Abstract

A retrospective study including a total of 44 ornamental and pet birds with neoplasms diagnosed at the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, Universidad Nacional Autónoma de México from January 2007 to April 2014 was conducted. Most of affected birds were Psittaciformes (n=26, 59%) including budgerigars (*Melopsittacus undulatus*) (n=12/26, 46.15%) and amazon parrots (*Amazona* spp.) (n=7/26, 26.92%), and followed by Passeriformes and Anseriformes (n=7/44, 15.90%, each) and Galliformes (n=4/44, 9.09%). The youngest studied bird was a 6.5-week-old lovebird (*Agapornis* sp.) with a papilloma, and the oldest bird was a 37-year-old yellow-naped parrot (*Amazona auropalliata*) with a hemangiosarcoma. Most of the affected birds were adults (n=23, 52.27%). The gender was determined for 17 birds (38.63%), of which eight (47.05%) were females and nine (52.94%) males. There were 45 reported neoplasms, as one salmon-crested cockatoo (*Cacatua moluccensis*) had two neoplasms. The two most frequent neoplasms were fibrosarcomas (n=9/45, 20%) and hemangiosarcomas (n=5/45, 11.11%). The largest number of neoplasms was found in the integumentary system (n=18/45, 40%), followed by the reproductive system (n=10/45, 22.22%). Of the 16 types of neoplasms, seven (43.75%) were malignant, six (37.5%) were benign, and three (18.75%) were potentially malignant. This study showed similarities with retrospective previously reported studies and contributes to the knowledge of the neoplastic diseases that occur in ornamental and pet birds in Mexico.

Key words: avian, pet, neoplasm, pathology, Mexico.

Introduction

Neoplasms are common in pet birds, especially in the *Psittacidae* family (7, 13, 14, 25, 27, 36, 42). The high incidence of neoplasms in these birds may be due to assisted inbreeding, their longer lifespan, which increases the exposure time to potential carcinogenic environmental agents, and the consequent risk of genetic errors or mutations (5, 42, 54). Pet birds with neoplastic diseases are currently more frequently submitted veterinarians before

death possibly because the medical care improvements for oncologic patients (44). The following types of neoplasms have been reported in pets birds: epithelial – folliculoma (3, 44), basal cell carcinoma (3, 44, 58), squamous cell carcinoma (12, 31), papilloma (29, 32, 38), cholangiocarcinoma (11, 15, 33), pulmonary carcinoma (20, 32), air sac carcinoma (30, 40, 42) and renal carcinoma (32, 54); mesenchymal – fibroma (32, 41) and fibrosarcoma (7, 27, 45), hemangioma and hemangiosarcoma (7, 44, 55), lipoma and liposarcoma (7,

27), chondrosarcoma (32), hemangiolioma (50), osteoma and osteosarcoma (6, 17, 51), leiomyosarcoma (2, 32), and rhabdomyosarcoma (1); hematopoietic and hemolymphatic – lymphoma (7, 8, 32), myelolipoma (25, 35) and thymoma (23, 44); glandular – adenomas and adenocarcinomas of different systems (15, 32, 40, 44); neuroendocrine – melanoma (7, 32, 53); ovarian – carcinoma and adenocarcinoma (21, 32, 44) and granulosa cell tumor (49); testicular – seminoma, Sertoli cell tumor, interstitial cell tumor and teratoma (26, 32, 44, 47, 49, 57); intracranial tumors – ependymoma, choroid plexus tumours, adenoma and adenocarcinoma of the adenohypophysis (22, 56) and neuroblastoma (9). A retrospective study of neoplasms was conducted of birds submitted to the named hospital from January 2007 to April 2014 in order to identify the neoplastic diseases affecting ornamental and pet birds diagnosed at the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, Universidad Nacional Autónoma de México.

Materials and methods

Data collection and analysis

The database of the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, Universidad Nacional Autónoma de México (UNAM) during the above mentioned period was analyzed. The identification, number and frequencies of ornamental and pet birds were obtained according to order, family, genus and species of affected bird with final histopathologic diagnosis of neoplastic conditions, cell line involved, gender of birds, affected system, and neoplasm biological behavior. In addition, the age of the studied birds was considered according to the species included in this study, being divided into the following categories: chick (weeks), juvenile (months/years), sexually mature (weeks/months/years), adult (weeks/years) and geriatric (years) as previously described (10, 59).

