Keywords: plasmonics, nanophotonic circuits, active photonic components

Abstract: Surface plasmon polaritons provide a unique opportunity to localize and guide optical signals on deeply subwavelength scales and can be used as a prospective information carrier in highly-integrated photonic circuits. Dielectric-loaded surface plasmon polariton waveguides present a particular interest for applications offering a unique platform for realization of integrated active functionalities. This includes active control of plasmonic propagation using thermo-optic, electro-optic and all-optical switching as well as compensation of propagation losses. In this review, we discuss the principles and performance of such waveguides and summarize the current status of the related active plasmonic

components which can be integrated in silicon or other nanophotonic circuitries. Comparison of dielectric-loaded and other plasmonic waveguides are presented and various material platforms and design pathways are discussed.

1. Introduction

Optical signals have undisputable advantage over electronic ones for data transmission, providing incomparably higher data transfer rate and enabling modern communications technologies. The implementation of optical communication principles on the nanoscale and integrating nanophotonics into electronic circuitry can in turn boost data transfer rates between and within electronic chips. This will resolve the problem of the electronic interconnect bottleneck which impedes the development of modern electronic chips and circuitry due to inability of nanoscale electric conductors to provide high bandwidth.^{1,2,3} Furthermore, optical data processing can occur at much faster rates in comparison with the characteristic speeds in the modern electronics,^{4,5,6} which creates a potential for the development of ultra-fast switching and routing optoelectronic components. These ideas of integrating optical data circuits in the existing electronic chips or even the development of all-optical information-processing in integrated circuits stumble however at the problem of size of photonic waveguides and components: due to the diffraction of light, the optical signal cannot be localized in a region of space much less than approximately $\lambda/2n$, where λ is the wavelength of light and n is the refractive index of the waveguide material. Therefore, with all the advantages of conventional photonic circuits, their integration level has one to two orders of magnitude mismatch with that of electronic chips: hundreds of nm in Si photonics vs. tens nm in modern electronic chips. Nevertheless, one can design photonic components based on metallic nanostructures, the so-called plasmonic components, which can trap optical field by coupling it to free-electron excitations near a metal surface on the length scales comparable to the sizes of electronic interconnects.⁷

1.1. Plasmonics and nanoscale optical circuitry

Plasmonics makes use of coupling between electromagnetic waves and free-electron excitations at the interface between negative permittivity materials such as metals (or degenerate semiconductors) and positive permittivity dielectrics.^{8,9} In different geometries,

plasmonic excitations manifest themselves as localized surface plasmons (LSPs) supported by metallic nanoparticles^{9, 10, 11, 12} or propagating surface waves, surface plasmon polaritons (SPPs) on an extended metallic interfaces (e.g., films or nanowires).^{7, 8, 13} Their unique properties associated with high electromagnetic field confinement and consequent field enhancement near the conductor's surface^{14, 15} have long attracted significant attention in chemo-^{16, 17} and bio-sensing due to strong refractive index sensitivity^{18, 19} as well as surface enhanced Raman scattering.^{20, 21} Nonlinear optical processes, which are proportional to the higher orders of the electric field, are also dramatically boosted due to the plasmonic field enhancement.^{22, 23} The examples include the enhancement of Kerr-type nonlinearity^{24, 25, 26, 27}, harmonic generation^{28, 29, 23} and four-wave mixing³⁰ in metal nanostructures and surrounding dielectrics, self-focusing and SPP-soliton formation³¹, and many others. Taking on the above properties, plasmonics offers a unique opportunity to combine the speed and the bandwidth of nanophotonics with the integration level of the electronics³² and provide superior active functionalities leading to the development on nonlinear nanophotonic components.

Based on this idea, numerous geometries for SPP waveguides have been proposed, covering the whole range of field confinement levels and achievable attenuation due to the presence on the plasmonic field in metal and consequent Ohmic losses. Generally, there is a trade-off between these two parameters: the higher the confinement, the larger portion of the electromagnetic field is localized in metal leading to the higher losses and the stronger signal attenuation. Long-range surface plasmon polariton modes, supported by thin (typically less than 20 nm) metallic stripes in symmetric environment (**Figure 1a**), have the longest propagation length (defined as the distance where the attenuation of the intensity is e times), which can reach centimeter range at the telecommunication wavelengths, paying the price of low confinement (several micrometers) which does not beat dielectric waveguides.³³ Such long propagation length is the result of interplay between the plasmonic oscillations at the top and the bottom interfaces of the stripe, resulting in the mode with the electromagnetic fields

pushed out of the metal and therefore decreased Ohmic losses. A typical example of the plasmonic modes which broke below the diffraction limit, but still have a reasonably long propagation length ($\sim 100 \mu\text{m}$) are channel plasmon polaritons (Figure 1b).³⁴ Here, the mode in the groove is formed by coupling of the plasmonic oscillations propagating along its opposite sides. Several approaches have been used to localize the plasmonic mode in truly nanoscale dimensions, with typical propagation lengths of tens of micrometers. Metal-dielectric-metal SPP mode (Figure 1c) has the same nature as the channel mode but offers much stronger confinement³⁵ having no limitation on a dielectric gap thickness (planar waveguides with 3 nm gaps have been experimentally demonstrated³⁶). Plasmonic mode propagating along a metallic nanowire^{37,38,39} (Figures 1d and 1e) can be considered as a wave of one-dimensional free charge oscillations. It also has no cut-off of the modes: the smaller the wire diameter, the stronger the field confinement. Coupled plasmonic oscillations in metallic nanoparticles arranged to form a chain waveguide, produce a highly-localized plasmonic mode (Figure 1f).⁴⁰ Essential improvement of guiding characteristics was achieved in hybrid⁴¹ plasmonic waveguides, where the mode is produced by coupling a plasmonic mode with a photonic mode in high refractive index materials of a nanoscale thickness next to a metallic surface (Figure 1g). Recently, plasmonic metamaterial-based waveguides have been shown to produce highly confined modes of bulk-plasmon-polaritons.^{42,43}

An extensive research has been conducted to increase the SPP propagation length. The basic idea here is to replace the dielectric at the SPP-guiding interface with the lasing medium,^{44,45} which will amplify the signal upon stimulated emission into the SPP mode. An essential increase of the propagation length has been demonstrated with free-space optical pumping of quantum dot⁴⁶ or dye⁴⁷ doped media or semiconductor structures⁴⁸, while all-plasmonic amplification (where the pumping signal is also an SPP wave) has been realized in Er-ion-doped gain medium.⁴⁹ As an alternative approach, electric pumping has been proved to be a very efficient and practically feasible approach providing full loss compensation.⁵⁰

Ultimately, these efforts led to the demonstration of optically-pumped^{51,52,53,54} or electrically-pumped⁵⁵ plasmonic lasers. Investigation of other amplification-related phenomena, such as excited-state dynamics near the metal surface^{45, 56}, which defines peculiarity of SPP amplification process and modulation speed, and amplified spontaneous emission of SPPs⁵⁷ have led to better understanding of the underlying processes.

A complete set of plasmonic circuit elements mimicking traditional dielectric photonic components have been demonstrated, such as bends, splitters, etc. In order to exploit the advantage of signal multiplexing for broadband data transmission, wavelength-selective plasmonic components, such as Mach-Zehnder interferometers (MZIs), waveguide-ring resonators (WRRs) and Bragg gratings have been developed.⁷ The functional plasmonic circuitry was further investigated which included active switching components.^{58,59,60,61,62,63,64} Particularly, an implementation of nanoscale electro-optic effects matching the plasmonic mode confinement has led to the realization of plasmonic switching components of the size of on-chip electronic components.⁶⁵ An additional advantage of the plasmonic guiding schemes is the possibility of sending both electric and photonic signals along the same circuitry, thus naturally incorporating electrically-controlled nodes in the plasmonic circuits. In the pursuit of even more ambitious goal of fully-functional all-optical circuitry, plasmonic switching by optical means has been demonstrated in femtosecond time scale.⁶⁶ Finally, the realization of SPP sources^{67,68,69,70} and detectors,^{71,72,73} complete the development of self-contained fully-functional plasmonic circuitry.

1.2. Dielectric-loaded plasmonic waveguides and competing technologies

One of the important types of the plasmonic waveguides for achieving active functionalities is dielectric-loaded SPP waveguides (DLSPWs), formed by a dielectric ridge on the metal surface (**Figure 2**). The dielectric results in a higher refractive index for a SPP wave at the metal-dielectric interface compared to that at the metal-air interface, giving rise to

SPP modes bound by the dielectric stripe in a way similar to the confinement of guided light modes in conventional optical fibers or planar dielectric waveguides. DLSPW waveguides provide a sought-for trade-off between subwavelength confinement and the propagation loss. High effective index contrast between the mode and the free-propagating SPP wave on the outer metal surface as well as light in the surrounding space leads to good guiding properties of DLSPWs. This allows bending and splitting waveguide elements to be just a few micrometers in size at telecommunication wavelengths. The decisive advantage of DLSPW compared to other SPP waveguide types is that the dielectric ridge can be easily functionalized to provide thermo-optical, electro-optical, or all-optical functionalities, which can be used for the development of active nanophotonic components.⁷⁴ Several industry-standard approaches, such as UV photolithograph⁷⁵, direct laser writing,^{76,77,78} nanoimprint⁷⁹ or electron-beam lithography⁸⁰ can be used for DLSPW fabrication. Finally, it should be noted that thermal dissipation is very important aspect of the implementation plasmonic waveguides, and here DLSPWs provide top performance.⁸¹ While, these type of waveguides do not provide highest confinement, they offer the design of enhanced active components with low control powers which can be used within either plasmonic or Si photonic circuitry or indeed integrated with optical fibers.

Si photonic waveguides have sizes comparable with DLSPW waveguides based on polymers and low propagation loss. In terms of active functionalities, the low propagation loss is essential in Si waveguides in order to harvest small refractive index changes of the mode index induced around the waveguide and influencing primarily the evanescent part of the mode field outside the waveguide. (The latter is in contrast to DLSPW where it can be induced inside the waveguide just acting at the mode where it has highest intensity.) Thus, the Si photonic components, e.g., MZIs and WRRs should have length sufficient to accumulate significant phase difference of the waveguided mode. This imposes the restrictions on both the minimum size of active components based on Si waveguides as well as the required

energies for switching modulation, as, e.g., larger volume should be heated as in the case of thermo-optical modulation. Various Si-based modulators and switches have been developed.^{82,83} The Si-waveguide MZI-based thermo-optical modulators have length ranging from several millimeters down to 60 micrometers and operate at speeds down to few microseconds and power consumption from tens to hundreds of mW for around 20 dB extinction ratio. In terms of a size-power figure of merit, this state-of-the-art performance of Si-based active components is inferior to the DLSPW-based approach.^{84,85} Photonic-crystal-based designs provide small required powers but have much increased lateral sizes in addition to the optical bandwidth decrease down to few nm.^{86,87} The use of fast carrier-injection modulation allows high modulation rates up to tens of Gb/s, but either at a cost of bigger size (millimeters^{88,89} vs. micrometers in the DLSPW case, e.g., Ref. ⁹⁰) or a decreased optical bandwidth (e.g., 0.02 nm for 12 μm ring resonator component⁹¹, or 18 nm for 80 μm photonic crystal based design⁹²).

