Abstract

The combination of design and subsequent fabrication of organic/inorganic nanostructures creates an effective way to combine the favorable traits of both to achieve a desired device performance. We demonstrate a miniature electrical read-out, and a sensitive temperature sensor/switch, based on a ZnO nanobelt/plasma-polymerized benzonitrile bimorph structure. A new read-out technique based on the change in the electric current flowing through the bimorph and the contact pad has been employed, replacing the conventional cumbersome piezoresistive method or tedious optical alignment. The thermal sensor demonstrated here has great prospects for thermal switching and triggered detection owing to the relative ease in the fabrication of arrays and the direct electrical read-out.

1. Introduction

Recently there has been an explosive interest in the fabrication and assembly of novel nanostructures with well-defined sizes, shapes, and composition, which determine the properties of these nanostructures and their final applications. The current challenge is to devise methods to effectively assemble the nanostructures into functional systems and subsystems. The unique combination of piezoelectric and semiconducting properties makes ZnO nanostructures one of the most prospective nanomaterials [1–8]. Fine control over the growth of complex ZnO nanostructures such as belts, helices, rings, and flowers has been achieved by chemical vapor deposition and more recently by wet chemical methods [1, 2]. Significant progress has been made in the application of ZnO nanostructures [3] in the fabrication of various electronic, optoelectronic, and sensor devices, which include nanolasers [4], photodiodes [5, 6], acoustic resonators [7], piezoelectric gated diodes [8], gas sensors [9], and nanogenerators [10]. In addition, the combination of design and subsequent fabrication of organic/inorganic

nanostructures has been employed for various applications, such as nanogenerators [11], light-emitting diodes [12–14], solar cells [15, 16], optoelectronic switches and memory devices [17].

A thermal sensor/switch is designed to control heat transfer by making and breaking thermal contact between two thermally isolated areas. Miniature, highly sensitive temperature sensors are extremely important in various civilian, industrial, and defense applications. For instance, a temperature sensor combined with actuation capability which can make and break thermal contacts at a desired temperature is highly desirable in automated systems, alarms, and process control units. A nanothermometer has recently been demonstrated in which carbon nanotubes have been filled with liquid Ga substituting the mercury in conventional thermometer [18, 19]. Microcantilever sensors, microscopic analogs of traditional bimetallic structures, have been employed for uncooled infrared (IR) detection [20–24]. The design uses the well-known phenomenon of temperature-induced bending (due to thermally induced stress) of bimorph

beams composed of two materials with different thermal expansion coefficients. For over 200 years, the coiled bimetallic strip thermometer has been used with little change and it is still useful today as common household thermostats and cooking thermometers.

There is a renewed interest in bimorph structures due to the advent of microcantilever systems. These systems have found a prominent place in various sensing applications due to several attractive features, namely, high sensitivity, miniature size, low cost, low power consumption, and versatility. There have been extensive efforts to maximize the bimaterial effect, involving the optimization of the differential thermal expansion, thermal conductivity, and mechanical properties of the cantilever and the sensitive layer. While microcantilevers have primarily been fabricated using conventional silicon microfabrication routines, various sensitive layers have been extensively investigated, including metals, homopolymer layers, and polymer composites. Very recently, we have introduced plasma polymers as the actuation layer, enabling a temperature resolution as low as 0.2 mK [25]. Various read-out techniques such as laser-beam deflection, interferometry, piezoresistive, piezoelectric, capacitance, and field-effect transistors have been exploited to detect the bimorph deflections [25–29]. All of the above-mentioned detection methods involve either complex microfabrication steps or tedious optical alignment.

In the present work, we demonstrate an electrical read-out temperature sensor which also acts as a thermal switch based on the bimorph structure of a ZnO nanobelt (NB) and plasma-polymerized benzonitrile (PP-BN). The working principle of the thermal sensor demonstrated here is based on the differential thermal expansion of the ZnO NB and the plasma polymer layer. The change of electrical current of the bimorph is initiated by the deflection of the bimorph at a particular critical temperature, which results in the change of the contact area of the ZnO NB and the Au metal pad (contact metal). This bimorph structure can also act as a switch at a predetermined temperature through an appropriate choice of the thickness of the ZnO NB and the polymer layer.