Histopathology

A complete evaluation of the 44 cases of birds diagnosed with neoplastic conditions was performed histopathologically. The formalin-fixed, paraffin-embedded tissue blocks of the named cases were sectioned at 3-µm thick and stained with hematoxylin and eosin (H&E) by routine procedures. To support the performed histological identification and classification, a selection of tumors was stained with Masson's trichrome (MT), periodic acid-Schiff (PAS), diastase-PAS (PAS-D), Mallory's phosphotungstic acid hematoxylin (PTAH) and Ziehl-Neelsen stains (ZN). The samples were obtained from 21 biopsies and 23 necropsies of the birds.

Immunohistochemistry

To support the diagnosis of some neoplasms, primary antibodies against desmin (labels smooth and striated muscle cells), actin smooth muscle (labels smooth muscle cells, myofibroblasts and myoepithelial cells), protein S-100 (labels glial, ependymal, and Schwann's cells), cytokeratin (labels keratinized and corneal epidermis, stratified squamous epithelia of internal organs, stratified epithelia, hyperproliferative keratinocytes, and simple epithelia), vimentin (labels intermediate filament protein of the cytoskeleton of vertebrate cells of mesenchymal origin), CD3 (labels T cells) and CD68 (labels monocytes, macrophages and myeloid cells) were applied (Table 1) (Dako North America, Inc., 6392 Vía Real Carpinteria, California 93013, USA). In all cases, the streptavidin-biotin-peroxidase complex method was used, biotinylated anti-mouse and anti-rabbit secondary antibodies were applied as appropriate, and diaminobenzidine was used as chromogen (Dako North America, Inc.) For the recovery of antigen in all cases, citrate buffer, pH 9, was used in a pressure cooker at 120°C for 3 minutes. Staining intensity was interpreted as immunonegative, immunopositive (weak, intermediate, strong) or inconclusive according to the reaction location (nucleus or cytoplasm) (Table 1).

Table 1. Immunohistochemical reagents and protocols used in selected neoplasms diagnosed at the Hospital de Aves of the Universidad Nacional Autónoma de México.

Antibody	Origin	Reactivity	Dilution	Clone	Reaction location
Smooth muscle actin*	mouse	Muscle (Smooth muscle)	1:400	1A4	Cytoplasm
Desmin*	mouse	Muscle	1:100	D33	Cytoplasm
S-100 protein*	rabbit	Neural crest cells	1:200	Polyclonal	Nucleus and cytoplasm
Cytokeratin*	mouse	Epithelium	1:50	AE1/AE3	Cytoplasm
Subfamily A and B					
CD68*	mouse	Macrophages	1:1600	KP1	Cytoplasm
Vimentin*	mouse	Mesenchymal	1:50	V9	Cytoplasm
CD3*	rabbit	T lymphocytes	1:250	Polyclonal	Membrane and cytoplasm

Results

Frequencies of birds with a neoplastic process according to their taxonomic classification, age, and gender

The total number of birds submitted to the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, UNAM during the studied period was 7,733, of which 139 (1.79%) were ornamental and pet birds with presumptive clinical diagnoses of neoplastic conditions; of these birds, 44 (31.6%) had definitive histopathologic diagnoses of neoplastic conditions. Of these 44 birds, in descending order, 26 (59.09%) were Psittaciformes, 7 (15.90%) Passeriformes, 7 (15.90%) Anseriformes, and 4 (9.09%) Galliformes (Tables 2 and 3). Of these birds, in descending order, 24 (54.54%) belonged to the family *Psittacidae*, 7 (15.90%) *Anatidae*, 5 (11.36%) *Fringillidae*, 4 (9.09%) *Phasianidae*, 2 (4.54%) *Cacatuidae*, 1 (2.27%) *Turdidae*, and 1 (2.27%) *Estrildidae*. Regarding age range, the youngest bird was a 6.5-week-old lovebird (*Agapornis* sp.) with a papilloma, and the oldest bird was a 37-year-old yellow-naped parrot (*Amazona auropalliata*) with a hemangiosarcoma. According to the age, 23 birds (52.27%) were adults, 3 (6.81%) juveniles, 1 (2.27%) sexually mature, 1 (2.27%) geriatric, and 1 (2.27%) chick (Table 2). For the remaining 15 birds (34.09%), no possible classification by age was made due to the lack of information (Table 3). Of the 44 birds, gender was determined for only 17 (38.63%), of which 8 (47.05%) were females and 9 (52.94%) males (Tables 2 and 3).