1.3. Review outline

In this review, we present the summary of the recent achievements in the development of integrated nanophotonic circuitry based on dielectric-loaded SPP waveguides, focusing on active functionalities. Plasmonics-enabled active components can provide smaller size and lower switching energy than traditional nanophotonics components and can be used within Si- or dielectric-based photonic integrated circuitry to reduce energy consumption or indeed in all-plasmonic integration approach on deep-subwavelength scales. In Section 2, the principles of confinement and guiding photonic signals in a form of plasmonic waves in highly-integrated photonic circuitry will be discussed and a general concept of dielectric-loaded plasmonic waveguides will be introduced. Sections 3, 4 and 5 will overview passive, wavelength-selective and active DLSPW components of various designs, respectively. Section 6 will benchmark the guiding performance of DLSPWs against that of other

plasmonic waveguides. Approaches for signal amplification in DLSPW waveguides will be introduced in Section 7. Finally, Section 8 will be devoted to the discussion of other plasmonic waveguide designs based on DLSPWs and applications of DLSPW beyond integrated nanophotonics.

2. Optical signal guiding in DLSPW waveguides

2.1. Guiding principle and modal properties

Guiding of a plasmonic mode along a DLSPW is based on a principle of refractive index contrast. A plasmonic wave propagating at a metal-dielectric interface has a wave vector

$$k_{SPP} = \frac{2\pi}{\lambda} \sqrt{\frac{\epsilon_d \epsilon_m}{\epsilon_d + \epsilon_m}} \quad (1)$$

defined by the dielectric constants of metal ϵ_m , dielectric constant of dielectric ϵ_d , and the wavelength of light λ . Due to the inherent losses, dielectric constant of metal possesses an imaginary part and, consequently, the wave vector of the SPP wave has a complex value. Its real part defines the effective index of the wave

$$n_{SPP}^{eff} = \frac{\lambda}{2\pi} \text{Re}(k_{SPP}) = \text{Re} \left(\sqrt{\frac{\epsilon_d \epsilon_m}{\epsilon_d + \epsilon_m}} \right), \quad (2)$$

while the imaginary part determines its propagation length (distance at which the intensity of the mode decrease in e times):

$$L_{SPP}^{prop} = \frac{1}{2\text{Im}(k_{SPP})} = \frac{\lambda}{4\pi \text{Im} \left(\sqrt{\frac{\epsilon_d \epsilon_m}{\epsilon_d + \epsilon_m}} \right)}. \quad (3)$$

In the case of the DLSPW waveguide, it follows that the effective index in the ridge region will be larger than that in the regions to the right and to the left of the ridge (Figure 2a)

$n_{SPP,2}^{eff} > n_{SPP,1}^{eff}$. Thus, in analogy to the optical fiber and planar dielectric waveguide geometries, a plasmonic mode supported by DLSPW will be formed. The propagation length in DLSPW depends on the proportion of the mode energy located in the metal and can be calculated using approximate methods or rigorous numerical simulations, as will be discussed below.

We initially consider an Au-based plasmonic waveguide with a low-index, polymer-defined dielectric ridge. Using approach based on effective-index method,⁹⁶ general rules and

trade-offs relevant to the DLSPPW design can be revealed (**Figure 3**). At the first step, considering 4-layer guiding structure at the telecommunication wavelength of 1550 nm (Figure 3b), the propagation length of the SPP wave was found to have a non-monotonous behavior as the thickness of the ridge-polymer layer is changed (Figure 3c). For all the modes supported by the structure, the propagation length initially decreases with the decrease of the polymer thickness below the value of 1 μm due to the electromagnetic field is efficiently pushed into the metal and experiences higher losses. However, for much thinner dielectric layers, e.g., 200 nm for TM_0 mode relevant for the formation of the fundamental TM_{00} DLSPP mode (Figure 2b,d,e), the propagation length starts to increase and becomes very similar to the SPP mode of an Au/Air interface.

Using the effective indexes of the 4-layer structure (Figure 3d), it was found that there is an optimal ridge width 500 to 800 nm, corresponding to the minimal lateral size of the DLSPPW mode (Figure 3e). At ridge widths larger than the optimal, the DLSPPW mode will occupy all the available space from one edge to another, corresponding to larger lateral mode sizes, whereas at ridge widths smaller than the optimal the SPP fields will be laterally pushed outside the ridge, leading again to poorer confinement. In addition to strong lateral confinement and low propagation loss, single-mode guiding by the plasmonic waveguide structures is usually desired in order to avoid various mode dispersion and interference effects. Accordingly, the condition for single mode guiding for the considered example is the waveguide thickness smaller than 600 nm and waveguide width smaller than 650 nm, which corresponds to the waveguide size of approximately $\lambda/2.5 \times \lambda/2.5$ in terms of the operational wavelength.

The results of effective-index modal analysis were compared with the rigorous finite-element simulations, and good agreement between the two methods was demonstrated.⁹⁶ The height and the width of the waveguide were optimized, defining figures of merit to describe the suitability of a given configuration to a particular application requiring either the longer

propagation length or stronger confinement.^{97,98,99,100,101} Other shapes of the dielectric ridge, such as the one produced by a nanofiber,^{102,103} semi-elliptical¹⁰⁴ or non-ideal ridge shapes formed in the actual fabrication process,¹⁰¹ have been investigated, considering the influence of the waveguide geometry on the DLSPW performance. The implementation of high-dielectric index material, such as Si or InGaAs, allows to reduce the width of the waveguide down to $200 \times 200 \text{ nm}^2$ (or approximately $\lambda/8 \times \lambda/8$), but for the price of active functionalities provided by doped polymer. High-dielectric index materials for defining a DLSPW and other plasmonic metals will be considered in details in Section 8.

Comprehensive numerical analysis of the guiding properties of DLSPW waveguides considered a polymer stripe waveguide with a rectangular cross section of $600 \text{ nm} \times 600 \text{ nm}$ deposited onto a gold surface (Figure 2a).¹⁰⁵ At wavelengths above $\sim 1250 \text{ nm}$, the waveguide is singlemode for SPP waves, supporting only a fundamental TM_{00} plasmonic mode. The mode is highly localized in the dielectric core of the waveguide at the metal-dielectric interface (Figure 2b,d,e). At low frequencies (Figure 2c), large amount of energy of the mode is located in the air region, and, therefore, the mode dispersion is close to the SPP dispersion at the metal-air interface. At higher frequencies, the mode energy is mostly localized inside the dielectric; consequently, the mode dispersion follows the SPP dispersion at the metal-dielectric interface. The dispersion curve experiences back-bending and crosses the light line due to the increased, frequency-dependent Ohmic losses in Au. For the signal wavelength $\lambda = 1550 \text{ nm}$, the chosen geometrical parameters of the waveguide provide the optimum ratio between mode confinement and attenuation.⁹⁶ The SPP mode propagates along the waveguide, keeping its field profile constant and its energy exponentially decays with distance due to the Ohmic losses in the metal. The mode characteristics were estimated from a complex value of its effective index, which gives $\text{Re}(n_{\text{eff}}) = 1.29$ and $L_{\text{prop}} = 44.2 \text{ }\mu\text{m}$ for the polymer refractive index of 1.5. The high mode effective index ensures strong guiding characteristics leading to a

small size of DLSPPW components, while relatively large L_{prop} gives the opportunity for the realization of elaborated circuitry network within the available attenuation length.

After observation of multimode DLSPP waveguiding¹⁰⁶, the first experimental studies of single-mode polymer-based waveguides were performed, revealing essentially the same guiding characteristics as predicted by theory.¹⁰⁷ The waveguides, fabricated using UV photolithography, were used with a funnel facilitating coupling of the excited broad SPP wavefront into the single mode waveguide. The optical characterization of the guided plasmonic modes was performed using scanning near-field microscopy (SNOM). The propagation length of the mode was observed to become gradually larger with the increase of the operational wavelength at the price of poorer mode confinement and lower mode effective index (**Figure 4**), confirming the theoretical predictions. It was found, however, that the measured propagation lengths, being in a qualitative agreement, were longer than those expected from the EIM calculations (Figure 4g). This most likely was due to the difference in the optical properties of the gold used in calculations and that in the experiment (gold permittivity is known to be essentially influenced by the deposition method employed). The intensity oscillation patterns (e.g., the one particularly pronounced in Figure 4f) are due to the interference of the DLSPPW mode with $\text{Re}(n_{eff}) = 1.21$ with its reflection from the waveguide termination.

2.2. Integration level and data transfer characteristics of a DLSPPW

The key question in practical applications of SPP guiding approach is the level of ultimate photonic integration of a circuitry built on its basis. It is determined by a cross-talk between two parallel DLSPP waveguides placed at some distance from each other (**Figure 5a**) leading to the signal mixing between the waveguides.¹⁰⁸ If the SPP mode is initially launched in one of the waveguides (bottom in Figure 5a field map), the energy can tunnel into the neighboring waveguide due to the overlap of the waveguides' modes. As a consequence, the mode starts to

oscillate between the waveguides with a gradually decreasing amplitude due to the Ohmic losses (Figure 5a). Clear beating of the DLSPPW mode between coupled waveguides was experimentally observed using the leakage radiation microscopy (Figure 5b).^{109,110} The strength of coupling between the waveguides is represented by a coupling length L_c , the distance along the waveguide at which the energy of the propagating mode is fully transferred to the neighboring one. The increase of the coupling length with the distance between the waveguides has an exponential dependence (Figure 5c).^{108, 111} When the waveguides are close to each other (e.g., $d = 700$ nm, so that the distance between the waveguide edges is 100 nm), the tunneling between the waveguides is very efficient with $L_c = 4.6$ μm . Making use of this strong coupling regime at smaller separations, waveguide couplers and splitters as well as wavelength-selective components in a form of directional couplers, were realized (Sections 3.3 and 4.3). In the other extreme case, when the cores of the waveguides are significantly separated (e.g., $d = 2.6$ μm), the coupling between the waveguides is extremely weak ($L_c = 2.3$ mm), so at this distance the waveguides are practically not coupled. Using as a criterion that less than 15% of signal cross-talk is allowed during the propagation in neighboring waveguides over the distance of L_{prop} , the single mode DLSPPW operating at the telecom wavelength provide the integration level of $d \approx 1.9$ μm , corresponding to $\sim 1.2\lambda$. The other characteristic defining the integration level of the photonic circuitry, such as the achievable size of the circuit components as well as their performance will be discussed below in Sections 3 and 6.

