Key Words: ordinal variables; longitudinal analysis; missing at random; multiple imputation.

#### Abstract

Multiple imputation (MI) is now a reference solution for handling missing data. The default method for MI is the Multivariate Normal Imputation (MNI) algorithm which is based on the multivariate normal distribution. In the presence of longitudinal ordinal missing data, where the Gaussian assumption is no longer valid, application of the MNI method is questionable. This simulation study compares the performance of the MNI and ordinal imputation regression model for incomplete longitudinal ordinal data for situations covering various numbers of categories of the ordinal outcome, time occasions, sample sizes, rates of missingness, well-balanced and skewed data.

## ACCEPTED MANUSCRIPT

## 1 Introduction

Longitudinal ordinal data arise naturally in many clinical settings. For example, in randomized treatment trials, the regular assessment of the patient's quality of life (QoL) by means of a Likerttype scale has become popular. In such longitudinal studies, however, subjects may drop out prematurely while others may miss one or more assessments. Rather than deleting missing values, it has been recommended to 'impute' them. The question of how to obtain valid inferences from imputed data was formally addressed by Rubin (1978) who introduced the multiple imputation (MI) method that replaces each missing value not only once but by a set of $M(M>1)$ plausible values whence reflecting the uncertainty about the prediction of the unknown missing values.

It is not uncommon in MI to rely on the assumption that the outcome variable follows a Normal distribution and hence ignore the categorical responses in the ordinal outcome. The present simulation study was designed to evaluate two MI methods for incomplete longitudinal ordinal data, one considering the outcome as continuous and the other as ordinal. The MI method for continuous outcome is based on the Markov Chain Monte Carlo (MCMC) method of data augmentation, while the MI method for ordinal outcome uses the proportional odds property of the ordinal logistic regression model. The paper will compare the performance of the two MI methods by focusing on the estimation of the parameters of the longitudinal ordinal logistic model. Both imputation methods were evaluated through Monte Carlo simulated artificial data sets. The simulations not only cover well-balanced data but also skewed distribution, as often observed in QoL studies.

The proportional odds model to analyze longitudinal ordinal data is briefly reviewed in Section 2, while a general overview of the problem of missing data is given in Section 3. Section 4 outlines the theoretical background of multiple imputation including those for continuous and ordinal variables. The simulation experimental design is described in Section 5 and results are presented in Section 6. Concluding remarks are given in Section 7.

## ACCEPTED MANUSCRIPT

## 2 Models for longitudinal ordinal data

### 2.1 The proportional odds model

Consider a sample of $N$ subjects and let $Y$ be an ordered variable with $K$ categories assessed on $T$ occasions on each subject. Then, let $Y_{i j}$ denote the assessment of the ordinal variable $Y$ for the $i$ th subject $(i=1, \ldots, N)$ at the $j$ th occasion $(j=1, \ldots, T)$. Hence, $\mathbf{Y}_{i}=\left(Y_{i 1}, \ldots, Y_{i T}\right)^{\prime}$ is the vector of the repeated assessments of the $i$ th subject. Associated with each subject, there is a $p \times 1$ vector of covariates, say $\mathbf{x}_{i j}$, measured at time $j$. Let $\mathbf{X}_{i}=\left(\mathbf{x}_{i 1}, \ldots, \mathbf{x}_{i T}\right)^{\prime}$ denote the $T \times p$ design matrix of the $i$ th subject. Covariates typically include time of measurement, age, gender, treatment group, interaction terms, and so on.

The ordinal nature of the outcome variable may be accounted for by considering the cumulative probabilities $\operatorname{Pr}\left(Y_{i j} \leq k\right), k=1, \cdots, K$. The cumulative proportional odds model is a popular choice to relate the marginal probabilities of $Y$ to the covariate vector $\mathbf{x}$ (McCullagh, 1980). Specifically,
$\operatorname{logit}\left[\operatorname{Pr}\left(Y_{i j} \leq k \mid \mathbf{x}_{i j}\right)\right]=\beta_{0 k}+\mathbf{x}_{i j}^{\prime} \boldsymbol{\beta}$,
where $\boldsymbol{\beta}_{\mathbf{0}}=\left(\beta_{01}, \ldots, \beta_{0, K-1}\right)^{\prime}$ is the vector of the intercept parameters and $\boldsymbol{\beta}=\left(\beta_{1}, \ldots, \beta_{p}\right)^{\prime}$ the vector of coefficients $(i=1, \ldots, N ; j=1, \ldots, T ; k=1, \ldots, K-1)$. Under the proportional odds assumption, $\beta$ does not depend on $k$.

