29

30 **Abstract**

31 This study investigated the influence of experienced reward distributions on the shape of utility
32 functions inferred from economic choice. Utility is the hypothetical variable that appears to be max-
33 imized by the choice. Despite the generally accepted notion that utility functions are not insensitive
34 to external references, the exact occurrence of such changes remains largely unknown. Here we
35 benefitted from the capacity to perform thorough and extensive experimental tests of one of our
36 evolutionary closest, experimentally viable and intuitively understandable species, the rhesus ma-
37 caque monkey. Data from thousands of binary choices demonstrated that the animals' preferences
38 changed dependent on the statistics of recently experienced rewards and adapted to future expected
39 rewards. The elicited utility functions shifted and extended their shape with several months of
40 changes in the mean and range of reward distributions. However, the adaptations were usually not
41 complete, suggesting that past experiences remained present when anticipating future rewards.
42 Through modelling, we found that reinforcement learning provided a strong basis for explaining
43 these adaptations. Thus, rather than having stable and fixed preferences assumed by normative eco-
44 nomic models, rhesus macaques flexibly shaped their preferences to optimize decision-making ac-
45 cording to the statistics of the environment.

46

47

48 **Introduction**

49 Every day we make choices between outcomes that vary widely, sometimes on the order of magni-
50 tudes. In a single morning, we can go from choosing between outfits, to choosing to visit our fa-
51 vourite cafe, to comparing the costs of a train or plane journey for our next holiday destination. Yet,
52 despite the complexity of representing all of these situations, we manage - with a relatively limited
53 brain - to mentalise and indeed optimise the majority of our choices.

54 Prospect Theory (PT), the dominant model in behavioural economics, posits that we optimize our
55 decisions by calculating the value of our choices relative to a reference-point (Kahneman &
56 Tversky, 1979; Tversky & Kahneman, 1986). That is, rather than objectively evaluating the out-
57 come of our choices, we perceive our options as gains or losses depending on what we are expect-
58 ing: if an outcome is better than our reference, we treat it as a gain; if it is worse, we treat it as a
59 loss. Mathematically, PT represents this behaviour with an S-shaped value (or utility) function
60 where the subjective value of gains and losses is given by concave and convex parts of the function,
61 respectively. This has important behavioural consequences, particularly for risky-decision-making,
62 as this normative (utility) framework predicts that people's tendency to make risk averse decisions
63 depends on their perception of outcomes as being gains or losses.

64 While the idea of reference-dependence has been readily adopted by modern decision theory
65 (Rabin, 2000; Wakker, 2010), economists are still unclear about how reference points form
66 (Barberis, 2012). In prospect theory (PT), Kahneman and Tversky abstractly define reference-points
67 as exogenous from the decisions being made. That is, the reference point is not directly explained
68 by PT and can be shaped by "*aspirations, expectations, norms, and social comparisons*" (A.
69 Tversky & Kahneman, 1991, p.157). Alternatively, recent economic models consider reference
70 points an epiphenomenon of the way in which our mind adapts to the statistics of the task at hand
71 (Delquié & Cillo, 2006; Köszegi & Rabin, 2006; Sugden, 2003) - a framework more in line with the
72 findings that, far from being restricted to human reasoning, reference-dependence is a homogeneous
73 feature of primate decision-making (Santos & Rosati, 2015) and the brain (Carandini & Heeger,
74 2012; Louie et al., 2013; Padoa-Schioppa, 2009; Tremblay & Schultz, 1999). Along these lines, one
75 particularly interesting proposal from the epiphenomenon framework is that of range-dependent
76 utility, or RDU (a play on reference-dependent utility; see Kontek & Lewandowski, 2018). Inspired
77 by psychology's *range-frequency theory* (Parducci, 1965, 2012) and neurobiology's *efficient-cod-*
78 *ing hypothesis* (Laughlin, 1981; Summerfield & Tsetsos, 2015), RDU suggests that decision-makers
79 evaluate the value of their options relative to not one, but two reference points: the minimum and
80 maximum rewards available in any given scenario. In this view, what PT identifies as a reference-
81 point could be nothing more than the product of a utility function that adapts to the distribution of
82 possible rewards: the point at a sigmoidal curve inflects from convex to concave (mimicking a neu-
83 ron's tuning curve; Carandini & Heeger, 2012; Webster, Werner, & Field, 2005).