A crucial parameter defining the performance of the waveguide is the data bit-rate it can support. For a single-mode waveguide, it is determined by the frequency dispersion of the waveguide modes, which leads to different propagation characteristics for spectral components within signal carrying pulses, broadening them as they propagate in the waveguide.¹¹² The maximum bandwidth in a single data stream for a waveguide of a given

length is then determined by the highest rate of the pulses, at which they can still be distinguished as separate at the output. In the case of lossy waveguides, the spreading of the pulses depends on the second order dispersion of both real and imaginary parts of the propagation constant β :¹¹²

$$B \sim L^{-1/2} \left(\left(\frac{\partial^2 \text{Re}\{\beta\}}{\partial \omega^2} \right)^2 + \left(\frac{\partial^2 \text{Im}\{\beta\}}{\partial \omega^2} \right)^2 \right)^{-1/4}. \quad (4)$$

For DLSPPWs and other plasmonic waveguides compared in this review (see Section 6), it was found that $(\partial^2 \text{Im}\{\beta\}/\partial \omega^2)^2 \ll (\partial^2 \text{Re}\{\beta\}/\partial \omega^2)^2$, and the bandwidth can be estimated as as⁵⁰:

$$B = \sqrt{\frac{1}{8\pi} \frac{1}{L \frac{\partial^2 \text{Re}\{\beta\}}{\partial \omega^2}}} = \sqrt{\frac{1}{8\pi} \frac{v_g^2}{L \frac{\partial v_g}{\partial \omega}}}, \quad (5)$$

where v_g is the group velocity of the mode, β is its propagation constant of the mode and L is the waveguide length. The bandwidth depends on the waveguide parameters, its geometry and material. Taking a characteristic length of DLSPPW interconnect to be $L = L_{prop}$, the theoretical limit for the bandwidth can be estimated (Table 1). Varying waveguide's height and width in the region 400-600 nm (lower values will give an effective mode index below 1.1, resulting in much worse guiding characteristics, while values higher than 600 nm results in multimode guiding), it was found that a PMMA-based 600 nm×600 nm waveguide has the highest bandwidth. Generally, the dispersion-defined DLSPP-based interconnect bandwidth B reaches very high values of tens of Tb/s. The practical bandwidth will be defined in this case by the bandwidth of available modulators and detectors and multiplexing methods.

Table 1. Theoretical limit for bandwidth of PMMA- or Si- on-gold DLSPP waveguides of various designs (width× height, core material), estimated at the wavelength of 1550 nm.

Design	600 nm×600 nm,	600 nm×400 nm,	400 nm×600 nm,	400 nm×400 nm,	200 nm×200 nm,
	PMMA	PMMA	PMMA	PMMA	Si
<i>B</i>	39 Tb/s	23 Tb/s	23 Tb/s	17 Tb/s	39 Tb/s

Experimentally, the bandwidth of 10 Gb/s in a single data stream has been directly experimentally measured for DLSPP waveguides (PMMA/Au, 500 nm×600 nm), with error-free operation and no visible distortion to the eye diagram in comparison with the reference measurements (**Figure 6**)¹¹³. Further improvements was obtained with the demonstration of 40 Gb/s data transmission rate in a single data stream and implementation of the WDM technique by sending multiple data streams using at different operational wavelengths.¹¹⁴ This yielded the multiplexed 12×40 Gb/s =480 Gb/s total data bit-rate experimentally demonstrated in a single DLSPP waveguide.

3. DLSPW passive components

In this section we will discuss various aspects of routing of plasmonic signals in DLSPW circuitry. Starting with an overview of diverse methods for DLSPW mode excitation, we will continue with interfacing of the DLSPW circuitry with conventional photonic waveguides, and then discuss the designs and performance of various DLSPW passive components, such as bends, splitters, and other components.

3.1. Excitation and detection of DLSPW modes

From practical point of view, coupling to DLSPW modes can simply be achieved by focusing the laser beam at the end of a DLSPW waveguide can be attracting.¹⁰⁹ Upon diffraction at the edge of the dielectric ridge, the necessary component can be supplied to the wave vector of the incident light to provide matching to the wave vector of the DLSPW mode, albeit with low efficiency (**Figure 7a**). To achieve better coupling efficiency to the

DLSPPW modes, two standard approaches to SPP mode excitation were successfully implemented: 1) based on total internal reflection and 2) grating-assisted coupling. In the first method, a plane SPP wave was excited using the Kretschmann-Raether configuration either in front of a funneling structure produced by gradual widening of the waveguide or directly inside it^{107,115} (the latter scheme greatly reduces background scattering signal). During propagation towards the narrow end of the funnel, the SPP wave is adiabatically confined to the waveguide and coupled to a well defined DLSPPW mode (Figure 4a,b). Since for the SPP wave interacting with the taper boundaries the total internal reflection conditions are satisfied, there is no leakage of the SPP waves outside the taper and high coupling efficiency can be achieved. The absence of the coupled mode beating inside the waveguide confirms that the designed DLSPPW structure indeed only supports a single TM plasmonic mode.

Another typical coupling approach is based on diffraction grating structures, which in the case of SPP excitation on a planar surface were experimentally shown to provide ~45% coupling efficiency.¹¹⁶ Combining this method with the tapering component, an efficient grating coupler to the subwavelength DLSPPW mode was developed (Figure 7b-d).¹¹⁷ The grating was realized in a form of periodic array of polymer ridges, which allows its fabrication together with the DLSPP waveguide in a simple one-step lithography process. By optimizing geometrical parameters of the grating, the coupling efficiencies up to 20% were achieved. To achieve coupling directionality from the symmetric grating, the Bragg grating (having potential reflectivity up to 85%¹¹⁸) was introduced to prohibit SPP excitation in the direction opposite to the waveguide (Figure 7b). The parameters of the reflector and the gap between the two gratings needs to ensure that generated (in the waveguide direction) and the reflected (from the Bragg grating) SPP waves are in phase (Figures 7c,d). The relatively low insertion loss of such couplers (down to 25 dB), low dispersion and loss below 35 dB in a wavelength range 1525-1575 nm insure suitability of these coupling components for the telecommunication applications. As a variation of this method, a semi-circular grating coupler

design which additionally provide focusing the launched SPP wave into the DLSPW waveguide was numerically investigated in Ref.¹¹⁹

An interesting DLSPW mode excitation method is based on excitation of SPPs directly in the waveguide using optical pumping of fluorescent medium in the waveguide. If an emitter (atom, quantum dot, dye molecule, etc.) is located in the vicinity of a metal surface (typically from tens to few hundreds of nanometers), it can spontaneously emit directly into the SPP mode. This process was used for generation of the plasmonic signal in PMMA DLSPW waveguides doped with Rhodamine B molecules (Figure 7e).¹²⁰ The SPP waveguided mode is excited and propagates along the DLSPW waveguide in both directions from the excitation spot. The wave vector of the mode was found to be $1.103 k_0$ ($k_0 = 2\pi/\lambda$, $\lambda = 576 \mu\text{m}$) which confirms that the excited mode is the fundamental TM_{00} mode of the DLSPW waveguide with width 160 nm and height 68 nm.

For practical applications, interfacing of DLSPW circuitry with the standard external optical networks has a particular importance. Several methods have been developed for coupling DLSPW waveguides to conventional optical fibres¹²¹ and silicon-on-insulator (SOI) ridge waveguides^{122,123}. The basic approach implemented here is the end-fire coupling when the fiber or a waveguide is positioned in line with the DLSPW waveguide in the near-field proximity to its edge. To achieve a better overlap between the fiber and waveguide modes, the DLSPW is usually gradually widened towards the fibre edge. The excited SPP mode is then funneled into the waveguide in the same manner as described above. One can also use the diffraction grating based coupler to interface fibres, similar to described above (Figures 7f,g).¹²⁴

A typical scheme of interfacing DLSPW with SOI circuitry is shown in Figure 7h. The particularly good coupling was achieved for PMMA-coated SOI waveguides, when the DLSPW ridge material seamlessly transforms into the SOI ridge waveguide coating (not shown in the figure), which automatically insures the good interface quality. The coupling

efficiency in this case was experimentally shown to reach almost 80% for both in-coupling (SOI-to-DLSPPW) and out-coupling (DLSPPW-to-SOI) scenarios.¹²² The coupling between uncoated SOI ridge waveguides and DLSPPWs was further extended to more compact Si-wire waveguides, when the silicon film in SOI ridge waveguide is removed (Figure 7h,i)¹²³. Upon optimization of the coupler geometrical parameters (Si-waveguide width and the waveguide vertical offset), the interface with Si-wire showed the coupling efficiency of ~85%. The experimentally measured coupling efficiencies for uncoated SOI ridge waveguide to DLSPPW was slightly lower due to imperfection of the facets, slight waveguide misalignment as well as the gap between the gold film and the silicon waveguide edge, but still approaching high values ranging from 35 to 60%, depending on the particular sample.

Integrated detector of the plasmonic mode completes the design of a DLSPPW-based interconnect (**Figure 8**).¹²⁵ A nanoscale slit was implemented beneath the DLSPP waveguide in the gold film, while the whole structure was fabricated on a Si substrate. When the DLSPPW mode reaches the slit, it is partly coupled to a gap SPP mode in the slit. The intense electromagnetic field of the mode produces hot electrons with kinetic energies exceeding the height of the Schottky barrier at the boundary of the metal and the semiconductor substrate. The hot carriers generate electron-hole pairs in silicon, which under applied voltage result in a photocurrent. Thus, monolithic integration of a detector with DLSPPW circuitry can be implemented.

3.2. Waveguide bends

A basic component required to build photonic circuitry is a waveguide bend. A 90° waveguide bend can be implemented using a waveguide section of a circular shape with a radius r (**Figure 9**).^{105,108} The calculated near-field distributions show that during propagation along the curved section, the SPP guided mode experienced radiation losses in a form of SPP waves on the surface outside the guide and free-space light. The dependence of

transmission $T_b = I_{b1}/I_{b0}$ through the bend T on the radius of the bend r (Figure 9a, curve (i)) is determined by a trade-off between two sources of losses. For small bend radii (sharp bends), radiation losses play the dominating role due to more efficient coupling to ‘free space’ plasmonic modes on the surrounding metal and light¹²⁶. For large radii, where the radiation losses are small, the absorption Ohmic losses become dominant due to the increase in the length of the bend section. At the optimal value of the bend radius $r \sim 5 \mu\text{m}$, when the total losses in the bend are minimal, the transmission is as high as 75% (corresponding to signal loss of 1.3 dB) at the telecom wavelength $1.55 \mu\text{m}$. Moreover, if the losses in metal are compensated by, e.g., gain (Section 7), the transmission can be above 95% (Figure 9a, curve (ii)). The obtained bend radius ultimately defines small size of DLSPPW components, such as splitters, waveguide ring resonators, etc.