### 2.2 Generalized estimating equations

Estimation of the regression parameters of marginal models can be approached by likelihood-based methods. One difficulty present with likelihood models resides in the complexity of the relationship

## ACCEPTED MANUSCRIPT

between the parameters of the model and the joint probabilities that define the likelihood. Therefore, alternative solutions have been explored, in particular the generalized estimating equations (GEE), quite popular for the analysis of non-Gaussian correlated data. This approach circumvents the specification of the joint distribution of the repeated responses by means of a 'working' correlation matrix and only the marginal distributions are specified. Since the proportional odds model is not part of the regular generalized linear model family, some transformations are required before applying the GEE method. Following Lipsitz et al. (1994), a ( $K-1$ )-dimensional expanded vector of binary responses has to be created for each subject at each occasion, $\mathbf{Y}_{i j}^{*}=\left(Y_{i 1 j}^{*}, \ldots, Y_{i,(K-1), j}^{*}\right)^{\prime}$ where $Y_{i k j}^{*}=1$ if $Y_{i j} \leq k$ and 0 otherwise. Now,
$\operatorname{logit}\left[\operatorname{Pr}\left(Y_{i j} \leq k \mid \mathbf{x}_{i j}\right)\right]=\operatorname{logit}\left[\operatorname{Pr}\left(Y_{i k j}^{*}=1 \mid \mathbf{x}_{i j}\right)\right], k=1, \ldots, K-1$.

Since the logistic regression model is a member of the generalized linear model family, the GEE method applies and consistent estimates of the regression parameters can be obtained by solving the estimating equations
$\sum_{i=1}^{N} \frac{\partial \boldsymbol{\pi}_{i}^{\prime}}{\partial \boldsymbol{\beta}} \mathbf{V}_{i}^{-1}\left(\mathbf{Y}_{i}^{*}-\boldsymbol{\pi}_{i}\right)=\mathbf{0}$,
where $\mathbf{Y}_{i}^{*}=\left(\mathbf{Y}_{i 1}^{*}, \ldots, \mathbf{Y}_{i T}^{*}\right)^{\prime}, \boldsymbol{\pi}_{i}=E\left(\mathbf{Y}_{i}^{*}\right), \mathbf{V}_{i}=\mathbf{A}_{i}^{1 / 2} \mathbf{R}_{i} \mathbf{A}_{i}^{1 / 2}$ with $\mathbf{A}_{i}$ the diagonal matrix of the variance of the elements of $\mathbf{Y}_{i}^{*}$, and $\boldsymbol{\beta}$ the expanded vector of intercepts and regression coefficients. The matrix $\mathbf{R}_{i}$ is the 'working' correlation matrix that expresses the dependence among repeated observations over the subjects ranging from independence to exchangeable, banded, or unstructured.

## 3 Missingness

The profile of incomplete observations in a longitudinal data set may exhibit a variety of patterns. When an individual withdraws from the study before its completion time, we have a case of dropout. The missingness pattern may be monotone or non-monotone. In a monotone pattern, if

## ACCEPTED MANUSCRIPT

$Y_{i j}$ is missing for some $j$, then $Y_{i k}$ is missing for all $k>j$. As a consequence, if $Y_{i j}$ is known, so are all $Y_{i k}(k<j)$. By contrast, in a non-monotone pattern, there will be missing data before last available assessment. In line with the notation introduced previously, consider the missing data indicators, $R_{i j}$, defined as follows:

$$
R_{i j}=\left\{\begin{array}{l}
1 \text { if } Y_{i j} \text { is observed } \\
0 \text { otherwise }
\end{array}\right.
$$

and let $\boldsymbol{R}_{i}=\left(R_{i 1}, \ldots, R_{i T}\right)^{\prime}$ the indicator vector corresponding to $\mathbf{Y}_{i}=\left(Y_{i 1}, \ldots, Y_{i T}\right)^{\prime}$. Now $\mathbf{Y}_{i}$ can be split into two subvectors $\left(\mathbf{Y}_{i}^{o}, \mathbf{Y}_{i}^{m}\right)$ where $\mathbf{Y}_{i}^{o}$ refers to the observed component of $\mathbf{Y}_{i}$ and $\mathbf{Y}_{i}^{m}$ refers to the missing component part. For monotone dropout, $\boldsymbol{R}_{i}$ is of the form $(1, \ldots, 1,0, \ldots, 0)$ and can be used to define the dropout indicator $D_{i}=1+\sum_{j=1}^{T} R_{i j}$ which represents the time at which subject $i$ dropped out.

When missing data occur, we are concerned with the distribution of the measurement process together with the missing-data process. Little and Rubin (1987) and Little $(1993,1995)$ identified two broad classes of joint models: the selection model and the pattern-mixture model. In the selection model, the joint distribution $\left(\mathbf{Y}_{i}, \boldsymbol{R}_{i}\right)$ is split into the marginal distribution of the measurement and the distribution of the missingness process conditional on the measurement $\mathbf{Y}_{i}$. By contrast, the pattern-mixture model specifies the marginal distribution of $\boldsymbol{R}_{i}$ and the conditional distribution of $\mathbf{Y}_{i}$ given $\boldsymbol{R}_{i}$. Here we shall focus on the selection model approach in which Rubin (1987) and Little and Rubin (1987) made essential distinctions between the processes responsible for the missingness: missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). The determination of the mechanism responsible for missing data has a decisive implication on the choice of the statistical method used to analyze the data. Under the MCAR mechanism, the probability of an observation being missing is independent of both $\mathbf{Y}^{o}$ and $\mathbf{Y}^{m}$. Under the MAR mechanism, the probability of an observation being missing is independent of $\mathbf{Y}^{m}$ given $\mathbf{Y}^{o}$. When neither MCAR nor MAR holds, the missingness mechanism is said to be MNAR,

## ACCEPTED MANUSCRIPT

so that the probability of an observation being missing depends on $\mathbf{Y}^{m}$.

