20 Abstract

21

The release of engineered nanoparticles (ENPs) into the environment has raised concerns about the 22 potential risks to food safety and human health. There is a particular need to determine the extent of ENP 23 uptake into plant foods. Belowground vegetables growing in direct contact with the growth substrate are 24 likely accumulate the highest concentration of ENPs. Carrot (Daucus carota) was grown in sand 25 amended with ZnO, CuO, or CeO₂ NPs or the same concentrations of Zn^{2+} , Cu^{2+} , or Ce^{4+} . Treatment with ZnO or Zn^{2+} produced a concentration-dependent decrease in root and total biomass. Ionic Cu²⁺ and Ce⁴⁺ 26 27 caused a greater reduction in shoot biomass as compared to the corresponding ENP treatments. 28 Accumulation of Zn, Cu, or Ce in the taproot was restricted to the taproot periderm. Metal concentrations 29 in the taproot periderm were higher for the ionic treatments than for the ENP treatments. Radial 30 penetration of the metals into the taproot and subsequent translocation to shoots was also generally 31 greater for plants receiving the ionic treatment than the ENP treatment. The distribution of the metals 32 from the ENP treatments across the periderm, taproot, and shoots differed from that observed for the ionic 33 treatments. Overall, the ENPs were no more toxic than the ionic treatments and showed reduced 34 accumulation in the edible tissues of carrot. The results demonstrate that the understanding of ionic 35 metal transport in plants may not accurately predict ENP transport and that additional 36 comparative study is needed for this and other crop plants. 37

1. Introduction

41 The nanotechnology industry is a rapidly expanding commercial sector. The market 42 share of commercial products incorporating nanotechnology reached \$174 billion in 2007 and is expected to grow to \$2.5 trillion by 2015.¹ The unique properties that emerge when materials 43 44 are fabricated at the nanoscale (i.e., at least one dimension <100 nm) have given rise to thousands of applications and proposed inclusion in hundreds of consumer, medical, and 45 46 industrial products.¹ The anticipated increase in the use of nanomaterials, in particular some 47 metallic oxide nanoparticles, has also produced concern that there may be detrimental effects of 48 these materials upon intentional or accidental release into the environment. Assessing the 49 toxicity of nanoparticles to animals, plants, fungi, and microorganisms has been a principle focus to date.²⁻⁶ Another concern is possible particle bioaccumulation in terrestrial food webs and the 50 human food supply.^{7, 8} 51

52 Crop plants could potentially come in contact with engineered nanoparticles (ENPs) through application of biosolids to agricultural fields ^{9, 10} or the application of nano-enabled 53 agricultural products to plants or to the soil.¹¹⁻¹³ Additional routes by which crop plants may be 54 exposed to ENPs include accidental discharges, contact with nanomaterials intended for soil or 55 56 water remediation, the application of irrigation water containing ENPs, and potential aerial 57 deposition. The presence of ENPs in plant foods represents a likely pathway by which the 58 general public might be exposed to these materials. A variety of studies have focused on the 59 accumulation of Ag and other metal oxide (e.g., CuO, CeO₂, ZnO) ENPs in the edible tissues of various crops.^{2-4, 14} Most of these studies have focused on leafy or stem vegetables (e.g., lettuce 60 and spinach), fruits (e.g., tomato, zucchini, legumes), and grains (e.g., barley, rice, maize). 61 62 Where data on accumulation in these and other plants is presented, the results frequently indicate that plant roots accumulate considerably higher concentrations of ENPs as compared to the aboveground tissues. This tendency of roots to retain ENPs has been attributed to the small pore size (2-20 nm) of the root cell wall network that is generally smaller than most ENPs ^{4, 15} and the capacity of the root to act as a selective "sieve" to trap ENPs.¹⁶ The propensity of roots to accumulate ENPs suggests that belowground root, tuberous, and bulb vegetables, due to their direct contact with ENPs in the growth substrate, may be more likely to accumulate ENPs.

