Abstract

The paper introduces ACO/F-Race, an algorithm for tackling combinatorial optimization problems under uncertainty. The algorithm is based on ant colony optimization and on F-Race. The latter is a general method for the comparison of a number of candidates and for the selection of the best one according to a given criterion. Some experimental results on the PROBABILISTIC TRAVELING SALESMAN PROBLEM are presented.

1 Introduction

In a large number of real-world combinatorial optimization problems, the objective function is affected by uncertainty. In order to tackle these problems, it is customary to resort to a probabilistic model of the value of each feasible solution. In other words, a setting is considered in which the cost of each solution is a random variable, and the goal is to find the solution that minimizes some statistics of the latter. For a number of practical and theoretical reasons, it is customary to optimize with respect to the expectation. For a given probabilistic model, the expectation can always be computed but this typically involves particularly complex analytical manipulations and computationally expensive procedures. Two alternatives have been discussed in the literature: analytical approximation and empirical estimation. While the former explicitly relies on the underlying probabilistic model for approximating the expectation, the latter estimates the expectation through sampling or simulation.

In this paper we introduce ACO/F-Race, an ant colony optimization algorithm [7] for tackling combinatorial optimization problems under uncertainty with the empirical estimation approach. F-Race [5, 4] is an algorithm for the comparison of a number of candidates and for the selection of the best one. F-Race has been specially developed for tuning metaheuristics. In the present paper, F-Race is used in an original way as a component of an ant colony optimization algorithm. More precisely, it is adopted for selecting the best-so-far ant, that is, the ant that is appointed for updating the pheromone matrix.

The main advantage of the *estimation* approach over the one based on *approximation* is generality: Indeed, a sample estimate of the expected cost of a given solution can be simply obtained by averaging a number of realizations of the cost itself.

 $^{^1}$ A public domain implementation of *F-Race* for R is available for download [3]. R is a language and environment for statistical computing that is freely available under the GNU GPL license.

On the other hand, computing a profitable approximation is a problem-specific issue and requires a deep understanding of the underlying probabilistic model. Since ACO/F-Race is based on the empirical estimation approach, it is straightforward to apply it to a large class of combinatorial optimization problems under uncertainty. For definiteness, in this paper we consider an application of ACO/F-Race to the PROBABILISTIC TRAVELING SALESMAN PROBLEM, more precisely to its homogeneous variant [9]. An instance of the PROBABILISTIC TRAVELING SALESMAN PROBLEM (PTSP) is defined as an instance of the well known TRAVELING SALESMAN PROBLEM (TSP), with the difference that in PTSP each city has a given probability of requiring being visited. In the paper we consider the homogeneous variant, in which the probability that a city must be visited is the same for all cities. PTSP is here tackled in the a priori optimization sense [1]: The goal is to find an a priori tour visiting all the cities, which minimizes the expected length of the associated a posteriori tour. The a priori tour must be found prior to knowing which cities indeed require being visited. The associated a posteriori tour is computed after knowing which cities need being visited, and is obtained by visiting them in the order in which they appear in the a priori tour. The cities that do not require being visited are simply skipped. This problem was selected as the first problem for testing the ACO/F-Race algorithm for two main reasons: First, PTSP is particularly simple to describe and to handle. In particular, the homogeneous variant is rather convenient since a single parameter, that is, the probability that each city requires being visited, defines the "stochastic character" of an instance: When the probability is one, we fall into the deterministic case; as it decreases, the normalized standard deviation of the cost of a given solution increases steadily. We can informally conclude that an instance of the homogeneous PTSP becomes more and more stochastic as the probability that cities require being visited decreases. This feature is particularly convenient in the analysis and visualization of experimental results. Second, some variants of ant colony optimization have been already applied to PTSP: Bianchi et al. [2] proposed pACS, a variant of ant colony system in which an approximation by defect of the expected length of the a posteriori tour is optimized. Gutjahr [8] proposed S-ACO, in which an estimation of the expected length of the a posteriori tour is optimized.

The rest of the paper is organized as follows: Section 2 discusses the problem of estimating, on the basis of a sample, the cost of a solution in a combinatorial optimization problem under uncertainty. Section 3 introduces the ACO/F-Race algorithm. Section 4 proposes some results obtained by ACO/F-Race on PTSP. Section 5 concludes the paper and highlights future research directions.