A comprehensive experimental investigation of bend-loss of single-mode DLSPPW was performed using S-bends, i.e., double-bends, connecting two parallel waveguides with an offset in respect to each other (Figure 10a).¹¹⁵ The design of S-bends was based on sine curves, ensuring continuous bend curvature and, therefore, adiabatic evolution of the DLSPPW mode throughout the bend. The bends with small offsets ($d \leq 5 \mu\text{m}$) show an excellent performance with the transmission up to 70% (Figure 10b), which gradually decreases with the offset increase due to the radiation losses (Figure 10c). At the same time, even the S-bend with the largest offset ($d = 15 \mu\text{m}$), corresponding to the smallest curvature radius of $1.95 \mu\text{m}$, transmits a substantial signal (Figure 10d), confirming robust guiding properties of DLSPPWs. The experimental and theoretical transmission values were found in good agreement with each other (Figure 10e). The striking agreement was also observed in the field maps comparing the intensity distributions from the simulations with the near-field images obtained in the experiment (c.f. Figures 10b,d and insets in Figure 10e). The transmission shown in Figure 10e reflects not only the radiation losses due to the waveguide

curvature, but also the DLSPPW mode propagation loss due to absorption in gold, accumulated over 10- μ m-long S-bends. With the known DLSPPW propagation length ($L_{prop} \sim 50 \mu\text{m}$), it was possible to separate the contributions of the loss channels. For $d \leq 3 \mu\text{m}$ the bend-loss was found to be less than 10%, whereas for $d > 6 \mu\text{m}$ it constitutes the main loss contribution. The numerical study of how the S-bend transmission depends on the S-bend shape and length, keeping the same offset between the waveguides shows that among various shapes of the S-bend, the shape defined by the sine curve provided the best performance.¹⁰⁵

3.3. Waveguide splitters

The performance of DLSPPW Y-splitters at telecommunication wavelengths was extensively studied using scanning near-field optical microscopy in conjunction with FEM numerical simulations.¹¹⁵ The splitters with different arm separations ranging from 3 to 30 μm were fabricated using deep-UV lithography, keeping the splitter length constant to have the same Ohmic losses (**Figure 11a,b**). The Y-splitters have a pronounced rounding of the junction area with $\sim 300 \text{ nm}$ radius (inset in Figure 11), due to limited resolution of the fabrication technique. Such a rounding prevents adiabatic transformation of the input mode into the outgoing modes in the waveguide branches, resulting, therefore, in a radiation loss mostly into smooth-surface SPPs propagating in the area between the branches (Figure 11c,d). The Y-splitters with a 300 nm radius rounding of the junction area show a $\sim 20\%$ decrease in transmission, compared to the adiabatic splitters in good agreement with the experimental results. The resolution in DLSPPW fabrication and consequently the performance of the splitters can be improved, e.g., by exploiting optical proximity correction techniques. The total transmission can be further increased up to $\sim 95\%$ for the 10 μm long splitter by introducing amplification to reduce absorption losses (see Section 7). Even without amplification, with the arm separation of 2.6 μm the splitter length can be reduced to about 6

μm without practical decrease of the splitter performance, providing the total signal in the outputs $\sim 75\%$.¹⁰⁵ It was also demonstrated that by breaking the symmetry of the splitter by vertical shifting the output waveguides with respect to the input one, it is possible to achieve any required splitting ratio of the SPP signal.¹⁰⁵

A number of alternative splitter designs was proposed for DLSPW circuitry. The discussed fork-shaped design can be modified by making one output arm separated from the input to obtain an asymmetric splitter.¹²⁷ A family of splitters is based on the strong coupling of the DLSPW waveguides located at small distances from each other (Figures 11e) allowing inter-waveguide mode coupling.¹⁰⁵ For these two approaches, however, precise fabrication is needed to obtain required characteristics with reasonable accuracy. On the other hand, a numerically demonstrated splitting approach based on multimode interference¹²⁸ (Figure 11f) is very robust in terms of fabrication, but for the price of fixed arm separation defined by the SPP interference pattern along with an increased required length and consequently higher absorption losses. Such splitter was used for experimental demonstration of DLSPW signal demultiplexing.¹²⁹

After successful demonstration of efficient DLSPW mode splitting, a Mach-Zehnder interferometer was developed composed of a Y-splitter followed by two parallel waveguides sections, which were recombined by a mirrored Y-splitter. Since in the symmetric Mach-Zehnder interferometer the path lengths of the two waveguide arms are identical (Figure 11g), constructive interference in the output is expected (Figure 11h): SNOM images indeed demonstrate efficient splitting and recombination of the DLSPW signal. With the arm length of $l \sim 45 \mu\text{m}$ for operating at $\lambda = 1550 \text{ nm}$, the MZI has a transmission of about 20%. Due to the overall length of the Mach-Zehnder interferometer, the losses are largely dominated by the DLSPW mode absorption accounting for $\sim 74\%$ of the total loss.

4. DLSPW wavelength-selective components

To fully exploit the advantages of the plasmonic approach for broadband data transfer in highly-integrated photonic circuits, such as wavelength multiplexing, and to achieve active functionalities, wavelength-selective components are needed. In this section we will overview various designs and performance of such components based on the DLSPW waveguides.

4.1. Bragg reflector

One of the most widely used method for the wavelength separation and selection is based on diffraction on periodic structures. The examples include the wavelength rejection or filtering, implemented, for example, in high-reflectance interference mirrors, high-extinction interference filters or fiber Bragg grating used for various sensing applications.¹³⁰ Various methods of the implementation of a Bragg reflector in a DLSPW waveguide were proposed and numerically investigated.¹⁰⁵ A compact Bragg reflector can be achieved by the variation of the ridge height (**Figure 12a**). With five-period component, the reflectivity did not exceed $R \sim 0.5$ even for optimized Bragg period, due to required large height modulation, leading to strong free-space scattering. As an alternative design, a Bragg reflector was implemented on the basis of square-wave or sinusoidal modulation (up to 20%) of the refractive index of the stripe (**Figures 12b and 12c**). A 20-period reflector, optimized by varying the high-refraction section length and the overall period, provides reasonably high reflectivity of $R \sim 0.7 - 0.8$. However, such high refractive index modulation is experimentally challenging, while the reflectors with lower modulation need to be rather long (~ 20 periods or more). From all the proposed approaches for Bragg reflector, the one based on metallic stripe Bragg grating under the polymer waveguide ridge provided the best performance with almost 90% of the SPP mode energy reflected using 11 μm Bragg reflector containing nine periods (**Figure 12de**).

A Bragg filter design based on variation of the waveguide width was also proposed.¹³¹

The variation of the waveguide width introduces the change of the effective index of the mode.

This makes it related to the Bragg reflector design based on modulation of the refractive index discussed above (Figure 12b), but with crucial advantage of a large modulation contrast. The DLSPW effective mode indexes in the narrow and widened sections are in the range from ~ 1.2 to ~ 1.4 , respectively. With 50% Bragg filter duty cycle, this results in the transmission minimum at $1.56 \mu\text{m}$. SNOM characterization of the SPP mode reflection from 30-period Bragg filter shows well-defined Bragg reflection accompanied by transmission extinction (band gap) in the wavelength interval from 1540 to 1600 nm (Figures 12f-j). Relatively low transmission levels (~ 0.3) observed outside of the band gap are partially accounted for by the DLSPW mode propagation loss reducing the transmission by the factor of ~ 0.7 on its own, the rest is related to out-of-waveguide scattering on the ridges.

4.2. Waveguide ring resonator

A compact and highly-efficient wavelength-selective component for integrated photonic circuits is a waveguide ring resonator (WRR, **Figure 13a-c**). It is formed by a waveguide loop placed in the vicinity of a straight DLSPW waveguide. When the input mode is passing the region adjacent to the ring, it is partially coupled to the waveguide forming a ring. The mode transferred in the ring starts to circulate around it, after each turn being partly decoupled back into the straight waveguide. The resulting interference of the directly transmitted and passed through the ring SPPs depends on the phase delay acquired by the mode traveling a complete circle around the ring, or in other words on the number of the mode wavelengths λ/n_{eff}^{ring} which can be placed along the ring circumference. Therefore, for different wavelengths, the changes in WRR transmission will be observed, resulting in quasi-periodic wavelength dependence of the WRR transmission featuring sharp minima (Figure 13h). The radius of the ring defines the periodicity, while the gap between the ring and the straight waveguide defines coupling strength, similar to one described in Section 2, and hence the modulation contrast

between transmitting/blocking WRR states¹³² (cf. red and blue lines in Figure 13h). The WRR transmission can be expressed as

$$T = \frac{\alpha^2 + t^2 - 2\alpha t \cos \theta}{1 + \alpha^2 t^2 - 2\alpha t \cos \theta}, \quad (6)$$

where

$$\theta = (2\pi/\lambda)n_{eff}(\lambda)2\pi r + \phi, \quad (7)$$

and t is the amplitude transmission coefficient for the straight waveguide mode directly passing the coupling region, α is the amplitude loss of the mode during the one-time round travel, λ is the free-space wavelength, r is the ring radius, $n_{eff}(\lambda)$ is the wavelength-dependent DLSPW effective index, and ϕ is the coupling-induced phase shift caused by mode perturbation in the coupling region¹³³ (in the first approximation it can be omitted). An alternative point of view which leads to the same result is to consider superposition of SPP mode circulating in the ring as a ring resonator mode, though strongly coupled to the straight waveguide.

DLSPW WRRs having a radius of only 5 μm do not exhibit noticeable ring mode excitation at a wavelength of 1.55 μm for the edge-to-edge gaps between the ring and the straight waveguide of $g \cong 2.53 \mu\text{m}$ and 1.53 μm (Figure 13).¹³¹ For a smaller gap $g \cong 0.53 \mu\text{m}$, WRR features very efficient ring mode excitation and well-pronounced wavelength-dependent behavior (Figures 13d-g). The experimental spectra are well described by the theoretical dependence (Equation 3) with calculated effective index dispersion $n_{eff}(\lambda) \cong 1.61 - 0.25\lambda[\mu\text{m}]$ and the WRR parameters $\alpha \cong 0.55$, $t \cong 0.7$, and $R \cong 5.43 \mu\text{m}$ (Figure 13h). The investigated WRR features nearly complete extinction of the mode, reaching ~ 13 dB at 1590 nm, with about 20 nm bandwidth.

As was discussed above, the coupling between DLSPW waveguides is highly dependent on the separation distance between them. As a consequence, the wavelength-

selective characteristics (particularly the depth on the resonance dip) are very sensitive to the fabrication precision of the WRR coupling region. To diminish the influence of the fabrication uncertainties, the resonating waveguide loop can be made in a form of a racetrack (two semicircles connected by straight waveguide sections parallel to the straight input waveguide). In this case the interaction length between the waveguide and the resonator is longer, and keeping the same coupling efficiency as in the case of the ring shape, the racetrack can be moved further, so the same fabrication error will have a smaller relative influence.¹³⁴ Another approach, which increase the tolerance of the structure performance to the fabrication uncertainties is using a disc resonator instead of the ring one, in this case the precise fabrication of the ring width is not needed.^{135,136}

4.3. Directional coupler

As was discussed in Section 2, the mode from a DLSPW waveguide can be efficiently transferred to the neighboring waveguide if the separation between them is sufficiently small. The coupling length (the length needed for the total energy transfer from one waveguide to another) depends on the DLSPW mode profile, which in its turn is wavelength-dependent. This effect can be used to realize a wavelength-dependent directional coupler (DC) component (**Figure 14a,b**). The length of the waveguides can be chosen so at a given wavelength after few oscillations between the waveguides, the mode can be fully localized in one of them, while for mode at another wavelength, having longer (or shorter) coupling length, the number of oscillations may be different, so that the mode will be fully localized in another waveguide. Directional couplers, comprising input and output S-bends have been realised^{137,110} (Figure 14). As predicted by the theory (Section 2), the coupling length L_c was found to have a strong dependence on the separation distance (cf. Figures 14c,e) and also to vary noticeably with the wavelength, influencing the power ratio between the output waveguides (cf. Figures 14c,d). At the same time, the sum of power flows in the output

channels is practically wavelength independent maintaining the level of ~ 0.23 , a value that is consistent with the loss incurred by 25- μm -long propagation ($\sim 40\%$) and two S bends ($\sim 35\%$ per bend). As expected, for shorter wavelengths, at which the mode localized stronger, the coupling is weaker and the coupling length is larger (Figure 14f).