69 There is limited information available on the accumulation of ENPs in belowground 70 vegetables; consequently, the study described here had two primary objectives. The first 71 objective was to assess the accumulation of Ce, Cu, or Zn in carrot (Daucus carota) when 72 irrigated with solutions of CeO₂, CuO, or ZnO nanoparticles or the corresponding ionic metal form of each. Carrot has been included in some prior studies with nanoparticles ^{17, 18} but the 73 74 response of this species to these metal oxide nanoparticles, and the resulting accumulation, have 75 yet to be evaluated. Carrot is also a nutritionally important root vegetable crop with >28,000 ha in cultivation in the US alone with a market value of >\$650 million for fresh carrots alone.¹⁹ 76 77 Carrot can be cultivated in soils receiving biosolid amendments in the US within the guidelines established by the US Environmental Protection Agency.²⁰ The second objective was to derive 78 79 basic information on the spatial distribution of the accumulated element in the carrot tissue. One 80 approach was to determine the extent to which the metals from the added nanoparticles 81 penetrated the outer "peel" of the carrot into the inner edible taproot flesh. The data derived 82 would help illustrate the degree to which this cell layer of the carrot taproot serves as a filter to 83 limit accumulation. Alternatively, the distribution of the metals across the three tissues (peel, taproot flesh, shoot) was examined as a function of treatment concentration and chemical form 84 85 (ENP or ionic) to provide information on the internal partitioning of the accumulated metals.

86

87 2. Materials and methods

88 2.1 Nanoparticles and Plant Materials

89 The three nanoparticles used, ZnO (30-40 nm), CuO (25-55 nm), and CeO₂ (30-50 nm), 90 were selected as representatives of the ten most commonly used materials as identified by Keller et al.²¹. The nanoparticles were obtained from US Research Nanomaterials, Inc. (Houston, TX). 91 92 The CuO (99.95% purity) was in powder form while the ZnO (99.5% purity) and CeO₂ (99.9% 93 purity) were obtained as aqueous dispersions in deionized water at initial concentrations of 20% 94 wt. The metal salts CuSO₄.5H₂O and ZnSO₄.7H₂O were purchased from Fisher Scientific (New 95 Jersey, USA) whereas Ce(SO₄)₂.4H₂O was obtained from Acros Organic (New Jersey, USA). 96 Seeds of carrot (Daucus carota cv Danvers Half Long) were obtained from Burpee Seeds and 97 Plants (W. Atlee Burpee & Co, Warminster, PA). 98 99 2.2 Preparation and characterization of nanoparticle solutions 100 Nanoparticle treatment solutions were prepared to provide final concentrations of elemental Zn, Cu, or Ce at 1, 10, 100, and 1,000 mg L⁻¹. Preparing the solutions based on the 101 102 concentration of the metal was to provide an alignment with the corresponding metal ion 103 treatments (see below). The ZnO and CeO₂ solutions were prepared by diluting the commercial 104 suspension with 18 m Ω deionized water to achieve the desired concentrations. To prepare the 105 CuO treatment solutions, the required mass of the nanopowder was mixed with deionized water 106 and each solution was sonicated (130 W, 20 kHz) for 15 min (model VCX 130, Sonics & 107 Materials Inc., Newtown, CT) to facilitate dispersion. The hydrodynamic size was determined

108 using a Zetasizer Nano ZS90 (Malvern Instruments, UK). All the measurements were taken in

109	triplica	ate. There was significant aggregation of ZnO in solution across the four concentrations,	
110	with h	ydrodynamic sizes ranging from <1,200 to >2,100 nm (Table S1). There was some	
111	eviden	ce of CuO aggregation in solution, with the greatest aggregation observed at the highest	
112	solutio	on concentration. The hydrodynamic size for the lower three CuO concentrations was	
113	simila	r (i.e., \sim 330 – 410 nm) but increased to >1,200 nm at 1,000 mg Cu L ⁻¹ . There was less	
114	aggreg	gation of CeO ₂ particles and the hydrodynamic sizes were consistent across the four initial	
115	concentrations (i.e., ~250 – 290 nm). The corresponding solutions of ionic Zn, Cu, and Ce were		
116	prepared by dissolving the required mass of the salts in deionized water. All solutions were		
117	prepar	ed fresh on the day that the treatments were to be imposed.	
118			
119	2.3	Plant Growth and Exposure	
120		Plastic pots (0.95 L total volume) were filled with 1.3 kg of dry coarse sand and wetted to	

