Abstract

We propose a systolic architecture for computing a singular value decomposition of an $m \times n$ matrix, where $m \geq n$. Our algorithm is stable and requires only $O(mn)$ time on a linear array of $O(n)$ processors. Extensions to algorithms for two-dimensional arrays are also discussed.

Key Words and Phrases: Systolic arrays, singular value decomposition, Hestenes method, threshold Jacobi method, real-time computation.

1. Introduction

A singular value decomposition (SVD) of an $m \times n$ $(m \geq n)$ matrix A is its factorization into the product of three matrices:

$$A = U \Sigma V^T , \tag{1.1}$$

where U is an $m \times n$ matrix with orthonormal columns, Σ is an $n \times n$ nonnegative diagonal matrix and the $n \times n$ matrix V is orthogonal. This decomposition has many important scientific and engineering applications (cf. [1], [5] and [11]), for some of which real-time computation is desirable. With the advent of VLSI technology, there is interest in a systolic network for computing the decomposition. In [3] Finn et al. describe one such architecture and two related algorithms. Unfortunately, the convergence of their algorithms is only an empirical observation and has not been proved. Heller and Ipsen [7] consider the problem of computing only the singular values of a banded matrix with bandwidth w. They present a systolic array of $O(w)$ processors and an $O(wn^2)$ algorithm.

In this paper we present a systolic array of $O(n)$ linearly-connected processors which computes the SVD in time $O(mn)$. Alternatively, a two-dimensional systolic array of $O(mn)$ processors with a more complicated interconnection pattern can compute the SVD in time $O(n \log m)$. Our systolic architectures implement a one-sided orthogonalization method due to Hestenes [8].

The Hestenes method is essentially the serial Jacobi procedure for finding an eigenvalue decomposition of the matrix A^TA, and has been used successfully by the second author [9] on the ILLIAC IV computer. A complication arises here in that, for the sake of parallel computing, we discard the classical scheme of rotating column pairs

in the order $(1,2),(1,3), \ldots, (1,n),(2,3), \ldots, (2,n),(3,4), \ldots, (n-1,n)$. To enforce convergence, we choose a threshold approach (see Wilkinson [13, pp. 277-278]).

2. Hestenes method

The idea is to generate an orthogonal matrix V such that the transformed matrix AV has orthogonal columns. Normalizing the euclidean length of each nonnull column to unity, we get the relation

$$AV = \tilde{U}\,\Sigma \,, \tag{2.1}$$

where $\tilde{U}$ is a matrix whose nonnull columns form an orthonormal set of vectors and Σ is a nonnegative diagonal matrix. A SVD of A is thus given by

$$A = \tilde{U}\,\Sigma\,V^{T} \,. \tag{1.1'}$$

As a null column of $\tilde{U}$ is always associated with a zero diagonal element of Σ , there is no essential difference between (1.1) and (1.1').

Hestenes [8] suggests that the orthogonal matrix V should be constructed as a sequence of plane rotations, say $Q_1, Q_2, \ldots$. Let

$$A^{c} \equiv A\,Q_1\,Q_2 \cdots Q_k \,. \tag{2.2}$$

Without loss of generality, we may assume that the next rotation acts on the i-th and j-th columns ($\underset{\sim}{a}_i^{c}$ and $\underset{\sim}{a}_j^{c}$, $i < j$) of the current matrix A^{c} . Let us consider

$$(\underset{\sim}{a}_i^{c}, \underset{\sim}{a}_j^{c}) \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} \equiv (\underset{\sim}{a}_i^{N}, \underset{\sim}{a}_j^{N}) \,. \tag{2.3}$$

Our problem is therefore choosing a rotation angle θ to generate an orthogonal pair of column vectors $\underset{\sim}{a}_i^{N}$ and $\underset{\sim}{a}_j^{N}$. We use the formulas given by Rutishauser [10]. Defining

(2.4) $$\alpha \equiv \|a_i^c\|_2^2 \ , \quad \beta \equiv \|a_j^c\|_2^2 \quad \text{and} \quad \gamma \equiv (a_i^c)^T(a_j^c) \ ,$$

we set $\theta = 0$ if $\gamma = 0$, and otherwise compute

(2.5) $$\xi = \frac{\beta - \alpha}{2\gamma} \ ,$$

$$t = \frac{\text{sign}\ (\xi)}{|\xi| + \sqrt{1 + \xi^2}} \ ,$$

$$\cos\theta = \frac{1}{\sqrt{1 + t^2}} \ ,$$

and $$\sin\theta = t.\cos\theta \ .$$

The rotation angle always satisfies

(2.6) $$|\theta| \leq \frac{\pi}{4} \ ,$$

which would guarantee convergence had we rotated the columns in the classical order of $(1,2),(1,3), \ldots, (1,n),(2,3), \ldots, (2,n),(3,4), \ldots, (n-1,n)$ (Forsythe and Henrici [4]). However, in order to perform the rotations in parallel, we choose a scheme (to be described in Section 4) in which all column pairs are rotated just once in any sequence (called a "sweep") of $n(n-1)/2$ rotations, but not in the above order. Very little is known about the convergence properties of this alternate scheme (see Hansen [6]), although we note that it has an asymptotically optimal "preference factor" [6, eqn. (23)]. To enforce convergence, we adopt a threshold approach (Wilkinson [13, pp. 277-278]). Let us associate with each sweep a threshold value, and when making the transformations of that sweep, we omit any rotation based on a normalized inner product

$$\frac{(a_i^c)^T(a_j^c)}{\|a_i^c\|_2\|a_j^c\|_2}$$

which is below the threshold value. Our method enjoys ultimate quadratic convergence (Wilkinson [12]) and numerical experience suggests that only six to ten sweeps are required (Rutishauser [10]).