Liang and Zeger (1986) pointed out that GEE are only valid under the restrictive assumption that the data are missing completely at random (MCAR). Alternative methods were investigated to allow the analysis of data under less strict missingness assumptions. Robins et al. (1995a, 1995b) developed an extension of the GEE, known as the weighted generalized estimating equations (WGEE), that provide consistent estimates of the regression parameters even under the MAR assumption. With their method, each subject's measurements is weighted in the GEE by the inverse probability of dropping out at that time point. Another alternative to analyze the data under the MAR assumption is multiple imputation based on GEE (MI-GEE). In this approach, missing values are imputed several times (Rubin, 1976, 1978) and the resulting completed datasets are analyzed using standard GEE methods. Using Rubin's rules, the final results obtained from the completed datasets are combined into a single inference. In the context of longitudinal binary data, Beunckens et al. (2008) showed by simulations that, in spite of the asymptotic unbiasedness of WGEE, the combination of GEE and multiple imputation is both less biased and more accurate in small to moderate sample sizes which typically arise in clinical trials. In this paper, focus will be on MI-GEE methods.

## 4 Multiple imputation

### 4.1 Theoretical framework

The idea behind multiple imputation is that instead of filling in a single value for each missing data, the technique is to replace each missing value with a set of $M>1$ plausible values drawn from the conditional distribution of the missing data given the observed data. This conditional distribution represents the uncertainty about the right value to impute in the sense that the set of $M$ imputed values properly represents the information about the missing value that is contained in the observed

## ACCEPTED MANUSCRIPT

data. These $M$ complete data sets are then analyzed by the method that would have been appropriate if the data had been complete. The model used in this last step is called the substantive model, while the model used in the imputation task is called the imputation model. Results derived from the substantive model are then combined using simple rules provided by Rubin (1987), resulting in a single inference about the parameters of interest that accounts for uncertainty due to missing data.

Using the notation introduced in previous sections, let $\boldsymbol{\theta}$ represent the parameter vector of the distribution of the response $\mathbf{Y}_{i}=\left(\mathbf{Y}_{i}^{o}, \mathbf{Y}_{i}^{m}\right)$. Note that $\boldsymbol{\theta}$ may differ from the parameters $\boldsymbol{\beta}$ of the substantive model. The observed data $\mathbf{Y}^{o}$ will be used to estimate the conditional distribution of $\mathbf{Y}^{m}$ given $\mathbf{Y}^{o}, f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \boldsymbol{\theta}\right)$. If $\boldsymbol{\theta}$ is known, the values for $\mathbf{Y}^{m}$ can be drawn from $f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \boldsymbol{\theta}\right)$. For $\boldsymbol{\theta}$ unknown, an estimate is obtained from the data, say $\hat{\boldsymbol{\theta}}$; then missing values will be imputed using $f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \hat{\boldsymbol{\theta}}\right)$. Frequentists incorporate uncertainty in $\boldsymbol{\theta}$ by using bootstrap or other methods. A Bayesian prior distribution for $\boldsymbol{\theta}$ can also be chosen. Given this distribution, a draw $\boldsymbol{\theta}^{*}$ is generated and now values for $\mathbf{Y}^{m}$ can be drawn from $f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \boldsymbol{\theta}^{*}\right)$. These two steps for the construction of the imputed data are the first phase of MI. Then the substantive model is applied to each of the $M$ completed data $\left(\mathbf{Y}_{i}^{o}, \mathbf{Y}_{i}^{m *}\right)$. Let $\hat{\boldsymbol{\beta}}_{m}$ and $\hat{\boldsymbol{U}}_{m}$ be the vector of estimates and the corresponding variance-covariance matrix for the $m^{t h}$ imputed data set ( $m=1, \ldots, M$ ), respectively. The last step of MI is the combination of the $M$ results. The MI point estimate for $\beta$ is simply the average of the $M$ complete-data point estimates (Rubin, 1987; Schafer, 1997),

$$
\hat{\boldsymbol{\beta}}^{*}=\frac{1}{M} \sum_{m=1}^{M} \hat{\boldsymbol{\beta}}_{m} .
$$

A measure of the precision of $\hat{\boldsymbol{\beta}}^{*}$ is obtained by Rubin's variance formula (Rubin, 1987) which combines the within- and the between-imputation variability. Define $\mathbf{W}$, the within-imputation variance, as the average of the $M$ within imputation variance estimates $\hat{\boldsymbol{U}}_{m}$,

$$
\mathbf{W}=\frac{1}{M} \sum_{m=1}^{M} \hat{\boldsymbol{U}}_{m}
$$

## ACCEPTED MANUSCRIPT

and $\mathbf{B}$, the between-imputation variance, measuring the variability across the imputed values,

$$
\mathbf{B}=\frac{1}{M-1} \sum_{m=1}^{M}\left(\hat{\boldsymbol{\beta}}_{m}-\hat{\boldsymbol{\beta}}^{*}\right)\left(\hat{\boldsymbol{\beta}}_{m}-\hat{\boldsymbol{\beta}}^{*}\right)^{\prime} .
$$

Then, the variance estimate associated with $\hat{\boldsymbol{\beta}}^{*}$ is the total variance

$$
\mathbf{T}=\mathbf{W}+\left(1+\frac{1}{M}\right) \mathbf{B},
$$

where $\left(1+\frac{1}{M}\right)$ is a correction factor for the finite number of imputations.