2. Experimental details

Details of the vapor–liquid–solid growth technique employed for the fabrication of the ZnO NBs has been reported elsewhere [30]. The synthesized ZnO NBs are transferred from the Al_2O_3 substrate to prepatterned Ti/Au electrodes by touching the NB sample with the electrodes. A single ZnO NB device lying across two electrodes could be easily achieved using this method. To reduce the contact resistance and customize the length of the ZnO NB device, a focused ion beam is employed to deposit a conducting mixture of Pt–Ga on the contacts between the ZnO and Ti/Au electrodes. Ti/Au electrodes for current–voltage (I – V) measurements were fabricated on 100 nm $\text{Si}_3\text{N}_4/\text{Si}$ wafer through a typical process described in the literature [31]. The electrode pattern was designed to have a few parallel electrodes separated by 5–20 μm . The oxygen plasma treatment was carried out to eliminate the surface contamination of the ZnO NB device

before depositing PP-BN (the chemical structure is shown as the inset of figure 1(c)). The NB device was coated with PP-BN using plasma enhanced chemical vapor deposition with argon (50 – $200 \text{ cm}^3 \text{ min}^{-1}$, 99.999%) as the carrier gas within a custom-built chamber as described in detail elsewhere [32]. The thickness of the plasma polymer coating was measured with an atomic force microscope (AFM) by scanning at the edge of the film. The AFM surface morphology and thickness measurement were performed using a DI-3000 AFM in tapping mode [33].

Theoretical values for the deflections of the NB/PP-BN bimorph structure have been estimated using finite element analysis (FEA) executed in the structural mechanics module of a commercial package (COMSOL Multiphysics 3.2). A typical FEA involves the reduction of the energy functional (E) of individual elements of the model. The minimization is attained by setting the derivative of E with respect to the displacement of the mesh element to zero. The principle of virtual work was selected as the implementation method for minimizing E . The model used a nonlinear mode to account for the probable saturation effects in the deformation.

3. Results and discussion

Figure 1(a) shows the schematic representation of the nanosensor/nanoswitch device, in which a ZnO NB bridges two electrodes with one of the ends clamped to the electrode underneath. The device architecture is similar to a conventional bimaterial microcantilever structure except that the free end of the ZnO NB rests on the electrode. Figure 1(b) shows the scanning electron microscope (SEM) image of the NB suspended across the two contact pads. The constrained and free end of the ZnO NB is identified on the SEM image. AFM imaging was performed directly on the ZnO NB to study the uniformity of the coating and surface morphology of the plasma polymer film. Figure 1(c) shows the AFM surface morphology of the PP-BN, depicting a uniform coating and the characteristic grainy surface morphology and low microroughness (below 2 nm within a 1 μm^2 area).

While the typical ZnO-Au contact is Schottky in nature, depositing a Pt-Ga mixture between the NB and Au electrodes usually results in ohmic characteristics [34]. The mixture provides low contact resistance of Pt-Ga/ZnO compared to the ultra-high contact resistance of pure Pt/ZnO reported in the literature [35]. The I - V characteristics of the bimorph device exhibited a temperature-dependent rectifying behavior, as shown in figure 2(a). The magnitude of the forward current at a given voltage decreases significantly with decreasing temperature.

As is known, the current through a Schottky barrier diode at a forward bias, based on thermionic emission-diffusion theory, is given by the relation [36]

$$I = A_d A^{**} T^2 [e^{(qV/kT)} - 1] e^{(q\phi_b/kT)} \quad (1)$$

where A_d is the diode area (the contact area of ZnO NB and Au metal), A^{**} is the effective Richardson constant, T is the

temperature in Kelvin, k is the Boltzmann constant, q is the electronic charge, and ϕ_b is the barrier height. According to equation (1), there are two factors leading to temperature-dependent current variation. First, increasing/decreasing the temperature will lead to proportional deflection of the bimorph due to differential thermal expansion [28]. Correspondingly, the deflection of the bimorph should reduce the contact area of the ZnO NB and Au metal pair, leading to an increase in the contact resistance. Second, the current is influenced directly by the $T^2 [e^{(qV/kT)} - 1] e^{(q\phi_b/kT)}$ term, which is partly attributed to the tunneling through a barrier from occupied levels, whose population is slightly modified by the elevated temperature, and a potential barrier that allows increasing penetration with increasing forward voltage. Owing to the two above-mentioned contributions, temperature-dependent I - V characteristics were observed. However, as the temperature reached 5 °C, the current dramatically dropped to noise level, indicating an open circuit.