We may compute the matrix V by accumulating the plane rotations. If we let

$$V^c \equiv Q_1 Q_2 \cdots Q_k \equiv (\underset{\sim}{v}_1^c, \ldots, \underset{\sim}{v}_n^c) , \tag{2.7}$$

then the (k+1)-st rotation will affect only the columns $\underset{\sim}{v}_i^c$ and $\underset{\sim}{v}_j^c$. We can therefore determine the new columns using

$$\begin{pmatrix} a_i^c, a_j^c \\ \underset{\sim}{v}_i^c, \underset{\sim}{v}_j^c \end{pmatrix} \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} \equiv \begin{pmatrix} a_i^N, a_j^N \\ \underset{\sim}{v}_i^N, \underset{\sim}{v}_j^N \end{pmatrix} , \tag{2.8}$$

i.e. we update both A^c and V^c simultaneously.

3. Generation of all pairs (i,j)

In this section we show how $O(n)$ linearly-connected processors can generate all pairs (i,j), $1 \le i < j \le n$, in $O(n)$ steps. The application to the computation of the SVD is described in Sections 4 and 5.

First suppose n is even. We use $n/2$ processors $P_1, \ldots, P_{n/2}$, where P_k and P_{k+1} communicate $(k=1,2,\ldots,n/2-1)$. Each processor P_k has registers L_k and R_k, output lines $outL_k$ and $outR_k$, and input lines inL_k and inR_k, except that $outL_1$, inL_1, $outR_{n/2}$ and $inR_{n/2}$ are omitted. The output $outR_k$ is connected to the input inL_{k+1} and the output $outL_{k+1}$ is connected to the input inR_k, as shown in Figure 1.

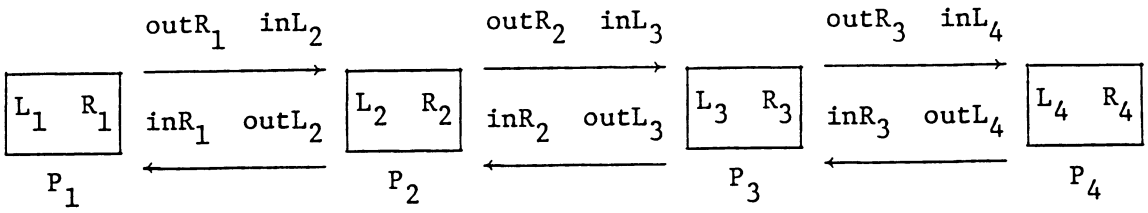

Figure 1: Inter-processor connections for $n = 8$

Initially $L_k = 2k - 1$ and $R_k = 2k$. At each time step processor P_k executes the following program:

```
if L_k < R_k then process (L_k,R_k) else process (R_k,L_k);
if k=1 then outR_k:=R_k
   else if k < n/2 then outR_k:=L_k;
if k > 1 then outL_k:=R_k;
{wait for outputs to propagate to inputs of adjacent processors}
if k < n/2 then R_k:=inR_k else R_k:=L_k;
if k > 1 then L_k:=inL_k;
```

Here process (i,j) means perform whatever operations are required on the pair (i,j), $1 \le i < j \le n$. The operation of the systolic array is illustrated in Figure 2.

We see that the index 1 stays in the register L_1 of processor P_1. Indices 2, ..., n travel through a cycle of length n-1 consisting of the registers $L_2, L_3, \ldots, L_{n/2}, R_{n/2}, R_{n/2-1}, \ldots, R_1$. During any n-1 consecutive steps a pair (i,j) or (j,i) can appear in a register pair (L_k,R_k) at most once. A parity argument shows that (i,j) and (j,i) can not both occur (see Figure 2). Since there are n/2 register pairs at each of n-1 time steps, each possible pair (i,j), $1 \le i < j \le n$, is processed exactly once during a cycle of n-1 consecutive steps.