2 The empirical estimation of stochastic costs

For a formal definition of the class of problems that can be tackled by ACO/F-Race, we follow Gutjahr [8]:

Minimize
$$F(x) = E[f(x, \omega)],$$
 subject to $x \in S,$ (1)

where x is a solution, S is the set of feasible solutions, the operator E denotes the mathematical expectation, and f is the cost function which depends on x and also on a random (possibly multivariate) variable ω . The presence of the latter makes the cost $f(x,\omega)$ of a given solution x a random variable.

In the *empirical estimation* approach to stochastic combinatorial optimization, the expectation F(x) of the cost $f(x,\omega)$ for a given solution x is estimated on the basis of a sample $f(x,\omega_1), f(x,\omega_2), \ldots, f(x,\omega_M)$, obtained from M independently-

extracted realizations of the random variable ω :

$$\hat{F}_M(x) = \frac{1}{M} \sum_{i=0}^{M} f(x, \omega_i).$$
 (2)

Clearly, $\hat{F}_M(x)$ is an unbiased estimator of F(x).

In the case of PTSP, the elements of the general definition of a stochastic combinatorial optimization problem given above take the following meaning: A feasible solution x is an a priori tour visiting once and only once all cities. If cities are numbered from 1 to N, x is a permutation of $1, 2, \ldots, N$. The random variable ω is extracted from an N-variate Bernoulli distribution and prescribes which cities need being visited. In the homogeneous variant of PTSP, each element in ω is independently extracted from a same univariate Bernoulli distribution with probability p, where p is a parameter defining the instance. The cost $f(x,\omega)$ is the length of an a posteriori tour visiting the cities indicated in ω , in the order in which they appear in x.

3 The ACO/F-Race algorithm

It is straightforward to extend an ant colony optimization algorithm for the solution, in the empirical approximation sense, of a combinatorial optimization problem under uncertainty. Indeed, it is sufficient to consider one single realization of the random influence ω , say ω' , and optimize the function $\hat{F}_1(x) = f(x, \omega')$. Indeed, $\hat{F}_1(x)$ is by itself an unbiased estimator of F(x). The risk we run by following this strategy is that we might sample a particularly atypical ω' which provides a misleading estimation of F(x). A safer choice consists in considering a different realization of ω at each iteration of the ant colony optimization algorithm. The rationale behind this choice is that unfortunate modifications to the pheromone matrix that can be caused by sampling an atypical value of ω at a given iteration, will not have a large impact on the overall result and will be corrected in following iterations. In this paper we call ACO-1 an ant colony optimization algorithm for stochastic problems in which the objective function is estimated on the basis of one single realization of ω which is sampled anew at each iteration of the algorithm.

A more refined approach has been proposed by Gutjahr [8] and consists in using a larger sample for estimating the value of F(x). In Gutjahr's S-ACO, the solutions produced at a given iteration are compared on the basis of a single realization. The *iteration-best* is then compared with the *best-so-far* solution on the basis of a larger sample whose size is determined dynamically on the basis of a parametric statistical test: Further realizations are considered till when either a maximum amount of computation is performed, or when the difference between the sample means for the two solutions being compared is larger than 3 times their estimated standard deviation. The selected solution is stored as the new *best-so-far* for future comparisons and is used for updating the pheromone matrix.

The ACO/F-Race algorithm we proposes in this paper is inspired by S-ACO and similarly to the latter it considers, at each iteration, a number of realizations for comparing candidate solutions and for selecting the best one which is eventually used for updating the pheromone matrix. The significant difference lays in the algorithm used at each iteration for selecting the best candidate solution. ACO/F-Race adopts F-Race, an algorithm originally developed for tuning metaheuristics [5, 4]. F-Race is itself inspired by a class or racing algorithms proposed in the machine learning literature for tackling the model selection problem [11, 12]. In F-Race, as in the other racing algorithms, a set of given candidates are sequentially evaluated on a number of test cases. As soon as sufficient evidence is gathered that a candidate is