84 Because studies on reference-dependence generally focus on identifying a unique reference-point
85 (Baillon et al., 2015), or on describing behaviours under specific reference predictions (Allen et al.,
86 2016; Crawford & Meng, 2011; Wenner, 2015), there is, as of yet, no way of corroborating or con-
87 tradicting the previous hypotheses on the emergence of reference-points. The few studies that con-
88 sider shifts in preferences generally do so in a single distribution, local context: they document ref-
89 erence-point changes following the wins or losses of risky gambles (Arkes et al., 2008, 2010; Shi et
90 al., 2015); never the impact that changes in expectation have on decision-making. Concurrently, lit-
91 tle is known about the impact of a task's structure on preferences, nor how different reward statis-
92 tics might translate to reference-points.

93 Animal experiments allow far higher trial numbers and longer experimental timescales than human
94 studies do, they allow us to explore the formation of reference-points both in utmost detail and in
95 subjects where exogenous factors have minimal impact (i.e. no contribution of language or higher

96 numerical ability). To that effect, we investigated how the reward distribution experienced in a bi-
97 nary choice task - defined on different reward magnitudes and spreads - shaped the preferences of
98 rhesus macaques (a species that displays many, if not most, of the fundamental choice patterns hu-
99 mans display; Heilbronner & Hayden, 2013, 2016; Stauffer et al., 2015). we presented macaques
100 with several sets of risky choice options in which the distribution of reward magnitudes remained
101 stable for weeks at a time, then suddenly shifted to a new distribution (higher/lower magnitudes or
102 wider/narrower spread). On each testing day, we fit the animals' choices with S-shaped utility func-
103 tions that could explain both risk seeking and risk averse choices (Genest et al., 2016; Stauffer et
104 al., 2014). We then looked at how the animal's risk preferences changed as a function of the reward
105 distribution they experienced. We found that, while utilities stayed relatively put for periods during
106 which a single reward distribution was experienced, the animals consistently shifted their prefer-
107 ences when a novel reward distribution was introduced. In fact, the shape of estimated utility func-
108 tions mirrored the lowest and highest rewards that monkeys had experienced over the course of the
109 preceding weeks – even if these now fell outside of possible. From these findings, we suggest that
110 far from being fixed and abstract, preferences follow the expectation of what animals think might
111 happen given the knowledge they have accumulated over time.

112 **Methods**

113 **Animals**

114 This research has been ethically reviewed, approved, regulated and supervised by the following UK
115 and University of Cambridge (UCam) institutions and individuals UK Home Office, implementing
116 the Animals (Scientific Procedures) Act 1986, Amendment Regulations 2012, and represented by
117 the local UK Home Office Inspector, the UK Animals in Science Committee, the UK National Cen-
118 tre for Replacement, Refinement and Reduction of Animal Experiments (NC3Rs), the UCam Ani-
119 mal Welfare and Ethical Review Body (AWERB), the UCam Biomedical Service (UBS) Certificate
120 Holder, the UCam Welfare Officer, the UCam Governance and Strategy Committee, the UCam
121 Named Veterinary Surgeon (NVS), and the UCam Named Animal Care and Welfare Officer
122 (NACWO).

123 Three male rhesus macaques (*Macaca mulatta*) weighing 11.2, 15.3, and 13.2 kg (Monkeys A, B
124 and C, respectively) participated in this experiment. All animals used in the study were born in cap-
125 tivity, at the Medical Research Council's Centre for Macaques (CFM) in the UK. The animals were
126 pair-housed for most of the experiment; monkeys B and C shared an enclosure. The animals ranged
127 in age from 5 to 8 years old, and all subjects had previous experience with the visual stimuli and ex-
128 perimental setup (Ferrari-Toniolo et al., 2019).

129 **Behavioural task and training**

130 Rhesus monkeys are the most commonplace species of non-human primate found in scientific re-
131 search (Capitanio & Emborg, 2008). There is therefore a rich literature reproducing human eco-
132 nomic choices in rhesus macaques. Most relevant here is that rhesus macaque behaviour can be suc-
133 cessfully predicted using PT (Farashahi et al., 2018; Ferrari-Toniolo et al., 2019; Genest et al.,
134 2016; Stauffer et al., 2015). In addition, macaque experiments allow us to control the pre- and post-
135 experimental environments in ways not possible for human studies – we can ensure that experi-
136 mental variables are independent of rewards and choices made outside of the experiment (Chen et
137 al., 2006). For this study, the delivery and distribution of rewards experienced were unique to the
138 experimental setup. The animals experienced nothing comparable outside of the laboratory.