### 4.2 Multivariate Normal Imputation Method

MCMC methods have been considered to explore and simulate the entire joint posterior distribution of the unknown quantities through the use of Markov chains, and thereby obtain simulation-based estimates of virtually any feature of the posterior that are of interest. For this reason, MCMC methods are widely applied in the imputation phase of multiple imputation methods.

Assuming that data arise from a multivariate normal distribution, Schafer (1997) developed a method based on MNI for generating proper imputations that accounts for between-imputation variability. This approach, based on the algorithm of data augmentation (Tanner and Wong (1987)), is a procedure that iterates between an imputation step (I-step) and a posterior step (P-step). Let the $T$ assessments of the ordinal outcome variable be viewed as a random vector, $\left(\mathbf{Y}_{1}, \cdots, \mathbf{Y}_{T}\right)^{\prime}$ assumed to follow a multivariate normal distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. In the I-step, given starting values for $\boldsymbol{\theta}=(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, values for missing data $\mathbf{Y}^{m}$ are simulated by randomly drawing a value from the conditional multivariate normal distribution of $\mathbf{Y}^{m}$ given $\mathbf{Y}^{o}$, $f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \boldsymbol{\theta}\right)$. The conditional mean, $\boldsymbol{\mu}_{m \mid o}$, and the conditional covariance matrix, $\boldsymbol{\Sigma}_{m \mid o}$, have to be derived. Let $\boldsymbol{\mu}=\left(\boldsymbol{\mu}_{o}, \boldsymbol{\mu}_{m}\right)$ be the mean vector of the variable calculated in the observed and in the missing part of the dataset. In the same way, suppose that the covariance matrix is partitioned as

## ACCEPTED MANUSCRIPT

follows,

$$
\boldsymbol{\Sigma}=\left(\begin{array}{cc}
\boldsymbol{\Sigma}_{o} & \boldsymbol{\Sigma}_{o, m} \\
\boldsymbol{\Sigma}_{o, m}^{\prime} & \boldsymbol{\Sigma}_{m}
\end{array}\right)
$$

where $\boldsymbol{\Sigma}_{o, m}$ denotes the covariance matrix between $\mathbf{Y}^{o}$ and $\mathbf{Y}^{m}, \boldsymbol{\Sigma}_{o}$ and $\boldsymbol{\Sigma}_{m}$ represent the variance matrix for $\mathbf{Y}^{o}$ and $\mathbf{Y}^{m}$, respectively. It has been shown (Goodnight (1979), Schafer (1997)) that the conditional covariance matrix, $\boldsymbol{\Sigma}_{m \mid o}$, can be expressed as:
$\boldsymbol{\Sigma}_{m \mid o}=\boldsymbol{\Sigma}_{m}-\boldsymbol{\Sigma}_{o, m}^{\prime} \boldsymbol{\Sigma}_{o}^{-1} \boldsymbol{\Sigma}_{o, m}$.

Thus,

$$
f\left(\mathbf{Y}^{m} \mid \mathbf{Y}^{o}, \boldsymbol{\theta}\right) \sim N\left(\boldsymbol{\mu}_{m \mid o}, \boldsymbol{\Sigma}_{m \mid o}\right),
$$

with $\boldsymbol{\mu}_{m \mid o}=\boldsymbol{\mu}_{m}+\boldsymbol{\Sigma}_{o, m}^{\prime} \boldsymbol{\Sigma}_{o}^{-1}\left(\mathbf{Y}^{o}-\boldsymbol{\mu}_{o}\right)$ and $\boldsymbol{\Sigma}_{m \mid o}$ given by (4).
After the first iteration, new values for $\boldsymbol{\theta}=(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ are drawn from its posterior distribution. Assuming a noninformative prior distribution for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$, their posterior distribution at the $\mathrm{t} t \mathrm{~h}$ iteration are given by a Normal and an inverted Wishart distribution (Schafer (1997)),
$\boldsymbol{\mu}_{\mid \Sigma}^{(t)} \sim N\left(\overline{\mathbf{Y}}, \frac{1}{n} \mathbf{\Sigma}^{(t)}\right)$,
$\mathbf{\Sigma}^{(t)} \sim W^{-1}[n-1,(n-1) \mathbf{S}]$,
where $(\overline{\mathbf{Y}}, \mathbf{S})$ are both determined by the observed data and the missing data imputed in the last Istep, as follows, $\overline{\mathbf{Y}}=1 / n \sum_{i=1}^{N} \mathbf{y}_{i}=1 / n\left(\sum_{i=1}^{N} y_{i 1}, \cdots, \sum_{i=1}^{N} y_{i T}\right)^{\prime}$ and $(n-1) \mathbf{S}=\sum_{i=1}^{N}\left(\mathbf{y}_{i}-\overline{\mathbf{Y}}\right)\left(\mathbf{y}_{i}-\overline{\mathbf{Y}}\right)^{\prime}$. Both steps are iterated, which creates a Markov chain $\left(\mathbf{Y}_{(1)}^{m}, \boldsymbol{\theta}_{(1)}\right),\left(\mathbf{Y}_{(2)}^{m}, \boldsymbol{\theta}_{(2)}\right), \cdots$ where each step depends on the previous one, introducing dependency across the steps. The two steps are then iterated long enough until the distribution becomes stationary. Imputations from the last iteration are used to impute the missing values of the dataset. The Expectation-Maximization (EM) algorithm was used to derive initial mean and covariance estimates for the MNI method. More detail about this procedure can be found in Schafer (1997).