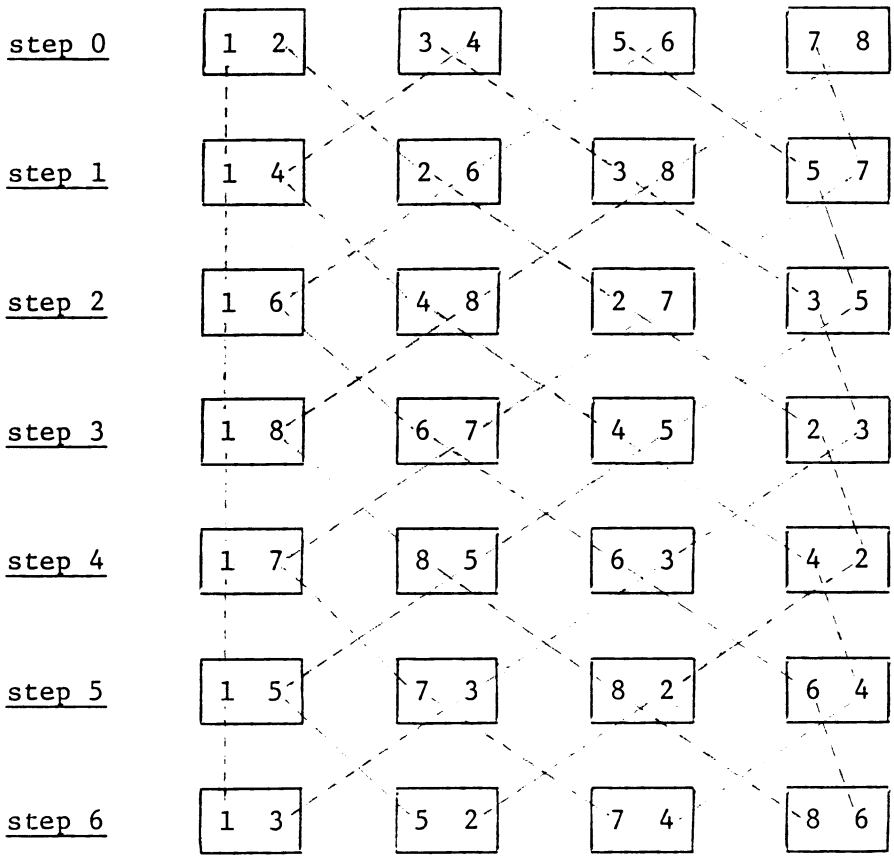

Figure 2: Full cycle of the systolic array for $n = 8$

If n is odd, we use $\lceil n/2 \rceil$ processors but initialize $L_k = 2k - 2$, $R_k = 2k - 1$ for $k=1, \ldots, \lceil \frac{n}{2} \rceil$ and omit any "process" calls from processor P_1.

4. A one-dimensional systolic array for SVD computation

Assume that n is even (else we can add a zero column to A or modify the algorithm as described at the end of Section 3). We use $n/2$ processors $P_1, \ldots, P_{n/2}$, as described in Section 3, except that L_k and R_k are now local memories large enough to store a column of A (i.e. L_k and R_k each have at least m floating-point

words). Shift registers or other sequential access memories are sufficient as we do not need random access to the elements of each row.

Suppose processor P_k contains column a_i^c in L_k and column a_j^c in R_k. It is clear that P_k can implement the transformation defined by (2.3)-(2.6) in time $O(m)$ by making one pass through a_i^c and a_j^c to compute the inner products (2.4), and another pass to perform the transformations (2.3) or (2.8). Adjacent processors can then exchange columns in the same way that the processors of Section 3 exchange indices. This takes time $O(m)$ if the bandwidth between adjacent processors is one floating-point word. (Alternatively, exchanges can be combined with the transformations (2.3) or (2.8).)

Consequently, we see that $n/2$ processors can perform a full sweep of the Hestenes method in $n - 1$ steps of time $O(m)$, i.e. in total time $O(mn)$. Initialization requires that the $(2k-1)$-th and $2k$-th columns of A be stored in the local memory of processor P_k for $k=1, \ldots, n/2$; clearly this can also be performed in time $O(mn)$.

Although the process is iterative, in practice only 6-10 sweeps are required to orthogonalize the columns to full machine accuracy (see Section 2). Hence, we have a systolic array of $n/2$ processors which computes the SVD in time $O(mn)$. By comparison, the serial Hestenes algorithm takes time $O(mn^2)$.

After an integral number of sweeps the columns of the matrix $AV = \tilde{U}\Sigma$ (see (2.1)) will be stored in the systolic array (two per processor). If V is required, it can be accumulated at the same time that AV is accumulated, at the expense of increasing each processor's local memory (but the computation time remains $O(mn)$): see (2.8).

5. Two-dimensional systolic arrays for SVD computation

It is natural to ask if a rectangular array of m by $n/2$ processors can be used to obtain a greater speedup than a linear array of $n/2$ processors. The only difficulty (but a major one) is in the fast accumulation of the inner products (2.4). If the processors have a binary tree interconnection pattern superimposed on each column of the rectangular array, so that the inner products (2.4) can be accumulated in time $O(\log m)$, then an array of $mn/2$ processors can compute the SVD of A in time $O(n\log m)$, by an obvious modification of the method of Section 4.

As observed in Section 1, Hestenes method is theoretically equivalent (with exact arithmetic) to the Jacobi method applied to A^TA. In [2] we show that Jacobi's method can be implemented in time $O(n)$ on a square array of $n/2$ by $n/2$ systolic processors with nearest-neighbour connections. Hence, the factor $\log m$ above (and the non-local connection pattern) can be avoided, at the expense of some loss of numerical accuracy.