Figure 2(b) shows the current versus temperature curve at the forward bias of 1 V, in the OFF and ON states, with the ON state clearly exhibiting a linear increase in the current with temperature. For further analysis of the thermal switch performance, the current-time measurement from 10 to 9 °C was investigated, as shown in figure 2(c). As the temperature was decreased from 10 to 9 °C, a notable sharp drop in the current was observed, corresponding to the separation of the ZnO NB and the Au metal pad pair, resulting in $A_d = 0$. The sudden snap-off of the ZnO from the metal electrode as the temperature is varied within a narrow window from 10 to 9 °C manifests itself as a thermal trigger switch.

Finally, the reversibility of the thermal bimorph nanoswitch was assessed by repeatedly cycling the switch. For testing the repeatability of this bimorph structure, the current was

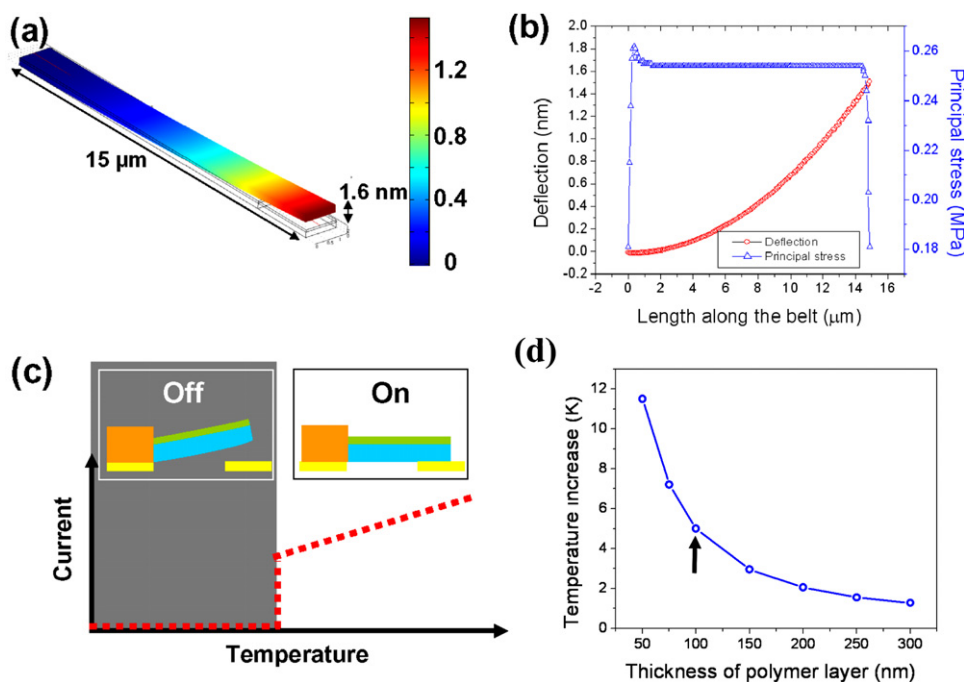

Figure 3. Finite element analysis (FEA) of the bimorph structure. (a) Deflection of the nanobelt bimorph structure for 1 K change in temperature assuming a free end of the cantilever. (b) Plot depicting the deflection profile along the length of the nanobelt and the principal stress at the top surface for 1 K change in temperature. (c) Schematic of the working principle of a thermal switch. Expected temperature dependence of the current, $I(T)$. At the moment when the metal pad and the bimorph are separated, $I(T)$ shows a switching action: a sharp drop occurs, corresponding to the current sharply reducing to 0. The arrow points to the thickness of the polymer layer fabricated in this study.

measured after the temperature was changed from 5 °C back to 20 °C. Figure 2(d) is the comparison of I - V measurement, indicating that there is no noticeable change, which demonstrates that this bimorph device can serve as an efficient thermal switch with repeatable ON/OFF cycling. Compared to time-consuming, delicate, and rather expensive observations using a transmission electron microscope (TEM) and laser-beam deflection methods [18, 25, 26], this stand-alone ZnO NB/PP-BN bimorph device is more straightforward and can be easily tuned to different threshold levels by utilizing different thicknesses of the PP-BN coating with high thermal expansion. The interfacial thermal stresses developed within these structures allows for the thermally induced actuation caused by reversible bending deformation of a bimorph due to a vast mismatch in film properties and thermal expansion coefficients of the materials within a wide range of temperatures.