When proceeding this way for an ordinal outcome, the imputed values obtained are no longer

## ACCEPTED MANUSCRIPT

integer values and need then to be rounded off to the nearest integer (category) or to the nearest plausible value. However, in the binary case, it was demonstrated that rounding is not recommended because the rounded imputed values may provide biased parameter estimates (Horton et al., 2003; Ake, 2005; Allison, 2005). In situations like ours, where one is concerned with presence of missing values for the outcome variable, unrounded values are physically not plausible. So, the rounding phase is unavoidable before application of the substantive model (e.g. GEE with proportional odds).

### 4.3 Ordinal imputation method

The ordinal imputation method (OIM) appears as an alternative to the MNI approach. To impute missing data for an ordinal outcome, one has to impose a probability model on the complete data. Multiple imputation of a longitudinal dataset with monotone missingness patterns consists in a sequential application of methods designed for univariate data by considering the previous fully observed assessment times as covariates.

In the presence of an ordinal outcome variable, a proportional odds model will be considered in the first step of the imputation phase to link the ordinal outcome to a set of $q$ covariates. In a longitudinal setting, the covariates typically include those of the substantive model $\boldsymbol{X}_{i j}$, possible auxiliary covariates $\boldsymbol{A}_{i j}$, and the previous outcomes $\tilde{\boldsymbol{Y}}_{i j}=\left(Y_{i 1}, \ldots, Y_{i, j-1}\right)$. Specifically $\mathbf{X}_{i}^{*}=\left(\boldsymbol{X}_{i j}, \boldsymbol{A}_{i j}, \tilde{\boldsymbol{Y}}_{i j}\right)^{\prime}$ and the model is written as :

$$
\begin{equation*}
\operatorname{logit}\left[\operatorname{Pr}\left(Y_{i j} \leq k\right) \mid \mathbf{x}_{i j}^{*}\right]=\gamma_{0 k}+\mathbf{x}_{i j}^{\prime *} \gamma . \tag{7}
\end{equation*}
$$

Regression coefficient estimates $\hat{\boldsymbol{\Gamma}}=\left(\boldsymbol{\gamma}_{0}^{\prime}, \boldsymbol{\gamma}^{\prime}\right)^{\prime}$, where $\boldsymbol{\gamma}_{0}=\left(\gamma_{01}, \cdots, \gamma_{0,(K-1)}\right)$, and corresponding covariance matrix $\boldsymbol{V}=V(\hat{\boldsymbol{\Gamma}})$ are obtained by fitting the proportional odds model to the observed

## ACCEPTED MANUSCRIPT

data. Based on these estimates, the algorithm to impute missing values at the $j$ th assessment, $Y_{i j}^{m}$, operates as follows:

1. Draw new values for parameters $\boldsymbol{\Gamma}$, assuming large-sample normal approximation $N(\hat{\boldsymbol{\Gamma}}, V(\hat{\boldsymbol{\Gamma}}))$ of its posterior distribution assuming the noninformative prior $\operatorname{Pr}(\boldsymbol{\Gamma}) \propto$ const. In other words, compute

$$
\Gamma^{*}=\hat{\boldsymbol{\Gamma}}+C^{\prime} \mathbf{Z}
$$

where $\boldsymbol{C}^{\prime}$ is the upper triangular matrix of the Cholesky decomposition, $\boldsymbol{V}=\boldsymbol{C}^{\prime} \boldsymbol{C}$ and $\mathbf{Z}$ is a $(K-1)+q$ vector of independent random normal variates.
2. For an observation with missing $Y_{i j}^{m}$ and corresponding covariates $\mathbf{X}_{i j}^{*}$, from (Eq. 7) compute the expected probabilities, $\pi_{k}=P\left[Y_{i j}=k \mid \mathbf{x}_{i j}^{*}\right](k=1, \ldots, K)$.
3. For each observation with missing $Y_{i j}^{m}$, draw a random variate from a multinomial distribution with the vector of probabilities $\left(\pi_{1}, \cdots, \pi_{K}\right)$ derived in the previous step.
4. Repeat steps 1 to 3 to obtain $M$ sets of imputed values $\left(Y_{i j}^{(1)}, Y_{i j}^{(2)}, \cdots, Y_{i j}^{(M)}\right),(i=1, \cdots, N$; $j=1, \cdots, T)$.

## 5 Simulation study

To assess the performance of both imputation methods (MNI and OIM), we conducted a large simulation study as described hereafter.