The obtained dependence of the coupling length was used for the development of the purpose-designed DCs. Generally, with only one waveguide being excited at the input, the output signals, i.e., straight T_s and cross T_c transmissions can be represented as:

$$\begin{Bmatrix} T_s(\lambda) \\ T_c(\lambda) \end{Bmatrix} = (T_{bend})^2 \exp\left(-\frac{L_p}{L_{prop}}\right) \begin{Bmatrix} \cos^2\left(\frac{\pi L_i}{2L_c(\lambda)}\right) \\ \sin^2\left(\frac{\pi L_i}{2L_c(\lambda)}\right) \end{Bmatrix}, \quad (8)$$

where the first factor reflects the S-bend transmission, the second one reflects the power loss during propagation through the straight waveguide section of length L_p , and L_i denotes the effective interaction length ($L_i > L_p$ due to the additional mode coupling in the S bends¹³⁸).

The interaction length was evaluated to be $L_i \approx 34 \mu\text{m}$, so that it is possible to obtain the wavelength division characteristics for any given DC length and therefore by choosing the appropriate value to design a DC structure that would ensure spatial separation of signals corresponding to different wavelengths. For example, an increase of the length of parallel section by $\cong 5.5 \mu\text{m}$ for the DC with $d = 1000 \text{ nm}$ would enable spatial separation of the wavelengths of 1400 and 1620 nm, belonging to E and L telecommunication bands (Figure 14g).

5. DLSPPW active components

As has been shown in the previous sections, DLSPPW approach proved to be efficient in guiding and passive manipulation of plasmonic signals. However, we will only be able to speak about plasmonics in the same way as we speak about optoelectronics, if active plasmonic components are designed and demonstrated.^{139,140,141} In this section, we will discuss various active functionalities realized on DLSPPW platform, such as switching, modulation or active routing of the plasmonic signal. The crucial advantage of the plasmonic approach, relying on high confinement level of plasmonic modes and excellent guiding characteristics of plasmonic waveguides, is a small size of active plasmonic components, which leads to high potential operational speeds and small energy consumption.

5.1. Design and optimization of DLSPPW active components

As was discussed in Section 4.2, transmission through the ring resonator is determined by a phase shift acquired by the mode in the ring during the round-trip, which depends on its effective index n_{eff} (Equations 6 and 7) and, therefore, on the refractive index of the ring material. With pronounced sharp minima in the spectral characteristics (**Figure 15a**), this naturally gives the opportunity to use WRR and an active switching component. Adjusting the ring radius so that the signal wavelength is located at the steepest slope of the transmission (red arrow in the figure), one can change the refractive index of the ring material via thermo-optic, electro-optic, or optically-induced nonlinear effect. Even with minute changes in the refractive index of the ring material, a related small shift in the resonances will lead to significant changes in the transmission at the signal wavelength (inset to Figure 15a).¹⁴²

Although the general principle of active WRR operation is very clear, the optimization of the WRR design, e.g. finding the ideal ring radius, is not so straightforward. With the increase of the ring radius the refractive index changes will produce larger phase shifts; at the same time this will result in higher losses which will reduce the maximum WRR transmission

and, therefore, the steepness of the resonance slopes, decreasing the modulation depth.

Additionally, this will also increase the component size. To account for this different trends, a figure of merit for an active WRR was introduced, benchmarking its performance and the integration level of an active WRR¹⁴³:

$$M_{WRR} = \frac{\partial T / \partial n}{R / \lambda} = 4\pi^2 \frac{\partial T}{\partial \theta} \frac{\partial n_{eff}}{\partial n}. \quad (9)$$

The high figure of merit corresponds to strong changes in WRR transmission with the refractive index of active material $\partial T / \partial n$ for the smallest possible size R of the resonator.

Here, $\partial T / \partial \theta$ is determined by the geometrical parameters of the structure, while $\partial n_{eff} / \partial n$ is the changes of the effective index of SPP guided mode in the resonator with the changes of the refractive index of dielectric material. For SPP modes, this term will always be greater than for all-dielectric WRRs due to the field confinement and enhancement in plasmonic waveguide. For each radius (corresponding to a certain losses α), the highest value of derivative $\partial T / \partial \theta$ can be found using Equation 6 by varying the transmission coefficient t , determined by the ring-waveguide gap g , and the dependence of the FOM on the radius r can be recovered (Figure 15b). One can see that for active WRR based on a single mode polymer-based DLSPPW, there is an optimal radius $\sim 6 \mu\text{m}$. The refractive index change of just $\Delta n \sim 5 \cdot 10^{-3}$ in the optimized design results in a drastic (~ 5 times) change in the WRR transmission (Figure 15a).

For comparison, one can consider the active component based on Bragg reflector (the same design as in Figure 12d,e, with a straight waveguide section after the component as an output).¹⁴² With the grating period adjusted so that the signal wavelength is at the edge of the bandgap (but still inside it), the induced changes in refractive index as small as 10^{-2} (possible, e.g., via thermo-optic effect) can shift the band structure of the Bragg grating so that at the considered wavelength the signal SPP will be in the transmission band. This effectively

changes the Bragg filter transmission and opens the way to DLSPPW signal modulation. In the case of an MZI with the arm length of $l \sim 45 \mu\text{m}$, the change of the effective index of the mode in one arm needed to achieve a complete extinction is $\Delta \text{Re}(n_{\text{eff}}) = \lambda/(2l) = 1.72 \cdot 10^{-2}$.¹¹⁵

5.2. Optically-controlled WRR component

Optically-controlled components on the basis of WRRs were introduced using the ring-resonator based on polymer DLSPPW doped with disperse red 1 (DR1) dye to achieve nonlinear response (**Figures 16a-e**).¹⁴⁴ Azobenzene chromophores, such as DR1, are attractive materials for studying various second order nonlinear optical effects and polarized light-induced anisotropy. Control light with a frequency near the main absorption resonance (490 nm) causes the azobenzene molecule to change from the *trans* to the *cis* configuration. This results in a substantial change in a molecule's dipole moment and, hence, the polarizability and refractive index of the material (Figure 16f). Both fast picosecond-scale processes connected of molecular transformation and much slower processes of molecular photo-orientation, happens when the control light is linearly polarized and results in pronounced light-induced anisotropy.¹⁴⁴

The typical dynamic switching may lead to the photo-induced changes as high as $\Delta n = 3.7 \cdot 10^{-3}$. Such large changes in the refractive index of the ring material are more than sufficient for significant modulation of the WRR transmission, as was observed experimentally in accordance with numerical simulations.¹⁴⁴ The introduction of the control light was initially followed by rapid decrease in the WRR transmission, which slowed down at higher powers due to the saturation of the DR1 molecular response (Figure 16g). The total transmission changes by more than 50% were observed, which is in good agreement with the simulations (Figures 16d,e). The switching is reversible, the transmission returns to the high level after unpolarized white-light illumination. This suggests that the dominating role in the

nonlinear response is the molecular reorientation processes leading to the refraction index changes. While the observed ON/OFF switching time is low for real time signal modulation and routing, the above discussed active WRR component has been proposed for designing of optically reconfigurable photonics circuits.

An alternative approach to optical DLSPW mode switching in a directional coupler geometry using photo-thermal effect in the polymer doped with gold nanoparticles was experimentally demonstrated transmission change with modulation depth of 100% in both source and cross DLSPW channels (these signals are in anti-phase).¹⁴⁵

5.3. Electro-optic DLSPW switches

In order to achieve the electro-optic functionality with WRR, the design was further developed to include the control electrodes via patterning a metal film (**Figure 17a,b**)¹⁴⁶. The same DR1 molecules as for the optically controlled component describe in Section 5.2 were used as a doping material due to large r_{33} coefficient, related to the same molecular processes that lead to optical nonlinearity, resulting in the refractive index change $\sim 10^{-4}$ in PMMA/DR1. For low applied control voltages, the WRR transmission shows a significant increase, but after the electric field passed the 8 MV/m, the transmission recovers to the initial value (**Figure 17c**). This was hypothesized to be the result of the structural deformation in the PMMA structure due to the electrostrictive effect. Time-resolved measurements with square-wave application of 25 MV/m electric field show fully-reversible electro-optical modulation of DLSPW signal with 18% modulation depth (**Figure 17d**). The response time of the transmission changes is in the second time-scale, which was in favor of electrostrictive nature of the effect. Interestingly, undoped PMMA WRRs exhibit 14% modulation depth, their response time was ten times slower. This can be understood by modification of PMMA plasticity by DR1 doping. The underlying switching mechanism can then be the combination

of electrostrictive and electro-optic effects. An alternative design with the second electrode on the top of the ring¹⁴³, being more efficient, is more challenging in terms of implementation.

An interesting approach for modulation in DLSPPWs, based on implementation of DLSPPW core as a channel filled with nematic liquid crystal and utilizing electro-optic effect in the directional coupling geometry, was also theoretically investigated, presenting signal modulation with extinction ratio of 12dB.¹⁴⁷ Finally, we note that conventional electro-optic materials provide too small refractive index modulation to be used in highly-integrated active components. Novel nonlinear polymers⁶⁴, naturally compatible with the DLSPPW technology, can pave the way for DLSPPW-based modulators operating in MHz-GHz range and in this respect matching the performance of the photonic ones⁸³. For example, such DLSPPW-based modulator with the design from Ref. 143 will also have energy consumption per bit¹⁴⁸

$\Delta E_{bit} = (1/4)CV^2 \sim 20$ fJ (calculated using estimated device capacitance of $C = 1.3$ fF and the required control voltage of $V = 7$ V), which is favorably comparable with the best values for photonic⁸³ and plasmonic^{64, 149} modulators.

5.4. Thermo-optic DLSPPW switches

DLSPPW active components utilizing a thermo-optic effect are the most investigated.¹⁵⁰ PMMA polymer, which is typically used for a DLSPPW dielectric core, has intrinsic large thermo-optic coefficient of $(\partial n / \partial T)_{PMMA} = -1.05 \cdot 10^{-4}$ 1/K. Hence, a moderate temperature increase by 50° results in a refractive index change as high as $\Delta n \sim 10^{-3}$, allowing DLSPPW signal modulation in components of various designs. Furthermore, the effect can be at least 3 times magnified by using alternative materials, such as CAP (see below).¹⁵¹ The temperature change can be induced using resistive heating in the same metal film that supports SPP mode and is located beneath the core. Therefore, the change is induced in an efficient way in the dielectric region where the SPP mode has highest intensity, exactly where it is needed. This is

different in the case of thermo-optical components based on dielectric waveguides, where the electrodes are located far in the cladding, and, thus, temperature induced changes are generated far from the mode and influence it much weaker.

The first designs of thermo-optic DLSPPW components were again based on WRR geometry (**Figure 18a**)^{150,151,90,152,113}. A PMMA-based ring resonator area was resistively heated by current passing through a metal strip underlying the structure. The temperature increase of 100 K resulted in a blue shift of the WRR resonances by ~4.5 nm. Due to high quality factor of the fabricated structures and sharp resonance minima, this led to the changes in the WRR transmission of up to 9 dB at the wavelength of $\lambda = 1538$ nm corresponding to the steepest slopes in the wavelength characteristic (Figure 18b-d).

The WRR operation as an active component discussed above is based on resonant effects and, thus, have narrow wavelength bandwidth. On the other side, if the broadband operation of the switch is needed, a classical design based on Mach-Zehnder interferometer is beneficial (Section 3). When a phase delay φ is introduced in one arm of MZI by external control signal, the interference of the signals propagating in 2 arms can be changed and efficient signal modulation can be achieved: destructive interference and a zero signal output can be obtained if $\varphi = \pi$ introduced. The induced phase $\varphi = 2\pi/\lambda \cdot \Delta nL$ is a weak function of the wavelength, therefore the modulation can be equally efficient in a broad wavelength range. This makes an active MZI useful for broadband signal switching, at the price of larger than for WRR required size (~50 μm) due to sufficiently long arms needed for accumulating a phase difference at realistic refractive index changes.