121 the equivalent of 80% field capacity with deionized water. Three carrot seeds were planted 122 approximately 1.5 cm below the sand surface. The pots were transferred to a phytotron growth chamber (16 h photoperiod, light intensity 200-350 µmol m⁻² s⁻¹, 18-22°C, and ambient relative 123 124 humidity) to facilitate germination. Pots were maintained during germination at 80% field 125 capacity by watering with deionized water every other day. The amount of water needed to 126 maintain 80% field capacity was determined by weighing the pots to estimate the water losses to 127 evaporation. After emergence, the plants were thinned to one seedling per pot. Once per week 128 after emergence, each pot received 0.05 L of nutrient solution with the following composition: 129 0.6 mM KNO₃, 0.4 mM Ca(NO₃)₂, 0.05 mM NH₄H₂PO₄, 0.1 mM MgSO₄, 50 µM KCl, 12.5 µM 130 H₃BO₃, 1 μ M MnSO₄, 1 μ M ZnSO₄, 0.5 μ M CuSO₄, 0.1 μ M NiSO₄, and 0.1 μ M H₂MoO₄. The 131 solution was buffered with 1 mM n-morpholinoethanesulfonic acid (MES), titrated to pH 6.0

with KOH. Iron was provided as 10 µM Fe-EDTA. Pots were weighed intermittently during the course of each week to assess water loss to evapotranspiration. Deionized water was added when needed during the week to maintain the soil moisture near 80% of field capacity. Plants were grown for 16 weeks to establish biomass and initiate formation of the taproot before treatments began.

137 For each of the three metals, the experimental design consisted of either the nanoparticle 138 or corresponding ionic solution at one of four concentrations (1, 10, 100, or 1,000 mg L⁻¹) and a 139 control treatment (i.e., no metal). Each treatment was replicated five times, giving 45 pots (one 140 plant per pot) per metal. The pots were randomly assigned to a treatment and arrayed in a 141 completely random pattern. The treatments were imposed by watering the pots once per week 142 for 13 weeks with 0.05 L of nanoparticle or ionic solution or with deionized water. By the end 143 of the 13 week treatment period, the calculated final concentration of these metals in the pots was 0.5, 5, 50, or 500 mg kg DW⁻¹ respectively. This broad range of concentrations was chosen 144 145 to be conservative due to the lack of information of the concentrations of ENPs in the 146 environment. The pots were also watered once per week with a 1:2 dilution of the nutrient 147 solution described above at a different time from the treatment irrigation. The nutrient solution 148 used to irrigate the pots prior to and through the entire treatment period introduced <0.1 and 149 <0.05 mg total of Zn or Cu, respectively, and therefore had a minimal effect on the total 150 concentration of either elements in the pots.

151 At harvest, plants were removed from the pots, separated into green, aboveground 152 petioles and stems (hereafter referred to as shoots) and belowground taproot and then rinsed with 153 deionized water. The carrot taproot was gently abraded with a vegetable brush to insure removal 154 of any adhering sand particles. The taproot was peeled with a standard vegetable peeler,

155 removing the outer 1-2 mm of the carrot taproot periderm (for simplicity, this tissue layer will be 156 referred to hereafter as the "peel"). The peeled taproot, comprised primarily of the secondary 157 phloem and xylem, was considered as the edible "flesh" of the carrot. The fresh weight of the 158 tissues was determined and all tissues were then dried to constant mass at 60° C. The dried peel 159 and flesh mass for each replicate was combined to represent total root dry weight. The dried tissues were ground to a particle size of <5 mm and digested using EPA method 3050b²² using a 160 161 combination of trace metal grade nitric acid and 30% hydrogen peroxide. The digested samples 162 were analysed for Zn, Cu, or Ce using inductively coupled plasma mass spectroscopy (ICP-MS, 163 Agilent 7500ce, Santa Clara, CA).