Frequency of neoplasms according to cell line, location and biological behavior

In the histological study, a total of 45 neoplasms were reported and included sixteen types of neoplasms which were identified according to cell line origin, of which, in descending order, 9 (20%) were compatible with soft tissue sarcomas (according to the histochemical and immunohistochemical results described further, they suggest being fibrosarcomas) (Fig. 1), 5 (11.11%) hemangiosarcomas, 5 (11.11%) carcinomas, 4 (8.88%) granular cell tumors, 3 (6.66%) adenocarcinomas (Fig. 2), 3 (6.66%) lymphomas, 3 (6.66%) seminomas, 3 (6.66%) teratomas, 2 (4.44%) lipomas (Fig. 3 and 4), 2 (4.44%) osteosarcomas (Fig. 5), and one case each (2.22%) of adenoma, osteoma, papilloma, mixed thymoma, granulosa cell tumor and leukemia (Tables 2 and 3).

The location of the 45 neoplasms in the 44 studied birds was as follows. A total of 18/45 (40%) were located in the integumentary system, of which 5 (27.77%) were fibrosarcomas, 4 (22.22%) hemangiosarcomas, 4 (22.22%) granular cell tumors, 2 (11.11%) lipomas, 2 (11.11%) basal cell carcinomas, and 1 (5.55%) papilloma. A total of 10/45 (22.22%) neoplasms affected the reproductive system, of which 3 (30%) were seminomas, 3 (30%) testicular teratomas, 2 (20%) ovarian carcinomas, 1 (10%) granulosa

cell tumor, and 1 (10%) ovarian adenocarcinoma. A total of 7/45 (15.55%) neoplasms affected the musculoskeletal system, of which 3 (42.85%) were fibrosarcoma, 2 (28.57%) osteosarcoma, 1 (14.28%) osteoma, and 1 (14.28%) hemangiosarcoma. A total of 5/45 (11.11%) neoplasms affected the hemolymphatic system, of which 3 (60%) were multicentric lymphomas, 1 (20%) mixed thymoma, and 1 (20%) leukemia. A total of 4/45 (8.88%) neoplasms affected the digestive system, of which 1 (25%) was hepatic adenoma, 1 (25%) adenocarcinoma of the cloaca, 1 (25%) fibrosarcoma of the beak, and 1 (25%) squamous cell carcinoma of the tongue. Only 1 (1/45, 2.22%) neoplasm, a pulmonary adenocarcinoma, was located in the respiratory system.

According to the biological behavior, of the 16 types of neoplasms, 7 (43.75%) were malignant including fibrosarcoma, hemangiosarcoma, carcinoma, adenocarcinoma, lymphoma, osteosarcoma and leukemia, 6 (37.5%) benign including granular cell tumors, lipoma, adenoma, osteoma, papilloma and mixed thymoma, and 3 (18.75%) potentially malignant including seminoma, teratomas and granulosa cell tumor (Tables 2 and 3).

Special stains and immunohistochemistry

Only 6 of the 9 neoplasms diagnosed as compatible with soft tissue sarcomas were stained with MT, which showed positivity for collagen (Fig. 1). The immunohistochemical results of 7 of 9 of these neoplasms showed variable immunopositivity for vimentin (4 weak, 3 intermediate and none strong) (Fig. 6), were immunonegative for cytokeratin and S-100 protein, and inconclusive for smooth muscle actin and desmin.

For the thymoma, the immunohistochemical results showed intermediate immunopositivity in lymphoid neoplastic cells for CD3, and the Hassall's corpuscles showed strong immunopositivity for cytokeratin. The 4 granular cell tumors showed PAS positive intracytoplasmic granules, resistant to digestion with PAS-D (which ruled out the presence of glycogen), and negative results for PTAH (no striations were observed) and ZN. The immunohistochemical results for one of these tumors showed intermediate immunopositivity for smooth muscle actin and desmin and was immunonegative for CD68, cytoqueratin and protein S-100.