139 Each animal used a left-right joystick (Biotronix Workshop, University of Cambridge) to make
140 choices between reward-predicting stimuli presented on a computer screen. After each choice, the
141 animals received their chosen reward in the form of a specific blackcurrant juice quantity delivered
142 probabilistically (matching the probabilities indicated by each stimulus).

143 The animals were presented with a simple visual stimulus consisting of one or two horizontal lines
144 positioned inside a frame of two vertical lines depicting reward options that varied both in magni-
145 tude (i. e. liquid quantities, ml) and in the probability of a reward being delivered. Reward magni-
146 tudes were represented by the vertical position of the horizontal lines on the screen, whereas reward
147 probability was represented by the length of the horizontal lines inside the framing lines (Fig. 1a).
148 Safe (riskless) options were represented by singular full-width horizontal lines that touched both
149 sides of the frames, whereas gambles with multiple risky rewards were signalled by multiple hori-
150 zontal lines within the vertical frame.

151 The animals were trained to associate these two-dimensional visual stimuli with blackcurrant juice
152 rewards over the course of >10,000 single-outcome, imperative trials. In these trials, a single reward
153 option was presented on either the left or right side of the screen. To obtain the cued reward, the an-
154 imals were required to select the side on which the reward was presented. After imperative training,
155 where only one option was presented, all experimental data were gathered within a binary choice
156 paradigm in which the animals chose one of two reward options presented simultaneously. One op-
157 tion was always a gamble; the other was always a safe, guaranteed reward. Every choice trial began
158 with a white cross at the centre of a black screen, followed by the appearance of a joystick cursor.
159 To initiate a trial the animal had to move the joystick cursor to the center cross and hold it there for

160 0.5-1s. After a successful central hold, two reward options appeared to the left and right of the cen-
161 tral cross (Fig. 1a). The animal had 3s to convey its decision by moving the joystick to the side of
162 its choice and holding it there for 0.1s to 0.2s, after which time the unselected option would disap-
163 pear. The selected option remained on the screen for 1s after reward delivery to strengthen any
164 stimulus-reward associations with visual feedback. A variable intertrial period of 1–2 s (blank
165 screen) preceded the next trial. Errors were defined as trials with an unsuccessful central hold, trials
166 in which the animal failed to hold the selected side, or trials in which the animal made no choices,
167 and resulted in a timeout of 6 seconds, after which time the trial was repeated.

168 Reward options were presented in pseudorandom alternation on the left and right sides of the com-
169 puter screen to control for any side preference. Event times were sampled at 2 khz and stored at 1
170 khz on a Windows 7 computer running custom MATLAB software (The mathworks, 2015a; Psych-
171 toolbox version 3.0.11), and all further analyses were done using custom Python code (Python
172 3.7.3, Scipy 1.2.1, Oliphant, 2007). Over the course of 63, 43 and 57 sessions an average of $259 \pm$
173 154 (mean \pm STD) trials, 317 ± 118 trials, and 131 ± 75 trials were collected for Monkeys A, B and
174 C, respectively. Crucially, animals received the reward they selected after each trial. This ensured
175 that they experienced the rewards they selected with minimal and constant delay, and contrasts with
176 human studies where only a randomly selected subset of trials are rewarded at the end of experi-
177 mental sessions. Delivering rewards after every trial also allowed us to capture preferences that
178 were contingent on experiences unique to the task - similar delivery method and reward distribu-
179 tions were not experienced in the housing environment.

180 **Measuring preferences for specific reward distributions**

181 To examine the degree at which preferences are shaped by available rewards, binary choice data
182 were collected from choices between reward options affixed to different reward distributions (Fig.
183 1b). Three reward distributions were defined in terms of their mean reward magnitude and the
184 spread of possible options i) low-narrow distribution, where tested magnitudes were generally set
185 between 0 ml and 0.5 ml; ii) high-narrow distribution, with magnitudes between 0.5 ml and 1.0 ml;
186 and iii) full distribution, with magnitudes between 0 ml and 1.0 ml (0.1 to 1.3 ml for Monkey C).
187 Importantly, every reward outcome (no matter which distribution) was repeated the same number of
188 times for each session – thus, every reward was equiprobable (flat distribution). We set distribu-
189 tions and kept them fixed for multiple weeks, measuring the effects of reward distribution over
190 weeks rather than blocks in a single session (Fig. 1c). Monkey A experienced a low distribution for
191 22 days (0 ml to 0.5 ml), a full distribution of rewards for 31 days (0 ml to 1.0 ml), and a high dis-
192 tribution of rewards for 17 days (0.5 ml to 1.0 ml). Monkey B experienced the low distribution for
193 33 days, then 19 days of high distribution, followed by 18 days of full distribution. Monkey C, quite
194 uniquely, offered a dataset with a longer timescale. He experienced the full distribution of 0.1 ml to
195 1.3 ml of reward for 14 days then switched to a low distribution of 0 ml to 0.5 ml for 54 weeks. Af-
196 ter this, his preferences were measured over 43 days.