164 The bioconcentration factor (BCF) in the tissues in response to treatment was calculated 165 by dividing the metal concentration in that tissue by the final metal concentration in the sand 166 growth medium. Using the tissue concentration and the total dry mass data, the total mass of Zn, 167 Cu, or Ce in each tissue was calculated. The transfer factor (TF) was calculated as the mass of a 168 metal in the shoot divided by the total mass of that metal in the taproot (i.e., total metal in peel 169 and flesh). The mass of an element in those three tissues was also summed to obtain the total 170 mass of that element per plant. The percent of Zn, Cu, or Ce element in each tissue was 171 calculated by dividing the mass of the element in that tissue by the total mass for that plant. The 172 percent of total added Zn, Cu, or Ce removed by a plant was determined by dividing the sum of 173 the total Zn, Cu, or Ce in an entire plant by the total mass of each element add to the substrate.

174

175 2.4 Data analysis

Each biomass parameter, the root:shoot ratio, shoot metal concentration, shoot BCF,shoot TF, and the percent of added metal removed per plant for a given element were analyzed

using a two-way ANOVA with treatment concentration and chemical form (nanoparticle or
ionic) as the main effects. For root dry weight concentration and root BCF, a three-way
ANOVA was used with treatment concentration, chemical form, and root tissue (peel or flesh) as
the main effects for a given element. As the plants used for the Zn treatments, the Cu treatments,
and the Ce treatments were grown sequentially not simultaneously during the course of this
research, data were not compared between elements, but only within each element.

184

185 **3. Results**

186 3.1 Influence of nanoparticle and ionic treatments on plant growth and development 187 During the course of the experiment, there were no overt signs of toxicity or stress (e.g., 188 chlorosis, necrosis) in any plants. There was no evident malformation or splitting of the taproots. 189 Within each metal treatment, the effect of the nanoparticle and ionic treatments had statistically 190 significant (Table S2) yet modest effects on tissue biomass and primarily at the highest 191 concentration of the ionic metal treatment. For Zn, there was no significant effect of treatment 192 on shoot biomass (Figure 1A) or root:shoot ratio (Figure 2A). There was for root mass a 193 significant concentration effect across both chemical forms of Zn, but not an effect of Zn 194 chemical form (nanoparticle versus ionic). The effect of Zn concentration can be seen most 195 notably in the reduction in root biomass at the highest ionic Zn treatment concentration. Total 196 plant biomass showed the same pattern as root biomass in response to Zn treatment (Table S2). 197 Both concentration and chemical form are significant factors for shoot biomass (Figure 1B) 198 (Table S2). There was no effect of Cu treatment on root biomass or root:shoot ratio (Figure 2B). 199 A significant interaction between concentration and chemical form was obtained for Cu for total 200 plant biomass, driven primarily by the reduction in root biomass seen for the two highest

201 concentrations of the ionic Cu treatment. There was a significant interaction (Table S2) between 202 the main effects for shoot biomass (Figure 1C) and for root:shoot (Figure 2C) ratio in response to 203 the Ce treatments. There was no significant effect of Ce treatment on root biomass and for total 204 plant biomass, the only significant effect was in response to the treatment concentration. 205 Overall, the change in biomass resulting from the nanoparticle treatments was generally not 206 different from the effects of the ionic metal treatments. A difference in biomass was not 207 observed until the highest treatment concentration for each element and it was the ionic treatment for Zn^{2+} or Cu^{2+} that produced the greatest decrease in biomass. 208

209

210 3.2 Influence of nanoparticle and ionic treatments on metal accumulation and partitioning 211 Within each of the three elemental treatments there were highly significant interactions 212 between the main effects with respect to the metal concentration in the taproot tissues or the 213 shoots (Table S3). For the taproot tissues, there were three patterns that were generally 214 consistent across the three metals. The first and most consistent pattern was that the peel tissues 215 from the taproot had significantly higher concentrations of the metal than the underlying flesh 216 tissues (Figures 3-5, Table S3). The peel concentrations of Zn, Cu, or Ce generally increased in 217 a concentration-dependent manner. One exception observed was for the two lowest 218 concentrations of the ZnO treatment where the peel concentrations did not differ significantly 219 from the control plants. The concentration of Zn, Cu, or Ce in peels varied from as little as two-220 fold greater than the flesh concentrations for the lowest treatment concentrations to an order of 221 magnitude higher than the flesh at the highest treatment concentration. 222 The second recurring pattern was that for a given concentration and element, the ionic

treatment resulted in a significantly higher concentration in both the peels and flesh as compared