Electrically-driven modulation of the MZI output signal via resistive heating of the top arm was demonstrated (Figure 18e).¹⁵¹ It was fabricated with a CAP polymer as a dielectric load, having a large thermo-optic coefficient $(\partial n/\partial T)_{PCAP} = -3 \cdot 10^{-4}$ 1/K, 3 times larger than PMMA. This has allowed to achieve a required $\sim 2\pi$ phase shift, which led to high

modulation depths and even to double switching (Figure 18f). Not complete signal extinction is related to the distortion of the amplitude and the zero-voltage phase by the presence of the electrode gaps, so that the equal-amplitude condition for zero-output destructive interference is not satisfied. The modulation depth can be increased to 100% by adjusting the splitting ratio to restore equal power levels at the arms outputs. As an additional advantage, CAP specific heat coefficient (amount of heat required to change the material's temperature) is 270 times lower than PMMA, which allows decrease of the switching times, heating up and cooling down, to the microsecond range, 20 and 15 μ s, respectively, so that the operation frequency of the device is about 50 kHz with 3 dB cut-off (Figure 18g).

The power required to switch the MZI, apart from geometrical parameters, is greatly influenced by thermal conductivities of the DLSPPW ridge material and that of the substrate. These parameters define how the available heating power is divided between the DLSPPW waveguide and the substrate. For example, for the substrate with high thermal conductivity, the supplied heat will be mainly dissipated through the substrate, therefore high switching powers is needed. Here, the choice of low heat-conductive CYTOP substrate ($\kappa_{CYTOP} = 0.12 \text{ W}/(\text{m} \cdot \text{K})$) results in a 10 fold decrease of the switching power in comparison to MgF_2 substrate ($\kappa_{\text{MgF}_2} = 11.6 \text{ W}/(\text{m} \cdot \text{K})$), resulting in milliwatt switching powers of the MZI. The actual power required for MZI switching is actually even smaller than in Figure 18f. Taking into account that only a fraction of the total power is dissipated in the MZI arm region, the switching power P smaller than the 3 mW was estimated to be sufficient for the actual switching process for 100% modulation contrast. This corresponds to the energy consumption of the order of $\Delta E_{bit} = P\tau_{rise} = 60 \text{ nJ}$ per bit, where $\tau_{rise} = 20 \mu\text{s}$ is the modulation signal rise time¹⁵¹.

The requirements on the electrode design and the electric isolation have an impact on the operation wavelength bandwidth and should be carefully considered. Due to the presence

of two electrode gaps, the electrically isolated arm section acts as a Fabry-Perot cavity for SPP modes if the reflection is significant. With multiple reflection at the edges, the transmission through MZI depends on the wavelength in a periodic manner and so does the resulting transmission modulation.¹⁵¹

Exploiting the strong refractive index modulation achievable via thermo-optic effect, a number of approaches for routing DLSPW signal have been proposed. Reversible switching of the mode between the outputs of the directional coupler via resistive heating of the coupling region was observed.¹⁵⁰ Alternative routing approaches, based on conventional designs of add-drop filters, i.e., single- or double-WRR structures, were investigated.¹⁵³ Low power consumption (down to a fraction of mW) and fast switching times (down to few μs) were experimentally demonstrated for switching the signal in silicon-on-silica photonic circuits via incorporated DLSPW-based active components.^{154,155}

6. Figure of merit for plasmonic waveguides in integrated photonic circuit

Following the advantages offered by the plasmonic approach in terms of localisation and active control of the optical signal, numerous plasmonic waveguiding geometries has been proposed (Figure 1). The designs cover the whole range of achievable mode sizes from tens of nanometers to micrometers, and related propagation lengths from sub-micrometer to centimeter scales. In fact, there is a general trade-off between these two characteristics: higher confinement usually corresponds to a larger portion of the mode propagating in metal, which leads to higher losses and therefore a lower propagation length. In these circumstances, to compare the diverse variety of plasmonic waveguides, a figure of merit (FOM) was introduced to quantitatively characterize their guiding performance.¹⁵⁶ As the best starting point, the figure of merit

$$M_1^A = 2\sqrt{\pi} \cdot \frac{L_{prop}}{\sqrt{S}} \quad (10)$$

represents a straightforward measure of the above-mentioned trade-off: a ratio between the signal propagation length L_{prop} , reflecting the propagation characteristic of the mode and the size of the mode \sqrt{S} (S is the effective mode area), reflecting its confinement. Although it has a clear physical meaning and gives a vivid characterization of the mode as such, it is not ideal for benchmarking the performance of the waveguide for implementation in highly-integrated optical circuits. The square root of the mode area in the denominator of M_1^A is effectively a measure of how closely parallel waveguides can be packed on a chip. However, modes with the same effective areas can be coupled more efficiently or less efficiently to the neighboring waveguide depending on their spatial field distributions. Furthermore, it has been shown that there is a variety of ways to quantify the effective mode area, frequently giving essentially different and even opposite results¹⁵⁷. Therefore, the above figure of merit was modified in order to include a direct measure of the coupling efficiency.^{39,99} When two parallel waveguides are placed next to each other, their coupling leads to the tunneling of the

mode from one waveguide to another with a full energy transfer after a distance L_{coupl} . With this in mind, the waveguide center-to-center separation d_{sep} corresponding to

$L_{coupl}(d_{sep}) = 4L_{prop}$ will give a direct measure of the achievable integration density: after one propagation length (when mode intensity will decrease in ~ 2.7 times), only 15% of the mode energy will be coupled in the neighboring ‘aggressor’ waveguide. Therefore, using the coupling distance approach, the figure of merit can be represented as:⁹⁹

$$M_1^B = \frac{L_{prop}}{d_{sep}}. \quad (11)$$

The second main parameter characterizing particularly the performance of a multi-branched waveguide circuitry is an ideal radius, minimising signal loss along a curved waveguide section. This parameter defines the size of all circuit components, such as splitters, WRRs, MZIs, etc. The ideal waveguide radius is a trade-off between Ohmic losses (higher for bigger radii) and radiation losses (higher for smaller radii).¹⁰⁸ Figure of merit introduced as¹⁵⁶

$$M_2 = 2L_{prop} \cdot (n_{eff} - n_{surr}),$$

where n_{eff} is the mode effective index and n_{surr} is the refractive index of the surrounding medium, gives only a partial answer, taking into account only the radiation losses: the further the SPP mode dispersion from the light line, the lower the coupling efficiency to the escaping light. At the same time, with the value of such FOM fixed, the radiation losses are also influenced by the particular waveguide geometry. As an alternative solution, the all-inclusive figure of merit for multi-branched plasmonic circuitry was proposed, taking into account both Ohmic and radiation losses and directly estimating the waveguide bends performance:³⁹

$$M_1^C = \frac{L_{prop}}{d_{sep}} \cdot \left(\frac{T(r)}{r} \right)_{\max}, \quad (12)$$

where $\left(\frac{T(r)}{r}\right)_{\max}$ is the maximum of transmission-to-radius ratio, found varying the bend radius. Here, as a universal building shape for both waveguide bends, splitters and ring resonators, we took the bending shape in a form of a circular arc. In more narrow case of waveguide bends and splitters, one can get approximately 10% improvement in performance (for reasonably high transmission levels) using harmonic function based shapes^{115,105}.

The obtained figure of merit was derived using ‘local’ characteristics of the waveguide performance: the cross-talk between neighboring waveguides and waveguide bend performance. The most relevant to the practical applications, however, is the estimation of the global performance of the multi-branched plasmonic circuit as a whole data communication architecture. The most general benchmark describing the performance from these prospective can be defined as a bandwidth per unit area achievable in the circuit divided by the power loss per unit area due to Ohmic and radiation loss. Considering the case of multi-branched circuitry containing both straight and curved waveguide sections, the following expression for such ‘global’ figure of merit can be derived:¹⁵⁸

$$M_{glob} = B \cdot \frac{L_{prop}}{d_{sep}} \cdot \left(\frac{L_{tot}(r)}{r}\right)_{\max}, \quad (13)$$

where B is the waveguide single-stream bandwidth (Equation 5, with the characteristic length $L = L_{prop}$) and $L_{tot}(r)$ is a mode propagation length along a waveguide curved section, influenced by both Ohmic and radiation losses. Strikingly, although the local (Equation 12) and global (Equation 13) figures of merit are derived from absolutely different perspectives, they reflect the same dependences on the waveguide performance characteristics. The only difference is that in the former case the bend transmission-to-radius ratio $T(r)/r$ is maximized, while in the second the same should be done for the propagation characteristic of

the section $L_{tot}(r)/r$. At the same time, the global FOM includes important parameter—the waveguide single-stream bandwidth—which was completely disregarded before.

The derived global figure of merit was applied to evaluate the performance of the main types of plasmonic waveguides (**Table 2**). The relevant waveguide characteristics were found using 2D eigenmode and full 3D finite element numerical simulations. For fair comparison all the waveguides were implemented on a gold material platform at telecommunication wavelength $\lambda = 1550$ nm. Additionally, in some cases Al and Ag platforms or $\lambda = 633$ nm operational wavelength were used to compare the design to the original experiments. As expected, for all the waveguides a trade-off between L_{prop} and d_{sep} is observed. The propagation length along the ideally curved section L_{tot} is a factor of 1.2-4 shorter than L_{prop} , while the ideal radius can be of the same order as the waveguide cross-sections, as in the case of the most highly-integrated waveguides, or can be up to 3 orders of magnitude larger, as in the case of e.g. long-range waveguides. Due to small interconnect lengths, the calculated bandwidths B reached extremely high values of tens of Tb/s, corresponding to the signal carrying pulses containing just a few field oscillations, thus practically the single-stream bandwidth will be limited by the current electronic data modulation technology presently capable of 10-100 Gb/s modulation rates, while overall bandwidth can be substantially increased using the WDM technique.

An interesting universal trade-off can be observed from Table 2 for the characteristics of plasmonic waveguides of completely different designs: the cross-talk limited photonic integration of straight data lines can be different by 2 orders of magnitude, the bend radii can be different by 5 orders of magnitude, propagation lengths can be different by 4 orders of magnitude (cf. d_{sep} , r and parameters e.g. for long-range and wire-MIM waveguides), but the global FOM values fall within 2 orders of magnitude interval for all considered waveguides. This, however, can be regarded as a considerable difference, and the derived figure of merit

can indeed be used to benchmark the performance of waveguides of various designs. Furthermore, as can be seen on the example of hybrid waveguides, the particular geometrical parameters and the operational wavelength can modify the figure of merit by an order of magnitude, which makes it useful to optimize the performance of a chosen type of the waveguide. Analyzing the results presented in Table 2, one can conclude that DLSPPW has as good guiding efficiency as other plasmonic waveguides, at the same time having all the advantages in terms of fabrication and the active functionalities, while its hybrid modifications demonstrate the best network performance in terms of the global figure of merit. It is also important to note that while FOMs provide a global overview of the generic performance of the different waveguides, practical requirements, such propagation length or mode confinement, should be considered for each application separately since they may be determining the design parameter space. Traditional silicon-on-insulator (SOI) technology provides the mode propagation distances L_{prop} on centimeter scale, practically limited by waveguide wall roughness¹⁵⁹. For typical sizes of 1 cm long, 450 nm×220 nm SOI waveguides, waveguide separation distances $d_{sep} \sim 1.2 \mu\text{m}$, waveguide bends $r \sim 1 \mu\text{m}$ and the data bandwidth of $B \sim 3.2 \text{ Tb/s}$ can be estimated (cf. Table 2).