Discussion

Of the 44 ornamental and pet birds with neoplastic conditions that were diagnosed during the study period, the largest number of cases belonged to the order Psittaciformes (n=26, 59.09%) including budgerigars (*Melopsittacus undulatus*) (n=12/26, 46.15%), amazon parrots [(*Amazona* spp.) (n=7/26, 26.92%); red-lored parrot (*Amazona autumnalis*) (n=3, 42.85%), white-fronted amazon (*Amazona albifrons*) (n=2, 28.57%), lilac-crowned amazon (*Amazona finschi*) (n=1, 14.28%) and yellow-

naped amazon (*Amazona auropalliata*) (n=1, 14.28%), lovebird (*Agapornis* sp.) (n=3/26, 11.53%), monk parakeet (*Myiopsitta monachus*) (n=1/26, 3.84%), salmon-crested cockatoo (*Cacatua moluccensis*) (n=1/26, 3.84%),

cockatiel (*Nymphicus hollandicus*) (n=1/26, 3.84%) and scarlet macaw (*Ara macao*) (n=1/26, 3.84%).

Table 2. Neoplasms, categorized by physiological stage, in 29 ornamental and pet birds diagnosed at the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, Universidad Nacional Autónoma de México from January 2007 to April 2014.

Taxonomy	Physiological stage/age	Neoplasm	Gender	Biological behavior
Psittaciformes	Chick			
Lovebird	6.5-week-old	Papilloma	NR	Benign
Psittaciformes	Juvenile			
Budgerigar	10-month-old	Fibrosarcoma	NR	Malignant
White-fronted amazon	2-year-old	Granular cell tumor	NR	Benign
Monk parakeet	2-year-old	Basal cell carcinoma	NR	Malignant
Psittaciformes	Mature			
Salmon-crested cockatoo	10-year-old	Fibrosarcoma and Lipoma	F	Malignant, Benign
Psittaciformes	Adult			
Cockatiel	10-year-old	Seminoma	M	Potentially malignant
Budgerigar	1.5-year-old	Fibrosarcoma	NR	Malignant
Budgerigar	Adult	Fibrosarcoma	NR	Malignant
Budgerigar	2-year-old	Fibrosarcoma	NR	Malignant
Budgerigar	4-year-old	Seminoma	M	Potentially malignant
Budgerigar	1 year	Squamous cell carcinoma of the tongue	NR	Malignant
Budgerigar	Adult	Granular cell tumor	M	Benign
Budgerigar	3-year-old	Hemangiosarcoma	NR	Malignant
White-fronted amazon	16-year-old	Ovarian carcinoma	F	Malignant
Red-lored Parrot	20-year-old	Leukemia	NR	Malignant
Red-lored Parrot	23-year-old	Lymphoma	NR	Malignant
Lilac-crowned parrot	28-year-old	Lung adenocarcinoma	NR	Malignant
Scarlet macaw	10-year-old	Lipoma	NR	Benign
Passeriformes				
Zebra finch	Adult	Basal cell carcinoma	M	Malignant
Canary	5-year-old	Fibrosarcoma	NR	Malignant
Canary	6-year-old	Lymphoma	NR	Malignant
Canary	7-year-old	Lymphoma	F	Malignant
Canary	2-year-old	Osteoma	NR	Benign
Galliformes				
Common pheasant	Adult	Hemangiosarcoma	F	Malignant
Chicken	4-year-old	Ovarian adenocarcinoma	F	Malignant
Chicken	1.6-year-old	Teratoma	M	Potentially malignant
Anseriformes				
Mallard	9-year-old	Adenocarcinoma of the cloaca	NR	Malignant
Mallard	Adult	Seminoma	M	Potentially malignant
Psittaciformes	Geriatric			
Yellow-naped Amazon	37-year-old	Hemangiosarcoma	M	Malignant

F=female, M=male, NR=not referred.

Table 3. Neoplasms in 15 ornamental and pet birds with no referred physiological stage diagnosed at the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, Universidad Nacional Autónoma de México from January 2007 to April 2014.