### 5.1 Longitudinal ordinal data-generating model

Correlated ordinal responses were generated with the SAS macro developed by Ibrahim and Suliadi (2011) and based on Lee's algorithm (Lee, 1997). The basic measurement model utilized in this study includes as covariates a binary group effect ( $X=0$ or 1 ), an assessment time $(T)$ and an

## ACCEPTED MANUSCRIPT

interaction term between group and time, so that the proportional odds model (Eq. 1) is written as $(i=1, \cdots, N ; j=1, \cdots, T ; k=1, \cdots, K-1)$ :
$\operatorname{logit}\left[\operatorname{Pr}\left(Y_{i j} \leq k \mid x_{i}, t_{j}\right)\right]=\beta_{0 k}+\beta_{x} x_{i}+\beta_{t} t_{j}+\beta_{t x} x_{i} t_{j}$.

The required arguments in Ibrahim's macro are: the marginal probabilities at each time point, the correlation structure and the sample size. To generate the longitudinal data in the two groups defined by the binary variable (i.e., $X=0,1$ ), the macro was applied twice. The corresponding marginal probabilities at each time point were derived using Eq. (8). As an example, for the group defined by $X=1$, the value of the group parameter, $x_{i}$, was fixed to 1 , the value of the time parameter, $t_{j}$, was fixed to $1, \cdots, T$ and the interaction term, $x_{i} t_{j}$, was given by the product of the two previously fixed parameters. Based on these values and using the theoretical values of the model parameters displayed in Table 1, the probabilities to be in each modalities of the ordinal outcome $Y$ at each time point was determined for the group $X=1$. For the correlation structure, the following exchangeable correlation structure was assumed:

$$
\operatorname{Corr}\left(Y_{i j}, Y_{i k}\right)= \begin{cases}1 & j=k \\ 0.2 & j \neq k\end{cases}
$$

$(i=1, \cdots, N ; j, k=1, \cdots, T)$.

Within the GEE framework, Liang and Zeger (1986) demonstrated that consistent estimates are obtained whatever the choice of the working correlation matrix. As a consequence, the correlation structure chosen in the simulations will have no impact on the derived results.

### 5.2 Missing data generating mechanisms

The mechanism used to generate MAR missingness data is based on the following binary logistic regression model $(i=1, \cdots, N ; j=1, \cdots, T ; k=1, \cdots, K-1)$ :

## ACCEPTED MANUSCRIPT

$\operatorname{logit}\left[\operatorname{Pr}\left(D_{i}=j \mid x_{i}, y_{i,(j-1)}\right)\right]=\psi_{0}+\psi_{x} x_{i}+\psi_{\text {prev }} y_{i,(j-1)}$.

Thus, the probability of drop out at a certain time point $j$ depends on the binary covariate $X_{i}$ and the outcome value at the previous time point $Y_{i,(j-1)}$. Verbiage about how to choose the population parameters to generate missing data was added in Appendix 8.2.

### 5.3 Simulation patterns

Theoretical values of the model parameters (see (Eq. 8)) considered in our simulations are given in Table 1 for well-balanced and skewed distributions. As an illustration, Figure 1 displays the distribution of the theoretical probabilities derived from Table 1 in each group and at each time point for $K=4$ for a short study $(T=3)$ under well-balanced and skewed settings.

Three distinct sample sizes $N$ were considered for the simulation: 100,300 and 500 , equally distributed between both groups. This covers small ( 50 subjects/arm) to large studies ( 250 subjects/arm). For the assessment time points $T$, two possibilities were envisaged corresponding to short $(T=3)$ or long $(T=5)$ longitudinal study. Note that for skewed data, only $T=3$ was considered. The ordinal outcome variable $Y$ covered various numbers of categories $K=2,3,4,5$ and 7, respectively. Finally, the population parameters of (Eq. 9) $\left(\psi_{0}, \psi_{x}, \psi_{\text {prev }}\right)$ were chosen to yield a rate of missingness approximatively equal to $10 \%, 30 \%$ and $50 \%$, respectively. The complete data case ( $0 \%$ missingness) was also considered. Thus, both imputation methods (MNI and OIM) were assessed on 90 different combination patterns. For each pattern, $S=500$ random samples were generated. The two MI methods (MNI and OIM) were applied to impute missing data on the same incomplete dataset allowing a paired comparaison of the two approaches. A GEE model was then fitted to the resulting multiply imputed datasets. For each MI method, the number of multiple imputation was fixed to $M=20$ (Rubin, 1987; Graham et al., 2007). As the generation of the MAR missingness was based on the binary covariate $X$, the latter had to be included in the imputation model. In the GEE model, the same working correlation as the one used in the generation data

## ACCEPTED MANUSCRIPT

process was considered, that is an exchangeable correlation matrix. The MI based on MNI and on OIM were carried out using the SAS MI procedure. The GEE SAS macro based on the extension of Lipsitz et al. method (1994) and implemented by Williamson et al. (1999) was used to analyze the imputed datasets. Ultimately, the SAS MIANALYZE procedure was used to pool the results obtained.

### 5.4 Evaluation criteria

For each simulation pattern, the relative bias $R B=\hat{\beta} / \beta$ expressed in percent was averaged over the $S=500$ replicated datasets. Likewise, the mean square error was calculated as

$$
M S E=\operatorname{Bias}^{2}+\operatorname{Var}(\hat{\beta}),
$$

with $\operatorname{Var}(\hat{\beta})=\sum_{s=1}^{S} \frac{\left(\hat{\beta_{s}}-\overline{\hat{\beta}}\right)^{2}}{(S-1)}, \overline{\hat{\beta}}=\sum_{s=1}^{S} \frac{\hat{\beta}_{s}}{S}$ and Bias $=\overline{\hat{\beta}}-\beta$.
The effect of the modeling parameters on RB was assessed by multiple regression analysis and so was the difference between RB obtained by MCMC and OIM, respectively. This statistical scheme was applied to both kinds of generated ordinal data, well-balanced and skewed distribution.