197 Utility functions were estimated for each probability distribution by presenting individual animals
198 with a series of choices between a safe reward (probability of reward, p (reward) = 1.0) and a bi-
199 nary, equiprobable gamble (each reward $p = 0.5$) from which Von Neumann–Morgenstern type util-
200 ities were estimated. Probability distortions are symmetric and usually minor at $p = 0.5$ (Stauffer et
201 al. 2015; Ferrari-Toniolo et al. 2019); therefore, to obtain utility functions with least fitting errors,
202 we neglected probability distortions and thus assessed $EU = p \cdot u(\text{ml})$. To estimate utility functions,
203 we used the fractile-bisection procedure (Machina, 1987), which involves successively dividing the
204 distribution of possible utilities into progressively smaller halves (or fractals) and estimating at each
205 step the magnitude of safe reward at which choices were indifferent against the specific gamble be-
206 ing tested, as done in our laboratory before (Genest et al., 2016; Stauffer et al., 2014). This magni-
207 tude is termed certainty equivalent (CE), and represents the subjective value of safe reward that is
208 equivalent to the value of the gamble.

209 The first step of the procedure involved presenting the animals with choices between this gamble
210 and varying safe rewards (in 0.05 ml increments); in these choices, the safe reward that was equiva-
211 lent to the gamble in utility terms was identified (i.e. the safe reward chosen in equal proportion to
212 the gamble; see Fig. 2a, b). To estimate this safe reward, the following logistic sigmoid curve was
213 fitted to the proportion of safe choices versus gambles for each of the gamble/safe pairing:

$$214 \quad P_{ChooseSafe} = 1 / (1 + e^{-\left(\frac{SafeReward_{ml} - x_0}{\sigma}\right)}) \quad \text{Eq. 1}$$

215 The probability of the animal choosing a safe reward over the 0.5 utility gamble ($P_{ChooseSafe}$) was
216 contingent on the safe option's magnitude ($SafeReward_{ml}$) and the two free parameters, x_0 : the x-
217 axis position of the curve's inflection point, and σ : the function's temperature. Importantly, this
218 function's inflection point represented the exact safe magnitude for which the animal should be in-
219 different between the set gamble and a given safe reward. Then we assigned utility to the lowest
220 juice reward amount (0.0 utils) and highest juice amount (1.0 util) for the currently tested distribu-
221 tion (Fig. 2b). Since the animals only experienced trials set between these reward magnitudes, this
222 constrained all utility estimates between 0 utils and 1 utils. The x_0 -parameter could thus be used as a
223 direct estimate of the gamble's CE: at choice indifference, the safe reward had the same utility as
224 the equiprobable gamble ($p = 0.5$ each outcome) formed of these two magnitudes, which amounted
225 to $0.5 = [0.5 * 0 \text{ utils}] + [0.5 * 1 \text{ utils}]$. In the subsequent step, a new equiprobable gamble was set
226 between 0 ml and the first CE's ml value and the CE elicitation procedure was repeated (logistic fit-
227 ting, Fig. 2a); their CE had a utility of 0.25 utils (1/4 of maximal utility). In the next step, two new
228 equiprobable gambles were set between the first CE's ml value and the maximum magnitude of the
229 currently tested reward distribution, i. e. 0.5 ml; their CE had a utility of 0.75 utils (3/4 of maximal
230 utility). Crucially, gamble/safe pairings for both gambles were interwoven in the same sequence –
231 to ensure a similar spread in the presented rewards. Only sequences that contained a minimum of
232 three different choice pairs (repeated at least 4 times) were used in the elicitation of CEs, and only
233 the fractile sequences where at least 3 utility values could reliably be estimated were used in further
234 analyses. The CEs assigned to each utility level, in each reward distribution, were compared via
235 two-way ANOVA.