To make this discussion complete, we need to point out that it is also possible to introduce a figure of merit for active waveguide components:¹⁵⁸

$$M_{act} = A \frac{\Delta f}{P}, \quad (14)$$

where A is the absorption loss, Δf is the operational bandwidth and P is the power consumed per switching event for a standard 3 dB modulator based on a given approach. At the same time, benchmarking of various active components is very design-specific and lies beyond the scope of this review.

Table 2. . Benchmarking characteristics for various plasmonic waveguide and comparison of the performance of the waveguides using global figure of merit (Equation 13).

7. Signal amplification in DLSPW waveguides

Although the propagation lengths of plasmonic waveguides are large enough to establish middle-range on-chip communication, it will be extremely beneficial to extend them to larger,

long-range scales. This can be done through amplification of the plasmonic signal and will be discussed in this section. Further development of the amplification approaches have led to the development of integrated plasmonic lasers.¹⁶²

7.1. Specifics of plasmonic signal amplification

The general approach for amplification SPP waves is straightforward with DLSPW:⁴⁴ a dielectric at the SPP-supporting interface should be a gain medium. Upon optical or electrical pumping, the emitters near (~ 100 nm) a metal surface can radiate directly in an SPP mode, and, if the radiation is coherent (stimulated emission), the SPP mode will be amplified.¹⁰⁵ The dielectric core of the DLSPW waveguide contains the predominant part of the mode energy and can be used as an active medium upon doping it with lasing atoms, molecules or quantum dots.

The dynamics of the emission in the active medium in the presence of plasmonic effects is, however, more complicated than in a conventional dielectric waveguide or fibre, and depends on the specifics of plasmonic amplification.⁴⁵ The excited state of the emitter has, in the presence of plasmonic material, a variety of ways to radiate: photonic and plasmonic relaxation channels, as well as nonradiative near-field quenching into metal.⁵⁶ This results in a spatial dependence of excited state life times, influencing gain dynamics, which should be taken into account in a rigorous way in rate equations. The theory of SPP amplification was first developed to one-dimensional guiding geometry of long-range SPP waveguide produced by a thin metal film⁴⁵ and then further extended to the case of localized DLSPW mode.^{163,164} The problem of competition of relaxation channels can generally be treated using Green tensor formalism¹⁶³ or a rigorous Purcell factor probing implemented in finite element method numerical simulations¹⁶⁴.

In the case of optical pumping, the nature of plasmonic waveguides possessing metallic components, inevitably leads to non-uniform spatial distribution of the pump

intensity, which also adds complexity to the process of excitation and SPP emission in a gain medium, due different field profiles. If an SPP wave is used for pumping, the required field overlaps can be optimized ensuring the delivery of the highest pump intensity exactly where it is needed the most – at the same metallic interface supporting the signal SPP mode, and the stimulated emission efficiency can be increased 10 fold.¹⁶⁵ The SPP pump is also advantageous from the point of view of integration, removing the need of the external illumination of the waveguide. It is however poses challenges in ensuring that a SPP pump has sufficient propagation length in the waveguide to provide the required energy exchange with the signal SPP. Finally, it should be noted that amplification of the propagating plasmonic waves presents a much easier task when the amplification of their localized counterparts¹⁶⁶, on which so called another nanoscale coherent light source ‘spaser’ is based¹⁶⁷.

7.2. Amplification of DLSPW mode using optically-pumped gain medium

Amplification of the plasmonic mode in DLSPW waveguide was experimentally demonstrated by introducing a gain material in the DLSPW dielectric core. PbS quantum dots (QDs) with emission peak near the SPP wavelength of $\lambda = 1525$ nm were considered (**Figure 19a**).¹⁶⁸ Under illumination the entire DLSPW structure with low intensity a 532 nm pump light, spontaneous emission of the quantum dots into the fundamental TM_{00} DLSPW mode was confirmed (Figure 19b). Plasmonic amplification was then demonstrated by adding the signal SPP with the wavelength resonant to the PbS radiative transition and achieving stimulated emission. A substantial increase of the apparent propagation length from 13.5 μm to 17 μm (approximately 25% increase) and associated with it modal gain was observed (Figure 19c). The stimulated emission phenomenon, the signature of which is the narrowing of the signal spectrum⁵⁷, was further confirmed by analyzing the width of the mode peak in the Fourier plane (Figure 19d)¹⁶⁸. The idea of QD-assisted plasmonic amplification in DLSPW

waveguides was later extended on shorter near-infrared wavelength region¹⁶⁹ and visible range¹⁷⁰.

7.3. SPP amplification in semiconductor-based DLSPP waveguides under electric pumping

Optical pumping approach requires the use of external powerful light sources, which is not always compatible with the highly-integrated plasmonic circuit architecture. Electrical pumping approach is better suited for direct integrating with optoelectronic applications. To realize electrical pumping, the approach based on metal-semiconductor Schottky contacts has been proposed.⁵⁰ The plasmonic waveguide was formed by interfacing a plasmonic film with an active InAs ridge where the SPP amplification via population inversion upon electronic injection can be achieved in a Schottky contact (**Figure 20a**). The lattice-matched $\text{AlAs}_{0.16}\text{Sb}_{0.84}$ electric back-contact completes the electric circuit, while low refractive index SiO_2 matrix insured high confinement of the plasmonic signal. The SPP waveguide was designed for a wavelength of $\lambda = 3.16 \mu\text{m}$, corresponding to the peak in InAs emission spectrum, with a width of 350 nm and a height 2000 nm and supports a highly-localized ($\sim \lambda/10$) fundamental DLSPPW-type TM_{00} mode with the effective index ($n_{\text{eff}} = 2.68$) and the propagation length of $L_{\text{prop}} = 72.2 \mu\text{m}$ (Figure 20b-d).

Upon application of bias voltage, electrons and holes are injected in the active InAs region, creating the population inversion (Figure 20a). When the energy separation between the quasi-Fermi levels of electrons and holes becomes equal to energy of the SPP, stimulated emission into the SPP mode is initiated. The SPP mode propagation losses can be fully compensated at moderate current densities $\sim 10\text{-}30 \text{ kA/cm}^2$; above these values the mode is efficiently amplified (Figure 20e). The possibility of loss compensation for the SPP signal

with 100 Gb/s bit-rate was demonstrated. This approach can then be further developed in a nanoscale plasmonic laser by adding feedback element, such as a SPP ring resonator.¹⁶⁴

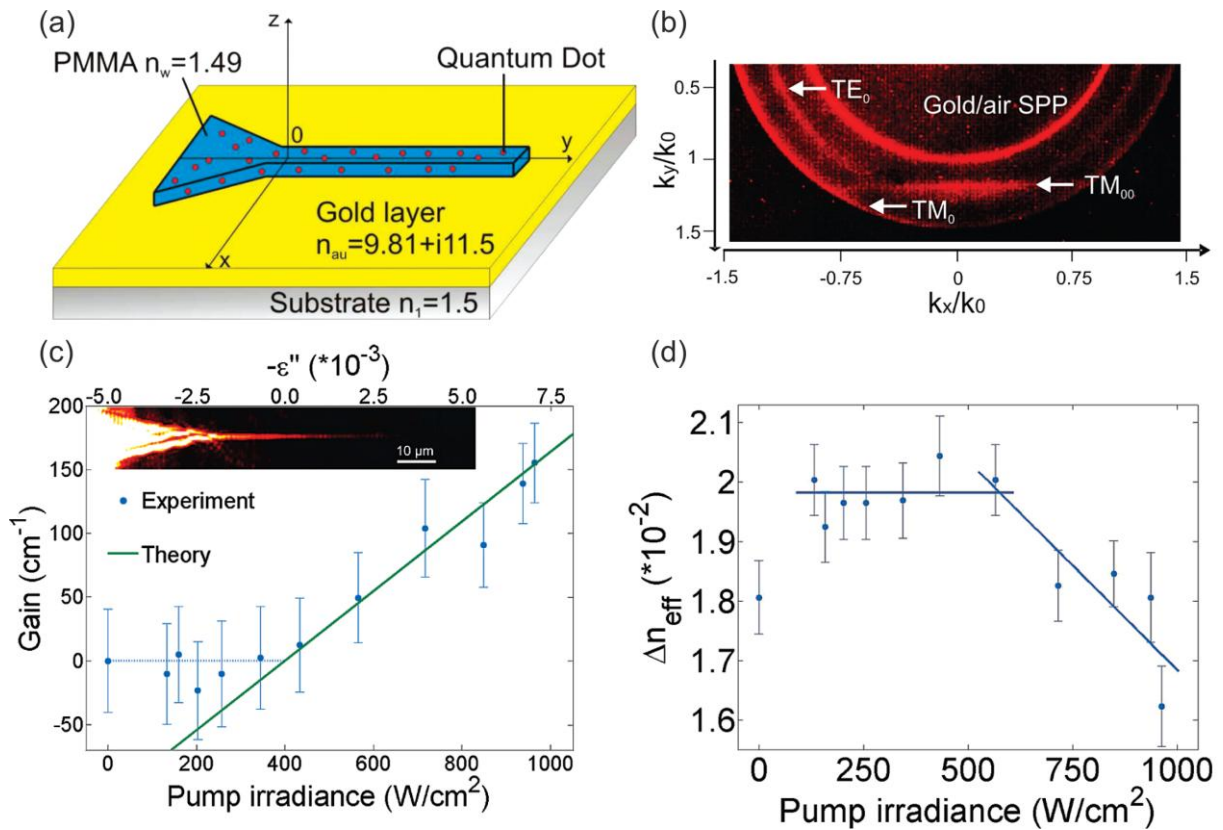

Figure 19. (a) Schematic of a DLSPW waveguide with the PMMA core doped with quantum dots. (b) QDs fluorescence recorded in the Fourier plane under the optical excitation ($\lambda = 532 \text{ nm}$). The arrows indicate the different effective indices ($n_{\text{eff}} = k_y/k_0$) of the modes existing within the illuminated area. (c) The intensity dependence of modal gain. Inset shows LMR image of taper-assisted launching of the DLSPW mode and its propagation along the waveguide. 8. Other types and applications of DLSPP-based plasmonic waveguides