## 6 Results

The values of the relative bias (\%) and the MSE calculated over the 500 replicate samples are detailed in Appendices for both imputation methods. For clarity, results for intercepts were omitted.

### 6.1 Well-balanced distributions

Relative bias. Table 2 presents the mean ( $\pm \mathrm{SD}$ ) of RB of each regression parameter derived from both imputation methods as well as their difference. Globally, the MNI method yielded highly underestimated values of the model parameters, whereas for the OIM method estimates were almost

## ACCEPTED MANUSCRIPT

unbiased. Therefore, the RB difference between the two imputation methods was highly significant ( $p<0.0001$ ) for all parameters, ranging from $9 \%$ to $16 \%$. A closer look at the results revealed that for the binary effect parameter, $\beta_{x}$, the relative bias using MNI was unchanged for $K, N$ and rate of missingness, and varied only slightly with the number of time points. Specifically, RB was lower in long term than in short term studies $(92.3 \pm 12.0 \%$ vs $86.5 \pm 13.5 \% ; p=0.034)$. The RB for the time effect parameter, $\beta_{t}$, decreased significantly with the number of categories $K$ ( $p<0.0001$ ) and with the percentage of missingness ( $p<0.0001$ ) but was unaffected by $N$ and $T$. It decreased from $96.4 \pm 5.31 \%$ for $\mathrm{K}=2$ to $76.6 \pm 9.07 \%$ for $\mathrm{K}=7$ and from $90.9 \pm 4.08 \%$ for $10 \%$ of missingness to $80.2 \pm 14.0 \%$ for $50 \%$ of missingness. The same observation was made for the interaction term, $\beta_{t x}$, except that a significant effect was noted for $T(91.7 \pm 5.82 \%$ vs 89.4 $\pm 5.47 \% ; p=0.007$ ). By contrast, when focusing on the OIM appraoch, the relative bias behaved similarly for each regression parameter. RB decreased significantly with the number of categories $K$ ( $p<0.0001$ ), as well as with the number of time occasions $T$ ( $p<0.05$ ) but increased with the sample size $N(p<0.05)$. Contrary to the MNI method, no effect of the percentage of missingness was observed. Looking at the RB differences between the two approaches, results for model parameters were comparable except for the time parameter $\beta_{t}$ where the bias was substantiably larger for $T=3$ as compared to $T=5(p=0.001)$.

Mean square error. The mean square error (mean $\pm$ SD) of each regression parameters under both imputation methods and their difference are given in Table 3. Globally, although results were highly significant ( $p<0.0001$ ), difference between MNI and OIM were minute and not practically relevant. From this perspective, MNI and OIM were similar. As expected, under both imputation methods and for each model parameter, the MSE decreased significantly ( $\mathrm{p}<0.0001$ ) with the sample size $N$. A decrease was also observed with $T$ ( $p<0.0001$ ). MSE values also got lower as the number of categories $K$ increased but the relationship did not always reach statistical significance. The rate of missingness did not really affect MSE except for the time parameter in

## ACCEPTED MANUSCRIPT

both imputation methods (MNI: $p=0.015$ and OIM: $p=0.0005$ ).

### 6.2 Skewed distributions

As already mentioned, the case of skewed ordinal data was investigated in the context of a short term study only, that is $T=3$. Simulation results are summarized in the Appendices.

Multiple linear regression of the MNI relative bias on all modeling parameters ( $K, N$ and missingness) showed that, except for the time effect, RB increased significantly with the number of categories $K\left(\beta_{x}: p<0.0001, \beta_{t}: p=0.068, \beta_{t x}: p=0.0002\right)$ and with the percentage of missingness ( $\beta_{x}: p<0.0001, \beta_{t}: p=0.57, \beta_{t x}: p=0.0005$ ). No relationship was observed between the OIM relative bias and the modeling parameters. Contrary to the well-balanced case, the MNI method overestimated the binary and the interaction term parameters of the model, while at the same time underestimated the time parameter $\beta_{t}$. As before, the OIM method yielded less biased estimates (see Figures 2 and 3). The RB of the time parameter, $\beta_{t}$, was more affected by the skewness of the ordinal outcome than the other model parameters and this effect was even more marked with the MNI method. In fact, the lowest RB value of $\beta_{t}$ was equal to $42.1 \%$ and the highest RB value was equal to $265.5 \%$; both extremes were obtained under the MNI method. The corresponding OIM relative biases were equal to $103.9 \%$ and $169.7 \%$, respectively.