237 **Parametric estimation of utilities from aggregate and single choices**

238 Parametric utility curves were fit onto the CE-Utility data to capture and predict an animal's choice
239 preferences over the entire distribution of rewards. These utility curves served as a direct signal of
240 the animals' risk attitude over the tested reward distribution: if the fitted utilities were convex (i. e.
241 increasingly curving upwards) the animals had demonstrated risk seeking behaviour; if the curves
242 were instead concave (i. e. gradually flattening), the animals had demonstrated risk aversion. Sev-
243 eral parametric utility models were compared to ensure the most reliable utility predictions; the
244 best-fitting functions would then be used for all further analyses. In accordance with the assump-
245 tions of the fractile method, each of these functions had to be anchored at 0% to 100% on the y-axis
246 — and we normalized the CEs on which they were fit to be between 0 and 1. Finally, because CEs,
247 not utilities, were the measured data (i. e. the error was relative to the x-axis), orthogonal distance
248 regression was used to fit each and every function (Boggs & Rogers, 2012). We fit two 1-parameter
249 functions ($U_{1-Power}$, $U_{1-Tversky}$),

$$250 \quad U_{1-power}(m) = m^\alpha \quad \text{Eq. 2}$$

251 with m for juice magnitude (in ml) of a given reward outcome and α as power parameter of the
252 function (if $\alpha < 1$ utility function is convex, if $\alpha > 1$ utility function is concave).

$$254 \quad U_{1-Tversky}(m) = \frac{m^\alpha}{(m^\alpha + (1-m)^\alpha)^{1/\alpha}} \quad \text{Eq. 3}$$

255 with α as temperature parameter of the function (if $\alpha > 1$ utility function is S-shaped, if $\alpha < 1$ utility
256 function is inverse S-shaped).

257

258 Two 2-parameter functions ($U_{2-Prelec}$, U_{2-SCDF}),

$$259 \quad U_{2-Prelec}(m) = e^{-\beta \times (-\ln(m))^\alpha} \quad \text{Eq. 4}$$

260 with α -parameter as temperature parameter of the function (generally, if $\alpha > 1$ utility function is S-
 261 shaped, if $\alpha < 1$ utility function is inverse S-shaped), and the β -parameter controls the height (or lo-
 262 cation) of the function's inflection relative a 45° line across the x- and y-axes of the function.

263

$$264 \quad U_{2-SCDF}(m) = \begin{cases} \beta \times \left(\frac{m}{\kappa}\right)^{1/\alpha}, & \text{for } 0 \leq m \leq \beta \\ 1 - (1 - \beta) \times \left(\frac{1-m}{1-\beta}\right)^{1/\alpha}, & \text{for } \beta < m \leq 1 \end{cases} \quad \text{Eq. 5}$$

265 with α as the power of the function's curvature (if $\alpha > 1$ utility function is S-shaped, if $\alpha < 1$ utility
 266 function is inverse S-shaped), and the β -parameter controls the x-axis position at which the func-
 267 tion's curvature inverts.

268

269 And one 3-parameter function ($U_{3-Power}$)

$$270 \quad U_{3-power}(m) = \begin{cases} (m - \gamma)^\alpha, & \text{for } m \geq \gamma \\ -\beta \times (\gamma - m)^\alpha, & \text{for } m < \gamma \end{cases} \quad \text{Eq. 6}$$

271 with α as the power of the function (generally, if $\alpha > 1$ utility function is S-shaped, if $\alpha < 1$ utility
 272 function is inverse S-shaped), the β -parameter accounts for any loss aversion.

273 Sets of daily Bayesian Information Criteria (BIC) were then calculated from the orthogonal resid-
 274 uals of each fitted model ($BIC_{RSS} = n \times \ln\left(\frac{\text{residuals}}{n}\right) + (k \times \ln(n))$). We selected the best fit-
 275 ting function using a one-way Friedman test followed by pairwise Wilcoxon signed-rank tests (Bon-
 276 ferroni-Holm corrected) and compared the estimated parameters specific to each reward distribution
 277 using a one-way MANOVA.

278 Since the fractile method relied on stepwise, chained measurements (where later metrics depend on
 279 earlier ones), utility functions were also estimated using a discrete choice model (DCM) fitted to
 280 single trials for comparison. By fitting a model on individual choices rather than aggregate CE se-
 281 quences, we avoided the propagation of estimation errors from earlier steps onto the next and there-
 282 fore reduced estimation biases for individual utility functions (Abdellaoui, 2000).