The significant difference between the NB/PP-BN bimorph structure and a conventional bimaterial cantilever structure is that in the former the free end of the NB rests on the substrate (electrode) as opposed to the freely suspended state in the latter. The differential surface stress and thus the deflection of the conventional bimaterial cantilever structure can be modeled by the modified Stoney equation [28]. However, in the case of the NB bimorph structure, interaction of the free end with the electrode plays a significant role in the deflection behavior of the NB owing to the nanoscale dimensions.

One of the primary contributions responsible for the adhesion between the ZnO NB and the Au (electrode) is the

capillary force between the two flat surfaces since the thermal switch was operated at ambient humidity conditions (~60%). The magnitude of the capillary force can be estimated from the Laplace pressure drawing the two plates together, given by $P = 2\gamma_L/x$, where x is the separation between the plates and γ_L is the surface tension of the water bridging the parallel plates [37]. For given geometrical parameters and a separation of 1 nm, the Laplace pressure drawing the ZnO belt to the Au electrode is calculated to be 130 MPa (assuming complete wetting of the Au pad and the ZnO belt). To compare this value with the differential stresses developed, finite element analysis (FEA) was employed to estimate the stress in the bimorph structure for the change in temperature [38]. The material properties of the ZnO (Young's modulus (E) = 210 GPa and thermal expansion coefficient (α) = $12 \times 10^{-6} \text{ K}^{-1}$) have been chosen from the standard COMSOL library. The elastic modulus of the plasma polymer film was measured to be 2 GPa by AFM nanomechanical probing [39]. The thermal expansion coefficient of the PP-AN was measured to be $100 \times 10^{-6} \text{ K}^{-1}$ by measuring the thickness of the film deposited on silicon using ellipsometry between 25 and 90 °C [38]. Figures 3(a) and (b) show the deflection profile and the surface stress on the polymer side of the bimorph structure. The bimorph structure exhibits a deflection of ~1.6 nm for 1 K decrease in temperature. The surface stress at the top surface of the cantilever was found to be close to 0.25 MPa. This is significantly smaller than the capillary force resisting the release of the ZnO belt from the surface of the Au electrode. This significantly high force of adhesion keeps the ZnO belt in

contact with the Au electrode for a large range of variation of temperature. However, decreasing the contact area (increasing the contact resistance) by decreasing the temperature results in a gradual decrease in the current. As the temperature is further decreased, owing to the inverse dependence of the Laplacian pressure on the distance, the adhesive force dramatically drops and the ZnO/PP-BN bimorph snaps off from the Au surface, resulting in an open circuit (OFF state of the switch in figure 3(c)). The switching temperature of the bimorph structure between ON and OFF states can be precisely adjusted by controlling the thickness of the actuating polymer layer. Figure 3(d) shows the plot of the temperature increase required to induce a deflection of 10 nm in the bimorph structure calculated using FEA. The arrow depicts the thickness of the plasma polymer layer (100 nm) discussed in this study. As can be seen from the plot, the temperature required to deflect the cantilever is highly sensitive to the thickness of the polymer layer. Assuming that the switch turns from ON to OFF state for a deflection of 10 nm, the switching temperature can be tuned by changing the thickness of the polymer layer. It is also important to note that the capillary force and hence the ON/OFF transition temperature depends on the humidity of the ambient. The effect of humidity on the device performance is currently under investigation and will be reported in a separate publication.

4. Conclusion

In summary, we have demonstrated a thermal nanoswitch/nanosensor based on a PP-BN/ZnO NB bimorph structure, which employs a novel read-out mechanism based on the variation of electric current with bimorph actuation. The bimorph demonstrated in this study obviates the use of complex microfabrication (to incorporate the piezoresistors into the cantilevers) or tedious optical alignment. We have demonstrated the unique combination of an electrical read-out of thermal detection and a thermally triggered ON–OFF switch. Furthermore, the device architecture demonstrated here offers the ease of array fabrication for prospective thermal imaging or switching in an arrayed manner. The technology demonstrated here can also be adapted to realize a highly sensitive chemical and biological sensing system by altering the sensitive layer.