Taxonomy	Neoplasm	Gender	Biological behavior
Psittaciformes			
Budgerigar	Hepatic adenoma	NR	Benign
Lovebird (2)	Fibrosarcoma	NR	Malignant
Budgerigar	Hemangiosarcoma	NR	Malignant
Budgerigar	Osteosarcoma	NR	Malignant
Budgerigar	Granular cell tumor	NR	Benign
Red-lore Parrot	Granular cell tumor	NR	Benign
Passeriformes			
Canary	Fibrosarcoma	NR	Malignant
American robin	Thymoma	F	Benign
Galliformes			
Chicken	Teratoma	M	Potentially malignant
Anseriformes			
Mallard	Ovarian carcinoma	F	Malignant
Mallard	Hemangiosarcoma	NR	Malignant
Mallard	Osteosarcoma	NR	Malignant
Mallard	Granulosa cell tumor	F	Potentially malignant
Muscovy duck	Teratoma	M	Potentially malignant

Figure 1. Fibrosarcoma of the skin of an adult budgerigar. Bundles of neoplastic fusiform cells with pleomorphic nuclei, prominent nucleoli (white arrows) and scanty cytoplasm which has indistinct borders and diffuse distribution of blue colored collagen (black arrows) are observed. Masson's trichrome staining. Bar = 50 µm.

In addition to the possible predisposition to the development of neoplasms in Psittaciformes, this finding reflects the popularity and preference for budgerigars and amazon parrots as pets in households mainly in and around Mexico City. This preference is probably due to their small size (budgerigars), the colors and brilliance of their plumage, and ease of reproduction in captivity, which contributes to inbreeding. Amazon parrots have been highly prized for their ability to imitate and repeat sounds emitted by their owners. In addition, in Mexico, there are

numerous free-living amazon parrots, which facilitate their illegal capture and sale. In other studies, the incidence of neoplasms in budgerigars is also reported to be high compared to that in other genera and species, similar to that found in the present study (13, 14, 32). However, the lower frequency of neoplasms in other birds, such as Passeriformes and Anseriformes (n=7/44, 15.90%, each) and Galliformes (n=4/44, 9.09%), found in this study does not necessarily indicate that they have a lower predisposition to the development of neoplasms but possibly indicate a lower demand for these birds as pets in Mexico.

Phenotypic characteristics are not always present to easily determine age in birds, and this could be a factor in why the physiological stage for 15 (34.09%) birds in the present study could not be determined. In this regard, it is known that the average lifespan of birds depends on the genus and species and can vary from 6 to 60 or more years (18). Most of the birds of our study were in the adult stage (n=23/29, 79.31%), similarly to a previously published study in which 17 of 23 adult parrots (73.9%), ranging from 1-to-5-year-old, were included (36). In this regard, adult birds in captivity, unlike free-living birds are recognized to be exposed for longer time periods to unfavorable nutritional factors, such as high fat consumption, prolonged mycotoxin consumption, and potential environmental carcinogens such as aromatic amines and polycyclic aromatic hydrocarbons (5, 13, 16, 54). Mycotoxicosis frequently affects psittacids because diets are composed mainly of grains and seeds, whose prolonged consumption has been associated with hepatic neoplasms (16).

Figure 2. Adenocarcinoma of the cloaca of a 9-year-old mallard. Marked anaplasia of epithelial cells that replace the mucosa of the organ is observed. The cells are pleomorphic, with marked anisokaryosis (white arrows) are observed. A variable amount of cytoplasm which has indistinct borders is observed. In addition some atypical mitosis (black arrows) are observed. H&E staining. Bar = 50 μ m.

Figure 4. Lipoma of a 10-year-old scarlet macaw. Well-differentiated mature adipocytes with a large vacuole in the cytoplasm (black arrow) and eccentric and small nuclei (white arrow) are observed. H&E staining. Bar = 50 μ m.

Figure 3. Gross image of the left pelvic limb of a 10-year-old scarlet macaw, shows a large subcutaneous, palpable, soft, oval-shaped not well delimited neoplasm corresponding to a lipoma (black arrows).

Of the 17 (38.63%) birds in which gender was determined, 8 (47.05%) were females and 9 (52.94%) males, not representing significant differences in gender predisposition to neoplasms. Although some birds of this study present sexual dimorphism, sex could not be determined in 27 (61.36%) of them. The absence of sexual dimorphism in juvenile and adult stages of many bird species showed difficulties to determine sex based on phenotype.