224 to the nanoparticle treatment (Figures 3-5, Table S3). There were only a few exceptions to this 225 trend, namely the peel Zn concentration for the highest concentration applied and also for the 226 peel and flesh Cu concentration for the lowest concentration applied. The third pattern was also 227 associated with a difference between the nanoparticle and the ionic treatment. For the three 228 highest Zn and Cu ionic treatments, the concentration of that metal in the flesh increased 229 significantly relative to the untreated control and the lowest ionic treatment concentration. The 230 flesh Ce concentration increased significantly compared to the control for all the ionic Ce 231 treatments. In sharp contrast, the concentration of Zn, Cu, or Ce in the edible flesh from the 232 nanoparticle treatment was significantly greater only for the highest treatment, which was still 233 less than that for the corresponding ionic treatment.

234 There were also highly significant differences and several significant interactions 235 between the main effects for the calculated BCF values for the root peel and flesh tissues (Table 236 1, Table S3). There were also three notable trends in the BCF results. Two of these trends were 237 the same as for the concentration data in that the BCF values were greater for peels as compared 238 to the taproot flesh and were significantly higher for carrot grown in the presence of ionic form 239 than the nanoparticle form. The third trend was an inverse relationship, where in most cases the 240 BCF value for peels and taproot flesh decreased as treatment concentration increased. The BCF 241 values were the largest at the lowest concentration and then decreased sharply from the 0.5 to 5 mg kg sand⁻¹ treatments. 242

The concentrations of each metal in the carrot shoots displayed the same pattern in response to the nanoparticle and ionic treatments as did the taproot tissues (Figures 3-5, Table S3). The BCF for each element in shoot tissues (Table 2) followed much the same patterns as for the root tissues with the same three general trends. With respect to the change in BCF value

247 as a function of treatment concentration, there were evident exceptions at the higher 248 concentration of Zn and Cu for plants receiving the ionic treatment where the BCF values showed a marked increase from the 50 to 500 mg kg⁻¹ treatment. There were significant effects 249 250 of form and concentration for all three elements but the interaction between these main effects 251 was significant only for Cu (Table S3). The transfer factors (TF), which expresses the ratio of 252 concentration in the shoot to that in the taproot, were between 0.01 and 0.5 for all Zn treatments 253 with the exception of the highest ionic treatment concentration (Table 2, Table S3). The TF 254 values for the ionic and nanoparticle Cu treatments were not significantly different from one 255 another while for the Ce treatments, there was a significant interaction between form and 256 concentration but not for either factor alone (Table S3).

257 Another perspective from which to consider the results, and perhaps the best to visualize 258 the distribution of each metal, is to express the data as the percent of total metal within each 259 plant tissue (Figure 6). This approach illustrates the partitioning of the metals from each 260 treatment across the taproot peel, taproot flesh, and shoot tissues. For the untreated control 261 plants, the peel and shoots accounted for the majority of the metal in each plant, 71.7% of the total Zn in the carrot, 75.2% of the total Cu, and 96.4% of the total Ce. More Zn was associated 262 263 with peels than shoots, but the converse was observed for Cu and Ce. The partitioning of the 264 metals between these three tissues differed between metals and in some cases between the 265 nanoparticle and ionic treatments. The percentage of total Zn associated with the root tissues 266 increased with nanoparticle concentrations but the percentage of Zn associated with the edible 267 flesh decreased. The pattern for ionic Zn was different, with both the total root Zn and the 268 percentage of Zn associated with the edible tissues increased with concentration, except for the 269 highest ionic Zn treatment where the majority of the Zn was associated with the shoot tissues. In

contrast to the difference between the two chemical forms of Zn, the partitioning of Cu within the plant tissues was somewhat similar between the nanoparticle and ionic treatments at each concentration, with the flesh Cu concentration generally decreasing with increasing treatment concentration. The results for Ce were comparable to those for Zn except that the concentration of Ce in the flesh was similar across the nanoparticle treatments and decreased compared to the ionic Ce treatments.