283 As is commonly done (McFadden, 2001; Stott, 2006), the likelihood that animals would choose the
 284 left option over the right one, given a set noise level and side bias, was modelled using a logit func-
 285 tion:

$$286 \quad P_{ChooseLeft} = \frac{1}{(1 + e^{-\lambda(EU_{Left} - EU_{Right} - \theta)})} \quad \text{Eq. 7}$$

287 The probability of choosing the left option was, therefore, in the DCM, a function of the expected
 288 utility difference between the left and right options, the temperature (or noise) parameter, λ , and θ
 289 which captured side bias parametrically. The expected utility of each option (eu_{left} , eu_{right}), as a
 290 function of their probability (p) and the utility function $U(m)$, was given by the functional form:

$$291 \quad EU(p,m) = p \times U(m) \quad \text{Eq. 8}$$

292 The model's best-fitting parameters were estimated by minimizing the following cumulative log-
 293 likelihood function:

$$294 \quad -LL(\theta | y) = -\left(\sum_{i=1}^n y_i \times \log(P_{Choose\ Gamble}) + \sum_{i=1}^n y'_i \times \log(P_{Choose\ Safe})\right) \quad \text{Eq. 9}$$

295 Where y and y' indicated a left or right choice (0 or 1), respectively, for each trial i ; n was the total
296 trial number for the session.

297 Again, the best-fitting discrete choice model was selected via BIC comparisons, this time defined
298 on the likelihoods ($BIC_{LL} = (k \times \ln(n)) - (2 \times \text{LogLikelihood})$). The parameters estimated in
299 each reward distribution were also using a one-way MANOVA.

300 **Validating utility predictions from out-of-sample certainty equivalents**

301 To validate the predictions of the utility functions, CE measures were gathered from binary choices
302 presented outside of the utility estimation sequences testing gambles not employed for the utility
303 estimation. These gambles were used to corroborate the risk attitudes predicted by the fractile- or
304 DCM-derived utilities. Two of the three animals were presented with three sets of four gambles
305 unique to each reward distribution for which we estimated CEs. We used these 12 CEs to validate
306 the risk-attitude predictions of the utility function estimated in each distribution. The gambles in the
307 narrow reward distributions had a spread of 0.15 ml, while gambles in the full distribution had a
308 spread of 0.30 ml – keeping the relative spreads equivalent across the distributions. Gamble means
309 were also, once normalized, centred around the same relative values. In percentage points, each
310 gamble spread over 30% of the reward distributions, and gamble was centred at a value representing
311 25%, 45%, 65%, or 85% of the reward distribution (Fig. 2c).

312 Taking the difference between the CEs of these gambles and their expected value (EV) as a proxy
313 for risk attitude ($CE - EV$), the risk-attitude estimated from these CEs were compared with the pre-
314 dictions from the fractile-estimated and discrete-choice utility curves. If the $CE - EV$ metric were
315 positive, it signalled that the animals were risk seeking. If instead the measures were negative, the
316 animals could be seen as being risk averse. Because of this, if the utility models imposed an S-shape
317 that was unrealistic (and a consequence of the function used) the $CE - EV$ fits would expose it right
318 away: they would not go from risk seeking to risk averse. These measures were repositioned rela-
319 tive to the inflection point at which fractile- and DCM-derived utilities predicted reversal of risk-
320 attitudes (i. e. the point of risk neutrality. Linear regressions were fit to the repositioned $CE - EV$
321 metrics in order to identify which of the two inflections proved most reliable in predicting out-of-
322 sample behaviour (fractile or DCM-derived):

$$323 \quad CE - EV = \beta_0 + \beta_1(EV - \text{inflection}) \quad \text{Eq. 10}$$

324 In the model, β_0 Indicated the point at which CE measures became risk-neutral, and β_1 Paralleled
325 the ‘depth’ of utility’s curvature. The R^2 -value associated with both regressions was compared to
326 see which of the two utility estimation procedures most reliably matched out-of-sample behaviour.
327 Put simply, these regressions allowed both the validation of predicted risk-attitudes, and the selec-
328 tion of the better-fitting procedure.

