of ARG found in an autochthonous bacterium in pristine environments was that of a chloramphenicol
- acetyltransferase (CAT) gene belonging to Salmonella sp. (100% identity with Ga0111015_155701; a nares sample) present in a marine
- bacterium found in Loihi (a submarine volcano) from the family *Rhodobacteraceae*. The presence of CAT from *Enterobacteriaceae* in
- 704 *Rhodobacter* has been previously described in the coastal water of Jiaozhou Bay, (Dang *et al.*, 2008). Chloramphenicol-resistant bacteria often
- harbor plasmids carrying the CAT gene (Shaw *et al.*, 1979) that could have been transferred to *Rhodobacter*. Desert photo taken from Boris
- 706 Ulzibat (PEXELS). Submarine volcano photograph courtesy of NOAA / NSF / WHOI page
- 707 (https://oceanexplorer.noaa.gov/facts/volcanoes.html).