276 While the concentration of each element in the various tissues tended to increase with the 277 treatment concentrations, the proportion of the total Zn, Cu, or Ce added to the substrate that 278 accumulated in the carrot plants showed a significant decrease along the same gradient (Table 3, 279 Table S3). Aside from the lowest concentration of each treatment, the plants removed <5% of 280 the added metal and for Ce the values were <2%. For Zn and Ce, significantly more of the ionic 281 metal added to the substrate was removed into the plant tissues than the corresponding 282 nanoparticle treatment, which is expected given the higher carrot tissue concentrations for each 283 element observed for the plants receiving the ionic treatments. There was no significant 284 difference for Cu in terms of chemical form.

285

286 **4. Discussion**

Even though there have been many studies examined the uptake and accumulation of ENPs by plant, only a handful of studies examined accumulation in comparison to the accumulation of the ionic forms of each metal, especially for underground vegetables.^{23, 24} Carrot was chosen both because of its popularity as a vegetable and its unique anatomical structure. Instead of a typical dicotyldenous root structure of central vascular bundle, endodermis, cortex, and epidermis, (i.e., anatomical organization from center radially outward),

the carrot taproot displays secondary growth analogous to that of woody plants. That is, as the carrot root enlarges radially, that growth is achieved by replacing the cortex and epidermis with concentric rings of secondary vascular tissues laid down by a mitotically active cambium cell layers.^{25, 26} The inner secondary vascular tissue is the secondary xylem and the outer is the secondary phloem. Immediately to the outside of the secondary phloem is the periderm. The periderm is a layer of dead cells that form the protective outer surface of the taproot. The "peel" collected here would have been comprised mostly of periderm.

300 The patterns observed in the data for metal accumulation were likely dictated by the 301 anatomy of the carrot taproot. The periderm for example displayed a clear capacity to retain a 302 large fraction of metals from either the ENP or the ionic treatments. Although correlating the 303 histological distribution to ENP to regions within the periderm is certainly of interest, this was not a goal in the currently investigation. Previous studies have shown that the cell wall of the 304 305 root epidermal layer has the capacity to trap ENPs. The typical pore size of the plant cell wall is 2-20 nm^{4, 15}, which is smaller than most metal oxide ENPs and smaller than the hydrodynamic 306 307 size measured for the ENPs suspensions used here (Table S1). Some studies have reported that ENPs can be found sorbed only to the epidermal cell wall surface.^{23, 27} Others have reported that 308 309 ENPs or the metal ions that dissociate from the ENPs penetrate into the root but may then 310 precipitate or aggregate in the root cell wall network, restricting further transport and accumulation.²⁸ The cork cell layer of the carrot taproot periderm is thicker than a typical root 311 312 epidermis. Moreover, as dead cells the cork layer could not only sorb metals in the cell wall 313 network but perhaps also retain metals within the cells themselves. One recent study examined 314 the distribution of potassium across the radius of 90 day old carrot taproots and found the periderm cells to have the highest concentration of that element.²⁵ The periderm of the potato 315

316 tuber has also been shown to retain Cd from the external media and restrict the penetration of 317 that element into the tuber interior.²⁹ Such results suggest that the periderm has a large capacity 318 to retain ions sorbed from the external media, as indicated by the BCF values obtained for the 319 peel tissues (Table 1). The affinity of the periderm for ions such as Zn, Cu, and Ce (whether as 320 ENPs or ions) must be quite high as the BCF values for those tissues were highest at the lowest 321 treatment concentrations. One could speculate that the periderm cells associated with the peel 322 sorbed a large fraction of the metals and that at low concentrations this accounted for a large 323 fraction of the total metal in solution. In other words, the sorption capacity of the periderm cells 324 was large enough to bind a large fraction of the metal in solution, hence the large BCF values. 325 Sorption capacity was likely finite however and as the treatment concentrations increased, the 326 cells could have become saturated with the metals giving rise to the decreasing BCF values with 327 increasing treatment concentration. Comparable inverse trends between tissue BCF values and 328 the external metal concentration have been observed in other studies with plants and metal absorption.³⁰⁻³³ The same rationale would likely explain the parallel trends in the taproot flesh, 329 330 but the correspondingly lower BCF values given the lower tissue concentrations for this taproot 331 tissue.

