### **ABSTRACT**

A shock-induced polymorph (TiO<sub>2</sub> II) of anatase and rutile has been identified in breccias from the late Eocene Chesapeake Bay impact structure. The breccia samples are from a recent, partially cored test hole in the central uplift at Cape Charles, Virginia. The drill cores from 744 to 823 m depth consist of suevitic crystalline-clast breccia and brecciated cataclastic gneiss in which the TiO<sub>2</sub> phases anatase and rutile are common accessory minerals. Electron-microprobe imaging and laser Raman spectroscopy of TiO<sub>2</sub> crystals, and powder X-ray diffraction (XRD) of mineral concentrates, confirm that a high-pressure,  $\alpha$ -PbO<sub>2</sub> structured polymorph of TiO<sub>2</sub> (TiO<sub>2</sub> II) coexists with anatase and rutile in matrix-hosted crystals and in inclusions within chlorite. Raman spectra of this polymorph include strong bands at wavenumbers (cm<sup>-1</sup>) 175, 281, 315, 342, 356, 425, 531, 571, and 604; they appear with anatase bands at 397, 515, and 634 cm<sup>-1</sup>, and rutile bands at 441 and 608 cm<sup>-1</sup>. XRD patterns reveal 12 lines from the polymorph that do not significantly interfere with those of anatase or rutile, and are consistent with the TiO<sub>2</sub> II that was first reported to occur naturally as a shock-induced phase in rutile from the Ries crater in Germany. The recognition here of a second natural shock-induced occurrence of TiO<sub>2</sub> II suggests that its presence in rocks that have not been subjected to ultrahigh-pressure regional metamorphism can be a diagnostic indicator for confirmation of suspected impact structures.