329 **Defining preference adaptation metrics**

330 Comparing the utilities estimated from choices in different reward distributions was done in one of
331 two ways: the first, assuming that preferences were fixed and did not adapt to the distribution of
332 possible rewards in a task; the second, assuming that preferences fully adapted to the reward spread
333 and magnitude of the task at hand. To test for the former, utilities estimated in narrow distributions
334 (i. e. low- and high-distribution) were compared to the full-distribution ones. For the assumption of
335 full adaptation, utilities were compared sequentially - looking for differences in the shape of the
336 utilities between different distributions.

337 The parametric utility functions had a unique inflection point, defined as a single point where the
338 utility function’s curvature reversed, and where the function’s first derivative was maximal. This
339 inflection identified the precise reward magnitude for which the animals’ risk-attitude changed, and
340 served as a good indicator for where and how the animals’ preferences would change depending on
341 the variance and mean of the reward distribution. The inflection points elicited in different

342 distributions were compared using a Kruskal Wallis test with Bonferroni-Holm corrected post-hoc
343 analysis (Wilcoxon test).

344 Another metric, the curvature ratio (CR) was defined as the normalized area under the utility func-
345 tions (the function's area divided by the total area in each distribution). The CR provided a direct,
346 normalized metric of the convexity/concavity interplay of daily utility estimates – reflecting overall
347 risk attitude to a greater degree than inflection points. A linear utility function would have a CR of
348 0.5, as would perfectly symmetric S- or inverse S-shaped utilities. A CR above 0.5 indicated that
349 the functions fell above the diagonal and predicted risk averse choices; conversely, a CR under 0.5
350 reflected more risk seeking choices. The CRs measured in the different distributions were also com-
351 pared using a Kruskal Wallis test followed by pairwise Wilcoxon rank sum comparisons (Bonfer-
352 roni-Holm corrected).

353 A final series of metrics, defined as adaptation coefficients, allowed for the quantification of rela-
354 tive changes in CRs. Between utilities that had been estimated in consecutive reward distributions.
355 A sequential adaptation coefficient (SAC) was calculated as:

$$356 \quad SAC = \frac{\left(\int_{min}^{max} U_n(m) dm - \int_{min}^{max} U_{n-1}(m) dm \right)}{\int_{min}^{max} U_{n-1}(m) dm} \quad \text{Eq. 11}$$

357 And it captured changes in the median utility of a given reward distribution n ($U_n(m)$), where m
358 represented every reward between the minimum and maximum rewards in the tested distribution,
359 relative to the median utility function in distribution $n-1$ ($U_{n-1}(m)$). Since all parametric functions
360 were defined from 0 to 1, comparing the area under each curve gave us a direct measurement of the
361 difference between the utilities that captured preferences in consecutive reward distributions.

362 A second coefficient, the general adaptation coefficient (GAC), compared the utility of low- and
363 high-reward distributions to the utility estimated from a animal's full reward distribution. The GAC
364 placed the narrow-distribution utilities (i. e. the low and high distribution ones) relative to the shape
365 of the full-distribution's utility function. That is, a GAC of 0 would indicate that the narrow-distri-
366 bution utilities are but segments of a fixed full-distribution one, whereas a GAC of 1 suggested that
367 utilities kept a similar form but fully shifted to represent preferences in the new distribution. For
368 any GAC where $0 < GAC < 1$, utilities had partially adapted. To calculate this, narrow distribution
369 utilities were rescaled to map onto the full distribution ones: the maximum value of the low-distri-
370 bution became the utility value of the full-distribution utility at 0.5 ml, and the utility value of the
371 full-distribution utility at 0.5 ml became the minimum value of the high-distribution. Then, the me-
372 dian utility of the full distribution (U_{Full}) was rescaled (into U_{adapt}) to match the domain and image
373 of narrow distribution utilities ($U_{Low-distribution}$ and $U_{High-distribution}$). The GAC was given by

$$374 \quad GAC = \frac{\left(\int_{min}^{max} U_{partial}(m) dm - \int_{min}^{max} U_{full}(m) dm \right)}{\left(\int_{min}^{max} U_{adapt}(m) dm - \int_{min}^{max} U_{full}(m) dm \right)} \quad \text{Eq. 12}$$

375 Where min and max are the minimum and maximum reward magnitudes in a narrow distribution
376 condition. A GAC of 1 signalled full adaptation while a GAC of 0 indicated that no adaptation had
377 taken place. Crucially, the GAC metric took no account of the order in which reward distributions
378 were tested; it relied instead on full-distribution utility function as a comparison template.