8.1. Long-range and symmetric DLSPP waveguides

The concept of long-range plasmonic modes can also be extended to the DLSPP waveguide geometry. It is based on the fact that if the thickness of the SPP-supporting metallic film becomes sufficiently small (few tens, typically, 20 nm), the SPP modes at its top and bottom interfaces become coupled.^{171,172} Particularly interesting is the film in a symmetric environment, when the dielectric above and below the metal film is the same material or

different materials with very close refractive indexes. For the mode with a symmetric field distribution of the normal-to-the-surface component of the electric field, the electromagnetic field is pushed out of the metal, which leads to the dramatic reduction of the absorption losses with SPP propagation length of the symmetric mode on the centimeter scale. Its counterpart is a highly-localized and very absorptive mode with an anti-symmetric field distribution. The metal film can be structured to achieve micrometer-wide metallic stripe waveguides for the a long-range SPP mode.³³ This long-range propagation however comes at the price of an increased modal size in the surrounding dielectric and the effective index of the mode being closer to the refractive index of the surrounding media. The latter defines the lower limit for the waveguide bending radius to be of the order of several millimeters (see Table 2). To counteract these effects, an approach based on loading the long-range metallic stripe waveguides with dielectric ridges was proposed^{173,174} (**Figure 21a**): the dielectric ridge both localizes the mode and increases the effective index contrast. In order to obtain the longest propagation length, the key approach here is ensuring the most symmetric field distributions above and below the metallic stripe, corresponding to the minimal confinement of the plasmonic field in the metal and, therefore, minimizing absorption losses. This was realized by placing a high refractive index buffer layer between the metallic film and a low refractive index substrate. Varying its thickness, waveguide width and height and the width of the gold strip, the optimal waveguide geometries for various materials were found with the mode propagation lengths approaching several millimeters.^{173,174} Well-defined propagation of the long-range DLSPW mode with confinement approximately 1 μm and even below was observed at telecom wavelengths (Figures 21b,c).^{175,176} The propagation length of the mode was about 0.5 mm (affected by the leakage due to a finite thickness of the dielectric layer and the fabrication imperfections), while the theoretical estimation for the potential propagation length is about 3 mm. An efficient transmission of the mode through a waveguide S-bend was demonstrated with just ~ 1.8 dB loss for the waveguide separation of 10 μm and the S-bend

length of 20 μm . An alternative development of the same idea is realized in the so-called symmetric DLSPP waveguides, where the dielectric core is mirrored across the thin metallic film with an identical or similar ridge.^{177,178} Symmetrization of the field profiles was achieved by varying the thickness of the bottom dielectric ridge h_{down} (Figure 21d).¹⁷⁸ At the price of acceptable increase of the modal size, the propagation length can be increased up to 321 μm . More importantly, the strong guiding performance of the DLSPPW is preserved: the quality factors of the ring resonators made from the waveguide of such geometry are actually improved. They are even higher than those of micro-ring dielectric resonators, with plasmonic waveguides having an additional advantage of possibility of efficient active control of the mode utilizing the metallic layer for active functions.

8.2. Semiconductor-loaded waveguides

As discussed above, one of crucial advantage of the plasmonic approach is its seamless integration into electronic microchips to realize hybrid electronic/photonic circuits where electronic and photonic signals can be transferred along the same lines. Furthermore, with the possibility of their interaction through electro-optic or thermo-optic effects, active control nodes can be introduced, making the circuitry fully-functional. In order to achieve such integration in the case of DLSPP waveguides, their material platform should be compatible with the CMOS fabrication processes used in microelectronics. Silicon in this case becomes one of the main candidates for the dielectric core material. An additional advantage of using high refractive index material is the possibility of higher confinement of the plasmonic mode, providing also an increase of the mode effective index. This makes the DLSPPW components more compact, allowing higher integration density. Comprehensive numerical analysis of Si-based DLSPP waveguides can be realized in conjunction with the CMOS-compatible aluminum or copper metallic platform.⁹⁹ As expected, with the DLSPPW design scaled down in 2-3 times, a substantial decrease of the mode area (~5-10 times) was observed accompanied

by a proportional decrease of the propagation length (below 10 μm). The performance of Si-based waveguides depends on their width-height relation. The dependence of the ‘local’ figure of merit (Equation 12) on the geometrical parameters of the Si/Al waveguide is presented in Figure 21e, implying the cross-section 300 nm \times 300 nm to be close to the optimal. Additionally, the performance of CMOS-compatible Al- and Cu-based Si-DLSPP waveguides was compared with that of the conventional Si-DLSPPW design utilizing gold. Aluminum showed the plasmonic guiding properties as good as those of gold, while for copper the propagation lengths were found to be \sim 2 times shorter. As was demonstrated later, the plasmonic properties of copper deposited in a standard CMOS fabrication process may match those of the noble metals, thus improving the FOM.^{179,180} DLSPP waveguides based on CdS nanostripe deposited on an Ag film were also demonstrated in visible frequencies.¹⁸¹

8.3. Hybrid DLSPP waveguides

An interesting approach for SPP mode confinement in DLSPPW-type waveguide relies on a stripe made of high refractive index material placed at nanometer distance above a metal surface using a low refractive index spacer (Figure 21f).¹⁸² Plasmonic oscillations at the metallic interface of the resulting gap produce the polarization charges at the stripe interface of the gap, efficiently screening the electromagnetic field penetration into the stripe. This results in a highly-localized plasmonic mode. In some sense, the nature of the mode here is similar to the one in metal-dielectric-metal plasmonic waveguides. In alternative consideration, the enhancement of the field can be regarded as a result of continuity condition for the electric displacement, resulting in stronger fields in the low refractive index gap. The term ‘hybrid’ comes from the fact that the origin of the mode can be traced to the coupling of a 2D plasmonic wave at the metal interface with a photonic mode in the high refractive index core.¹⁸²

This approach was first developed for silicon dielectric core separated from a silver surface by a 50 nm silica providing strong confinement of the mode in the silica gap (Figure 21g).^{160,183,184} Such waveguides show smaller cross-talk in comparison with the plasmonic DLSPW design, allowing a 1.5 μm center-to-center integration level without noticeable signal transfer. The theoretical propagation length of the mode was found to be 64 μm for silver¹⁸⁵ while for gold¹⁸⁶ it is reduced to approximately 15 μm . Component integration level on the other hand offer a promise to be at a 1 μm level: the mode transmission $\sim 70\%$ was demonstrated through a bend of this radius¹⁶⁰ and through a splitter of this size¹⁸³ as well as a coupler to conventional silicon waveguiding circuitry.¹⁸⁷ The wavelength-selective components such as WRRs and add-drop filters of 2 μm radius were also demonstrated¹⁸⁴, and seems feasible that their size can be further reduced. The advantage of hybrid approach is larger propagation length with approximately the same effective mode index and mode size.¹⁸⁸ An alternative design of hybrid Si-plasmonic waveguide uses a void along an axis of a Si ridge.¹⁸⁹

Combining the hybrid-DLSPW approach with the idea of increasing the mode propagation length using symmetric distribution of the SPP mode in thin metal film geometry (discussed in the previous section), symmetric hybrid-DLSPP waveguides were proposed (Figure 21h).^{190,191} With the optimal geometrical parameters of such waveguides, the propagation length can be increased to almost 1 mm level at a cost of a cross-talk defined integration level of 3-3.5 μm . On the other hand, using metal instead of high-index dielectric material (which implements MIM-type guiding principle in the so called metal-loaded SPP waveguides) allows extremely high mode confinement levels and strong guiding properties (integration level of 65 nm, electronic circuit scales waveguide bending with a vanishing bending radius), as usual, at the price of the increased attenuation $L_{prop} \sim 0.5 \mu\text{m}$ (see Table 2).⁶⁵ The implementation of active, e.g., III-V, semiconductor materials for the waveguide core has a crucial advantage for the realization of the amplification of the guided mode in this

geometry.^{50,48} Finally, it should be noted that recently graphene-based DLSPW waveguides have been proposed, promising electrically-controlled active functionalities and enhanced nonlinear properties in mid- to far-infrared regions.^{192,193}

8.4. Other applications of DLSPWs

We will finally briefly overview other functionalities and applications offered by the DLSPW approach. The portfolio of DLSPW passive, wavelength-selective and active components was further extended with experimental demonstration of an integrated power monitor. Propagating along a straight waveguide section, the DLSPW mode inevitably experiences absorption, which leads to a temperature change in the metallic film supporting the waveguide. This results in a change of the film resistance, which can be monitored by a carefully balanced electrical scheme (Wheatstone bridge).¹⁹⁴ The waveguide section of 46 μm length provides approximately 1.8 $\mu\text{V}/\mu\text{W}$ sensitivity having only a weak dependence on the signal wavelength with a bandwidth up to 550 Hz in modulation frequencies. The SPP signal power as low as fractions of microwatts can be detected.

As discussed above, the transmission through the DLSPW ring resonator is highly sensitive to the phase delay acquired by the mode during a cycle around the ring, which in its turn is defined by the refractive index of the ring material. In case of polymers, the refractive index is temperature-dependent and can be changed through a resistive heating of the underlying metallic film. This was used to realize DLSPW thermo-optic components. Looking from another prospective, this means that the WRR transmission is sensitive to the ambient temperature, leading to the idea of a WRR-based temperature sensor.^{195,196} The temperature variations of about ~ 1 $^{\circ}\text{C}$ were monitored with the estimation of a minimal detectable level of 10^{-2} $^{\circ}\text{C}$. The component size of ~ 10 μm makes it specifically suitable for local temperature detection, furthermore by design being easily integrated into an on-chip architecture.

The idea of adiabatic filed compression was used to develop a triangular DLSPPW profiles for nanofocusing of the supported SPP modes; the focusing down to 100 nm size was demonstrated.¹⁹⁷ Similarly, nanofocusing to truly nanoscale dimensions was reported by incorporation into the dielectric core of DLSPPW a triangular metallic ridge waveguide with adiabatically increasing height (Figure 21k).¹⁹⁸ Through adiabatic transformation of the DLSPPW mode, a dramatic concentration of the SPP field at the ridge tip can be achieved in the approximately 11 nm×5 nm area. This focused mode can be impedance matched to a neighboring material to provide effective light absorption in 30 nm×30 nm area in the near field of the waveguide tip. Such local effects are highly demanded for development high-density data storage, and in particular for heat-assisted magnetic recording.¹⁹⁹ Alternative applications of this phenomenon include sensing, scanning near-field microscopy and the realization of nanoscale light sources.

It is hardly possible to give an exhaustive list of DLSPPW applications. Concluding this section, we will just highlight the DLSPPW-related approaches in refractive index sensing for bio-^{200,201} and chemical sensing^{202,203}, for studies of quantum properties of plasmons^{204,205,206} and their Anderson localization.²⁰⁷

9. Conclusions

Plasmonics offers a unique opportunity to introduce light into the nanoworld. Breaking the diffraction limit of light, the plasmonic approach makes a qualitative step into a new spatial domain, where optics can now play an important and promising role. From the practical point of view, plasmonics offers a vast family of applications in the various fields from biology and sensing to metamaterials and quantum technologies. We focused here only on applications of plasmonics in the highly-integrated fully-functional optical circuits which can match the integration level of their electronic counterparts and are easily integratable into them to produce new generation of hybrid electronic/photonic devices. We overviewed the recent advances in developing active and passive components for such circuits on the basis of dielectric-loaded plasmonic waveguides. DLSPPW approach provides subwavelength confinement of the plasmonic mode along with the micrometer level of photonic integration, allowing experimentally proven WDM data transmission rates of up to 0.5 Tb/s, while the theoretically limited by ~10 Tb/s in a single data stream. A complete toolbox of passive and wavelength-selective components including bends, splitters, Bragg reflectors, ring resonators, etc. has been demonstrated. Furthermore, all-optical, electro-optical and thermo-optical components have been developed for active functionalities. DLSPPW approach provides vast opportunities for the development of other improved/purpose-fit plasmonic waveguide designs as well as has a potential for a number of alternative applications. Such waveguides can be incorporated in other photonic networks based, e.g., on Si photonics to provide low-energy, high-speed active components, which can be realized engineering strong light-matter interaction in plasmonic devices.