The capacity of the periderm peel to screen ENPs is evident when contrasted with the results observed for the ionic treatments. The ions more readily migrated through the periderm layer into the carrot taproot flesh and reached the secondary xylem for translocation to the shoots as indicated by the significantly larger shoot concentrations and shoot BCF values for the ionic treatments. The radial transport and translocation of Zn^{2+} and Cu^{2+} is not unexpected as these two elements are essential micronutrients for plants, needed in both the belowground and aboveground tissues. Cerium from rare earth element fertilizers and other sources has been

detected in plant shoots, indicating that this element can be translocated to plant shoots in the
ionic form.^{8, 34, 35} The significant aggregation of the ENPs in the initial suspensions (Table S1)
suggested that these ENPs were not stable in liquid suspension and quite likely contributed to
their greater association with the periderm and the lower translocation of the associated elements
to shoots.

344 The accumulation of Zn, Cu, or Ce from all the treatments was generally greater in the 345 shoots than in the flesh of the carrot taproot, which may also be attributable to the anatomy of the 346 carrot taproot. The majority of the carrot taproot is vascular tissue (secondary phloem and 347 secondary xylem) rather than the cortex tissues found in most herbaceous plant roots. While 348 these secondary vascular tissues do have a storage capacity, that storage is devoted principally to 349 the accumulation of sugars and starch, along with osmotically active solutes to maintain the proper water status of those cells.²⁵ If the distribution of potassium in the carrot taproot is used 350 351 as a general guide for the pattern of ion distribution, results have shown that the concentrations 352 are highest in the periderm and pith of the mature taproot, and significantly lower in the secondary phloem and xylem tissues.²⁵ Potassium was found predominantly in the apoplasm, 353 354 which likely allowed this element to migrate through the wall space radially to the carrot taproot 355 core (i.e., secondary xylem and pithlike center), giving rise to the reported pattern. The same 356 might not necessarily be observed for every nutrient or trace element but such information is 357 lacking for this plant species. The results for Cu and Ce from this study, and for the ZnO 358 treatment, suggest a similar radial migration pattern for Zn, Cu, and Ce, with the elements 359 readily reaching the secondary xylem for translocation to shoots and retained to only a modest 360 extent in the secondary phloem that comprises the bulk of the taproot diameter. The results for 361 the ionic Zn treatments demonstrate a more extensive retention in the taproot flesh. The reason

for this specific pattern of Zn accumulation is not clear at present but may be related to the aforementioned control of osmotically active solutes and ions in the taproot. The flush of Zn^{2+} that was translocated to the carrot shoots at the highest Zn^{2+} concentration was unexpected but may be related to the decrease in biomass of the taproots in this treatment, and possibly the onset of phytotoxic effects. Such conclusions are speculative and would require further study to clarify.

368 The study performed here did not attempt for the ENP treatments to determine whether 369 the Zn, Cu, or Ce accumulated in the taproot tissues or translocated to the shoots was parent ENP 370 or dissociated ions from the ENP. There have been reports that intact ENPs are translocated to aboveground plant tissues ³⁶ but most studies report xylem translocation of the metal from the 371 ENP, but not the intact metal oxide ENPs themselves.^{23, 37-39} Intact ENPs could readily reach the 372 373 secondary xylem for translocation if there was splitting of the carrot taproot to expose the core, 374 but no splitting was observed in this study. In the absence of splitting, intact ENPs would either 375 have to migrate radially across the taproot diameter across the secondary phloem and vascular 376 cambium or would have to reach the secondary xylem via the more direct connections created by 377 xylem rays (Figure S1). Xylem rays are reportedly present however only in the early stages of 378 taproot development and are lost later in development as secondary growth continues and the 379 taproot matures ²⁶, but this conclusion was based on one anatomical study. Small xylem rays have been observed in field grown carrot after harvest.⁴⁰ No splitting of the taproots was 380 381 evident in this study, but an anatomical examination for the presence or absence of xylem rays was not performed. Both ZnO and CuO can undergo dissolution, releasing Zn^{2+} or Cu^{2+} , 382 respectively.^{24,41} Dissociation of ZnO or CuO in the sand culture and/or in the periderm may 383 384 have released ions which were transported radially and then translocated. The dissolution of