The MSE of each regression parameter under both imputation methods and their differences are displayed in Table 4. Comparison of the MSE calculated in presence of skewed ordinal outcomes with those derived in well-balanced setting showed that MSE values were larger in presence of skewness. The conclusions made previously on MSE values in case of well-balanced distributions can be transported here. Specifically, MNI and OIM mean square errors were similar and differences of MSE under both methods were not meaningful, even if statistically significant. As expected, the MSE decreased significantly ( $p<0.0001$ ) with the sample size. The MSE decreased

## ACCEPTED MANUSCRIPT

with the number of categories of the ordinal outcome for the binary effect under OIM ( $p=0.009$ ) and less markedly for both time effect and interaction terms of the model. The effect of the rate of missingness on MSE was significant for the time effect parameter, under both imputation methods (MNI: $p=0.001$ and OIM: $p<0.0001$ ) and the MSE of the interaction term of the model derived under OIM $(\mathrm{p}=0.017)$. Although not relevant, the difference in the MSE of both imputation methods decreased with the sample size for the time and the interaction term of the model. The MSE difference for the latter further deteriorated with higher rates of missingness ( $p<0.0001$ ). The number of categories of the ordinal outcome affected differently the MSE difference of the binary and the interaction terms of the model. For the binary effect of the model, the difference in MSE increased with the number of categories of the ordinal outcome ( $p<0.0001$ ), while for the interaction term the MSE difference decreased ( $p=0.0009$ ).

## 7 Discussion

This paper compared the performance of two imputation methods available in statistical packages, namely the MNI algorithm and the ordinal imputation regression model, in the context of longitudinal ordinal datasets with missing values. The comparison was based on a comprehensive simulation plan covering a wide range of real life situations. Specifically, the parameters of the experimental design included the number of categories of the ordinal outcome $(K)$, the number of time points $(T)$, the sample size $(N)$ and the rate of missingness (\%) but also the form of the distribution (well-balanced or skewed) of the ordinal outcome data. The performance of the two methods (MNI and OIM) was appraised by the relative bias and the mean square error of the regression parameters of the model. The latter included a group effect and a time effect, as well as their interaction.

In the well-balanced setting, the estimates of the model parameters obtained with the MNI approach were markedly underestimated ( $\mathrm{RB} \ll 100 \%$ ). By contrast, estimates derived with the

## ACCEPTED MANUSCRIPT

OIM method were almost unbiased. These general observations however have to be tempered according to the study pattern. For example, RB differences between MNI and OIM for the binary and the interaction model parameters vanished with increasing $K$, the number of categories. By contrast, for the time effect parameter, the RB difference increased with $K$ but decreased with $T$, the number of time points. For all regression parameters, the MSE of both imputation methods were almost equal but departed slightly for larger sample sizes and higher missingness rates. For skewed data, estimates under MNI method were positively biased, except for the time effect, and MSE were comparable.

In conclusion, based on the results of this large simulation study, the MNI method is not really recommended to analyze longitudinal ordinal data with missing values. Preferably, it is advisable to impute missing ordinal data using an appropriate regression model. The OIM method however requires the construction of an imputation model. Meng (1994) showed that, as long as the imputation model is not grossly misspecified, MI approach will perform well. From a practical point of view, the imputation model should at least include any variable structure (e.g. interaction) present in the substantive model (Fay, 1992). The inclusion of other available covariates, which are not necessarily of interest in the substantive model, is unlikely to produced biased results. Therefore, Rubin's rule which consists in including as many variables as possible when performing multiple imputation (Rubin, 1996) is recommended. Furthermore, in the binary setting with MAR missingness, Beunckens et al. (2008) demonstrated the robustness of MI-GEE when misspecifying either the imputation or measurement model. Those findings were extended in the MNAR case (Birhanu et al., 2011).

As a final remark, we should noted that, contrary to the MNI method, the use of the OIM method is limited to the situation of monotone missingness. In the presence of non-monotone missingness, a solution to minimize the imputation's bias could be to iterate between application

## ACCEPTED MANUSCRIPT

of MNI and OIM methods to first monotonize the dataset before application of the OIM method. This proposal, however, requires additional researches.

### 8.2 Selection of population parameters to generate missing data

The population parameters in (Eq. 9) were chosen using the following pragmatic way. First, rewrite the dropout probability model as follows,

$$
\operatorname{Pr}\left(D_{i}=j \mid x_{i}, y_{i,(j-1)}\right)=\frac{e^{\psi_{0}+\psi_{x} x_{i}+\psi_{p r e v e} y_{i,(j-1)}}}{1+e^{\psi_{0}+\psi_{x} x_{i}+\psi_{\text {pree }} y_{i, j-1)}}} .
$$

Let us assume that the ordinal outcome $Y$ has $K$ categories and that their probabilities of occurring, $p_{y}(y)$, are known. Let us also assume that $X$ has two categories and that we know their probabilities of occurrence $p_{x}(x)$. In line with our simulation plan, assume that these two occurrences are independent, so that $p(x, y)=p_{x}(x) p_{y}(y)$. Then, we chose parameter values for $\psi_{x}$ and $\psi_{\text {prev }}$, leaving only $\psi_{0}$ unspecified. Let the proportion of missingness aimed for be $\pi$ (e.g. $10 \%, 30 \%$, or $50 \%$ ), we then found the values for $\psi_{0}$ (by trial and error) that satisfied

$$
\pi=\sum_{x} \sum_{y} p(x, y) \frac{e^{\psi_{0}+\psi_{x} x_{i}+\psi_{p r e v e} y_{i, j-1)}}}{1+e^{\psi_{0}+\psi_{x} x_{i}+\psi_{p r e v} y_{i, j-1)}}}
$$