Figure 5. Osteosarcoma in a budgerigar. Pleomorphic osteocytes with large euchromatic nuclei and prominent nucleoli (white arrows) are observed. In the lower right corner, a multinucleated cell corresponding to an osteoclast (black arrow) is observed. A small amount of light eosinophilic extracellular matrix possibly consistent with osteoid are observed. H&E staining. Bar = 50 μ m.

In the present study, neoplasms were most commonly located in the integumentary system ($n=18/45$, 40%), similarly to other previous studies reporting the skin as the most frequent target of neoplastic conditions in pet birds (7, 24, 25). In the present study, the most frequent neoplasms in this location were fibrosarcoma ($n=5/18$, 27.77%) and hemangiosarcoma ($n=4/18$, 22.22%). Some studies mentioned fibrosarcoma and lipoma as the skin neoplasms most commonly found in pet birds (7, 24, 27). In the present study, only 2 (11.11%) lipomas were identified affecting skin, both 10-year-old salmon-crested cockatoo and scarlet macaw. Lipoma, which were widely

described in budgerigars, cockatiels, yellow-crowned amazon (*Amazona ochrocephala*) and rose-breasted cockatoo (*Eolophus roseicapillus*) (14, 24, 44), are benign neoplasms that are clinically identified and can be treated avoiding high-energy diets, exercise routines or by surgical resection (24, 48). Based on our experience at the Hospital de Aves, Facultad de Medicina Veterinaria y Zootecnia, UNAM, the first above mentioned 2 options are suggested before surgical recession; this may be the reason of the low incidence of lipomas found in our study at our hospital. In addition to the skin fibrosarcomas, 3 other fibrosarcomas were identified in the musculoskeletal system and another in the beak, being the most frequent neoplasm in our study (n=9/45, 20%). This result is similar to previously reported findings in a study were 23 parrots with neoplastic conditions were included and showing the highest incidence of fibrosarcoma (17.3%) (36). These neoplasms generally involve skin and subcutaneous tissue; the anatomical sites frequently affected are the pelvic limbs and wings, are locally invasive, and rarely metastasize (44). The higher frequency of fibrosarcoma in the present study was directly related to higher number of budgerigars (n=12/44, 27.27%) submitted to our hospital, and of these, 4 (33.33%) presented with this neoplasm. In this regard, budgerigars have been reported as one of the bird species with the highest frequency of neoplasms and that fibrosarcoma can constitute from 3% to 14% of neoplastic conditions in these birds (13, 24). In our study, the histochemical stains and the use of the immunohistochemistry, supported the diagnosis of at least 6 of the 9 soft tissue sarcomas. In this regard, although fibrosarcoma and leiomyosarcoma are immunopositive for vimentin, in 6 soft tissue sarcomas which were stained with MT, collagen fibers were detected stained blue, unlike muscle cells whose cytoplasm stains red. On the other hand, the fibrosarcomas are immunonegative for S-100 protein as in 7 of these neoplasms, unlike peripheral nerve neoplasms which are immunopositive for this protein. The combination of the immunohistochemistry results and the detection of collagen fibers in association with the histological characteristics of the neoplasms, suggested that they were fibrosarcomas.

After fibrosarcoma, hemangiosarcoma were the second most frequently diagnosed neoplasms in our study (n=5/45, 11.11%); in addition to the 4 hemangiosarcoma located in the skin, 1 hemangiosarcoma was located in the locomotor system. These neoplasms were diagnosed in 2 budgerigars, 1 yellow-naped amazon, 1 common pheasant (*Phasianus colchicus*) and 1 common mallard (*Anas platyrhynchos*). Cockatiels have been recognized as the pet bird most affected by hemangiosarcoma (44). Other psittacine birds such as budgerigars and yellow-naped amazons were reported to be commonly affected by this neoplasm also, similarly to the findings of the present study (44, 55). Cutaneous hemangiosarcoma has been located more frequently in the wings, pelvic limbs and cloaca and have been detected in waterfowl at skin sites

with few feathers, suggesting an association with exposure to sunlight, which could have happened in birds with cutaneous hemangiosarcoma in our study (43).

Figure 6. Fibrosarcoma in a lovebird with a fusocellular pattern. Cytoplasmic immunostaining of intermediate intensity for vimentin (white arrows) is observed. Immunohistochemistry. Bar = 200 μ m.