385 ZnO or CuO was either limited in extent or kinetically slow otherwise the accumulation of Zn 386 and Cu from the ZnO and CuO treatments would have been more similar to the comparable ionic 387 treatments. CeO₂ ENPs are more stable and reportedly do not undergo significant dissolution ³⁵, 388 which likely explains the greater retention of Ce from the ENP treatment as compared to the 389 ionic treatment. Nonetheless the results here demonstrate that Ce from the added CeO₂ ENPs 390 migrated radially through the flesh and was translocated to the shoots. Similar results for Ce translocation have been reported for other food crops ^{8, 28, 38, 42}, including radish ⁴³, which shows 391 392 secondary growth comparable to that of carrot. There is little evidence that intact CeO_2 ENPs 393 are translocated to plant shoots; most studies have detected cerium in plant shoots but not necessarily intact CeO₂ ENPs.^{35, 37, 38} One recent study demonstrated that Ce uptake from CeO₂ 394 395 ENPs may involve dissolution of Ce to ionic form, uptake of the ion, and reassembly of the Ce into ENP form within the plant.⁴⁴ The tissue distribution data for each element (Figure 6) 396 397 demonstrated that the metal from the nanoparticles was distributed quite differently from the 398 ionic forms. This underscores the need to understand the specific aspects of the interaction of 399 plants with each ENP.

400

401 **5.** Conclusions

In conclusion, carrot showed significantly less accumulation of Zn, Cu, or Ce from ENPs than from the ionic forms of each element. These results are in agreement with other studies that have compared the uptake of metal oxide ENPs to their ionic counterparts.^{23, 24} The accumulation of the elements principally in the taproot peel (which we presume corresponds primarily to the periderm layer of the carrot taproot structure) and the shoots, along with lower accumulation in the edible flesh (i.e., secondary tissues and pith), are probably functions of the

408 specific anatomy of the carrot taproot and is similar to the distribution of cerium accumulation 409 reported for radish ⁴³, another vegetable with a comparable root anatomy and secondary growth. 410 The contribution of xylem rays to radial movement and translocation is one particular aspect of 411 the root anatomy that may be important. In the absence of specific data on the dissolution of the 412 ENPs in the sand culture system or the chemical form of Zn, Cu, or Ce in the carrot tissues, no 413 specific conclusion can be drawn here as to whether intact ENPs are transported radially within 414 the taproot or translocated to shoots. Additional study will be required to address these 415 questions, including a focus on how ENP aggregation alters the hydrodynamic size and 416 properties of the nanomaterials. Although there were obvious differences in most data between 417 the ENP and ionic treatments, when viewed from the perspective of the overall mass of added 418 metal removed from the sand culture systems, the results were much more similar for the two 419 chemical forms of each element except at the lowest treatment concentration. On the other hand, 420 given the results in Figure 6 showing the distribution of metal across the peel, taproot flesh, and 421 shoots as a percentage of total metal in the plant, there are more obvious differences between the 422 two chemical forms (ENP versus ionic) and between the three metals in terms of their fate within 423 the plant tissues. This distribution is directly germane to human health as it relates specifically 424 to the presence of those metals in the edible tissues as well as to decisions associated with the 425 basic preparation of that plant food for consumption (i.e., how important is peeling the taproot). 426 In order to corroborate such an assumption, more detailed anatomical and histological studies 427 will be needed to relate specific aspects of the carrot taproot structure to the capacity to retain 428 ENPs. Further comparative studies between the ENPs and their ionic equivalents will be 429 necessary to understand the difference in behavior of the two chemical forms of these elements. 430 The information obtained from these continued studies will be necessary to understand the fate

431	and transport of these ENPs and to assess the potential food safety risks that may be associated
432	with the consumption of carrots or other edible plants grown in the presence of these metal oxide
433	nanomaterials.