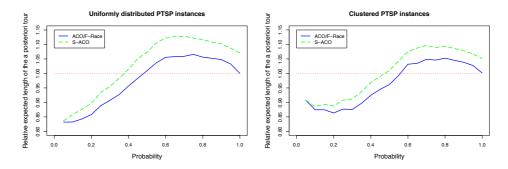

Figure 1: Experimental results on *uniformly distributed* and *clustered* instances. The plots represent the the expected length of the *a posteriori* tour obtained by ACO/F-Race and S-ACO, normalized by the one obtained by ACO-1.

worse than at least another one, the former is discarded from the race and is not further evaluated. The race terminates when either one single candidate remains, or when a maximum amount of computation time is reached. The peculiarity of *F-Race* compared to other *racing* algorithms is the adoption of the *Friedman two-way analysis of variance by ranks* [6], a nonparametric statistical test that appears particularly suitable in the context of racing algorithms.

At each iteration of ACO/F-Race, m ants, where m is a parameter, construct a solution as it is customary in ant colony optimization. In particular, we have adopted here the random-proportional rule [7]. The m solutions built by the ants, together with the best-so-far solution, are evaluated and compared via F-Race. The procedure consists in a series of steps at each of which a new realization of ω is considered and is used for evaluating the solutions that are still in the race. At each step, a Friedman test is performed and solutions that are statistically dominated by at least another one are discarded from the race. The solution that wins the race is used for updating the pheromone and is stored as the best-so-far to be used in the following iteration of the algorithm.

4 Experimental results

In our experimental analysis we compare ACO/F-Race with ACO-1 and S-ACO. The three algorithms differentiate only for what concerns the algorithm used for selecting, at the end of each iteration, the best-so-far solution that gets reinforced. Apart for this element, the algorithms are identical. The implementation used in the experiments is based on Stützle [13]. The problems considered are homogeneous PTSP instances obtained from TSP instances generated by the DIMACS generator [10]. We present the results of two experiments. In the first, cities are uniformly distributed, in the second they are clustered. For each of the two experiments, we consider 100 TSP instances of 300 cities. Out of each TSP instance we obtain 21 PTSP instances by letting the probability range in [0,1] with a step of 0.05. The run time is of 60 seconds on an AMD OpteronTM 244. The three algorithms were not fine-tuned, and the parameters adopted are those suggested in Gutjahr [8] for S-ACO. This might possibly introduce a bias in favor of S-ACO. The solutions selected by each algorithm on each instance were then evaluated on 300 freshly-selected realizations. The results are reproduced in Figure 1.

Although trivial, the evaluation method adopted by ACO-1 gives the best results when the variance of the length of the *a posteriori* tour is small (or null), that is, when probability is close to 1. This is easily explained: using large samples for

estimating F(x) is simply a waste of time when the variance of $f(x,\omega)$ is low. On the other hand, when the probability decreases and the problem indeed becomes stochastic, considering a larger sample does repay, and ACO/F-Race and S-ACO obtain better results than ACO-1. Further, Figure 1 shows that F-Race improves over the parametric procedure adopted in S-ACO: Throughout the whole range of probabilities, ACO/F-Race is significantly better than S-ACO according to a paired Wilcoxon test ($\alpha = .01$).

5 Conclusions and future work

The preliminary experimental results proposed in Section 4 confirm the generality of the approach proposed in Gutjahr [8], and show that the *F-Race* algorithm can be profitably adopted for comparing solutions in the framework of applications of ant colony optimization to combinatorial optimization problems under uncertainty.

Further research is needed for properly assessing the quality of ACO/F-Race. We are currently developing an estimation-based local search for PTSP. We plan to study the behavior of ACO/F-Race enriched by this local search on homogeneous and non-homogeneous problems.

In the experimental analysis proposed in Section 4 the goal was to compare the evaluation procedure based on F-Race with the one proposed in Gutjahr [8] and with the trivial one based on a single sample. For this reason, solution construction and pheromone update were implemented as described in Gutjahr [8]. We plan to explore other possibilities, such as construction and update as defined in \mathcal{MAX} - \mathcal{MIN} ant system [14]. Applications to other problems, in particular of the VEHICLE ROUTING class, will be considered, too.