The identification of granular cell tumors (n=4/18, 22.22%) affecting the integument of 2 budgerigars, 1 red-colored parrot and 1 white-fronted amazon in our study is highlighted. The histological characteristics and the results of the histochemical stains were very similar to those previously described for this tumor (37, 39). The immunohistochemical results in a granular cell tumor in an adult male budgerigar, suggested myogenic or myofibroblastic origin since it showed intermediate immunopositivity for smooth muscle actin and desmin and was immunonegative for CD68, cytoqueratin and protein S-100. These results are similar to those found in another granular cell tumor diagnosed in a cockatiel (37), which was immunopositive for desmin, muscle common actin and actin, but immunonegative for vimentin and protein S-100. Further, in another granular cell tumor diagnosed in a Puerto Rican amazon parrot (39), the tumor, in addition to being immunopositive for desmin, was also immunopositive for vimentin suggesting mesenchymal origin in birds. However, the cellular origin of this neoplasm remains controversial since in other immunohistochemical studies performed in these tumors in humans (46) and horses (4), were immunopositives for protein S-100, which suggests that arise from Schwann cells. The majority of granular cell tumors are benign, although some display malignant behavior (4, 44).

Of the 18 neoplasms in the integument, 2 basal cell carcinomas (11.11%) were identified, 1 in a monk parakeet and one in a zebra finch (*Poephila guttata*), as well as a papilloma in a lovebird (5.55%). Basal cell carcinoma is a very uncommon epithelial tumor in pet birds; one case has been reported in an Indian runner duck (3) and another in a blue-fronted amazon parrot

(*Amazona aestiva*) (58). This neoplasm grows from pluripotent basal cells of the epidermis, and its degree of malignancy is variable (44). In our study, we found 1 papilloma in the skin of a lovebird. Skin papillomas are a benign neoplasms induced by a papillomavirus type 1 and has been reported occasionally in European finches (*Carduelis carduelis*), canaries (*Serinus canaria*), chaffinches (*Fringilla coelebs*), bramblings (*Fringilla montifringilla*), yellow-necked francolin (*Pternistis leucoscepus*) and African grey parrot (*Psittacus erithacus*) affecting the eyelids, junction between the beak and face, cloacal mucosa, legs and toes (24, 29, 38, 50). A herpesvirus also has been suggested to be involved in the etiology of internal papillomatosis of parrots (19).

The reproductive system was the second most frequent location of neoplasms in our study (n=10/45, 22.22%). In males, seminomas were found (n=3/10, 30%) in cockatiel, budgerigar and mallard, and testicular teratomas (n=3/10, 30%) were found in chickens (*Gallus gallus*) (n=2) and Muscovy duck (*Cairina moschata*) (n=1). In our study, testicular teratomas were composed of the 3 germ layers (endoderm, mesoderm and ectoderm) and they did not invade other organs. Testicular neoplasms are uncommon in birds, and, apparently, the highest incidence occurs in budgerigars and cockatiels (44, 49). Seminomas usually affect a single testis, they are usually locally invasive masses, showing potential malignant behavior (47). Ovarian neoplasms have been reported more frequently in psittacids, mainly affecting cockatiels and budgerigars (44); In this regard in our study in addition to the ovarian carcinoma identified in 1 white-fronted amazon (psittaced) (10%), 3 additional ovarian neoplasms were identified in other genera: an adenocarcinoma in a chicken (10%), a granulosa cell tumor in a mallard (10%), and another ovarian carcinoma in a mallard (10%).

The musculoskeletal system was the third most common location of neoplasms in our study (n=7/45, 15.55%). In addition to fibrosarcoma (n=3/7, 42.85%) and one hemangiosarcoma (14.28%), two osteosarcomas were diagnosed (28.57%) in one budgerigar and one mallard, together with one osteoma (14.28%) in a canary. Although osteosarcomas are more frequent than osteomas in pet birds, both neoplasms are uncommon in these birds due to the scarcity of reports (6, 17, 51), similarly to the low frequency found in the present study.

Although multicentric lymphoma is one of the most commonly diagnosed neoplasms in domestic, free-living and pet birds such as Psittaciformes and Passeriformes (7, 24, 32, 44, 45, 52), of the neoplasms located in the hemolymphatic system in the present study (n=5/45, 11.11%), only three were multicentric lymphomas (60%). One was in a red-lored parrot and in 2 of 5 canaries (40%) in which was previously considered common neoplasm (52). In turn, lymphoma in domestic birds have been associated with a herpesvirus (Marek's disease) and a retrovirus (avian leukosis virus); however, there is no evidence that in pet birds this neoplasm is due

to a viral infection (52). Lymphoma can have a nodular or diffuse appearance involving a wide range of organs including the liver, spleen, kidneys, integument, bone, gastrointestinal tract, thyroid gland, oviduct, lungs, sinuses, thymus, testes, brain, mesentery, trachea, fat, periorbital muscles and pancreas (32, 52). In our study, multicentric lymphomas were found mainly in the gastrointestinal tract (proventriculus, ventriculus, small and/or large intestine). Notably, our case of leukemia, which seems to be rare in pet birds (5, 17), was diagnosed in a 20-year-old red-lored parrot showing neoplastic lymphocytes infiltrating the bone marrow, liver and spleen, similarly to those findings diagnosed in an adult double yellow-headed amazon parrot with chronic T-cell lymphocytic leukemia (34). Of the hemolymphatic neoplasms, the mixed thymoma diagnosed in an American robin (*Turdus migratorius*) was considered to be an uncommon finding, which was in accordance to the current literature (23, 24, 44). For the diagnosis of this tumor of this bird, in addition to considering to the location (cranioventral of the neck) and histological characteristics of the neoplasm, the immunohistochemistry results supported the diagnosis, since lymphoid neoplastic cells showed CD3 intermediate immunopositivity, and the Hassall's corpuscles showed strong immunopositivity for cytokeratin. Thymomas are benign tumors classified as epithelial, lymphocytic or mixed, according to the neoplastic transformation of the cells (24).

Four of the 45 neoplasms (8.88%) were located at the digestive system. Squamous cell carcinoma of the tongue was identified in a 1-year-old budgerigar; notably, this neoplasm has been reported with relative frequency in this system (43, 44). In addition to the oral cavity, avian squamous cell carcinoma has been identified in the nasal sinuses, esophagus, crop and proventriculus (28, 44). The hepatic adenoma found in a budgerigar of our study is considered to be rare in birds. Of the hepatic tumors, cholangiocarcinoma (bile duct carcinoma) appears to be more frequent in avian species affecting several wild, domestic and captive bird species (11, 15, 33, 44). The adenocarcinoma of the cloaca identified in our study in a mallard was also an uncommon finding; however, adenocarcinomas in the digestive tract have been reported relatively frequently in other psittacid birds (15, 25, 44).

In the respiratory system, only one lung adenocarcinoma was identified in a 28-year-old lilac-crowned amazon (n=1/45=2.22%). Few cases of carcinomas or adenocarcinomas located at the nasal or sinus mucosa, glandular epithelium, air sacs or lungs have been previously described in birds (24, 30, 40, 44, 52). Tumor metastases to the lungs of pet birds include adenocarcinoma and carcinoma from various primary organs, melanoma, mesothelioma, fibrosarcoma, liposarcoma, lymphoma, and osteosarcoma (52).

In the present study, the use of several primary antibodies (Table 1), which were designed for the diagnosis of neoplasms in humans, indicated a useful

cross-reaction with bird tissues and represented a valuable diagnostic tool for the identification and classification of neoplasms in this animal species.

The results of our study showed similarities with other retrospective studies conducted in other countries. Regard to a retrospective study in California, USA, the prevalence of neoplasms was also higher in budgerigars (20.6%) than in other psittacine species (3.6%), no significant gender-related differences could be demonstrated, the skin represented the most often affected organ, and most of the tumors were classified as malignant (13). In another study conducted in Brazil, all birds undergoing surgery belonged to the order Psittaciformes and most neoplasms affected the integumentary system (7), statistics similar to a survey of neoplasia in pet birds conducted in the USA (25). Additionally in another study conducted in the state of Victoria, Australia, budgerigars were the birds mostly affected by neoplasms and fibromas and fibrosarcomas were the second most prevalent tumors (45). Our study provided for the first time knowledge of the neoplastic diseases that occur in ornamental and pet birds in Mexico.