379

380 **Results**

381 **Experimental design**

382 In order to investigate the adaptation of utility functions to different reward distributions, macaque
383 monkeys were presented with sequences of binary choices while reward distributions were kept
384 constant over consecutive days and then suddenly changed. Thus, without other task changes, the
385 animals experienced periods of relatively low reward reward magnitudes, periods of relatively high

386 magnitudes, and periods with a mix of both (Figs. 1c; 3). On each day the animals were presented
387 with either a utility estimation sequence, an equivariant gamble sequence (out-of-sample valida-
388 tion), or both.

389 In utility estimation sequences, utility measurements were derived from the choices that animals
390 made between sets of gambles and safe rewards. Using the fractile method (see *Methods*), utilities
391 were derived from the certainty equivalents (CEs) of specific sets of binary, equiprobable gambles
392 ($p = 0.5$ each outcome; the magnitude of safe reward that was subjectively equivalent to the gam-
393 ble). In validation sequences, the animals' risk preferences were measured directly using the CEs of
394 out-of-sample binary, equiprobable gambles. These measurements were then used to confirm the
395 utilities estimated in elicitation sequences.

396 For each reward distribution, sets of daily utilities were estimated using the fractile method. The
397 way reward magnitudes (CEs) mapped onto these utilities (once normalized to the minimum and
398 maximum rewards in a distribution) could then be compared within and between the different re-
399 wards distributions. To do so, and because utilities were defined from 0% to 100% regardless of
400 their distribution, the CEs were normalized relative the maximum and minimum magnitudes in the
401 appropriate reward distribution (Fig. 3). As expected, higher utility values mapped onto higher re-
402 ward magnitudes (higher CEs), but the way in which they did so differed markedly depending on
403 the current distribution. The same utility levels (12.5%, 25%, 50%, 75% and 87.5%) in different re-
404 ward distributions did not map onto the same relative magnitudes (i. e. normalized CEs). We con-
405 firmed this statistically using a two-way ANOVA with the main factors being the utility level tied
406 to individuals CEs and the reward distribution from which they had originated. The ANOVA con-
407 firmed that there was a significant main effect of utility level on the value of the estimated CEs
408 (Monkey A: $F(4,295) = 64.301$, $p = 4.812 \times 10^{-39}$; Monkey B, $F(4,192) = 50.51$, $p =$
409 4.107×10^{-39} ; Monkey C: $F(4, 295) = 609.547$, $p = 3.254 \times 10^{-141}$). The distribution in which
410 utility-specific CEs had been estimated also had a significant main effect on the value of the esti-
411 mated CEs (Monkey A: $F(2,295) = 356.415$, $p = 1.991 \times 10^{-79}$; Monkey B, $F(2,192) = 8.994$, $p =$
412 0.003×10^{-3} ; Monkey C: $F(1, 295) = 16.204$, $p = 7.235 \times 10^{-5}$). Together, these corroborated what
413 we could see graphically (Fig. 3): higher CEs correlated with higher utilities in all distributions, but
414 these CEs were all relatively lower once a shift from low- to full- or high-distribution had occurred.
415 Supporting the two other main effects, there was a significant interaction effect of utility level and
416 distribution on the estimated CEs, in two of the three animals (Monkey A: $F(8,295) = 1.156$, $p =$
417 0.326 ; Monkey B, $F(8,192) = 5.217$, $p = 1.829 \times 10^{-5}$; Monkey C: $F(4, 295) = 8.488$, $p =$
418 1.707×10^6). That is, the steepness of the utility-CE pairings changed between the different reward
419 distributions – rather than simply shifting and recalling, utilities in different distributions seemed to
420 follow different patterns.

421 **S-shaped utilities best fit choices**

422 Parametric utility functions were fitted to the daily utility measurements to better compare and un-
423 derstand the relationship between the utilities estimated in each distribution. To do so, several dif-
424 ferent functional forms of utility were first compared; the most reliable function was then used for
425 all further analyses. Power functions are commonly used to model utility functions. We therefore fit
426 a 1-parameter power ($U_{1-Power}$), 2-parameter CDF of a two-sided power (U_{2-SCDF}), and a 3-parameter
427 anchored power functions ($U_{3-Power}$) to the animal's CE-utility pairings. In addition to power-type
428 functions, we looked at functions typically reserved for probability distortion modelling (Ferrari-
429 Toniolo et al., 2019; Stott, 2006): the 1-parameter Tversky function ($U_{1-Tversky}$), and the 2-parameter
430 Prelec ($U_{2-Prelec}$) – two functions that could readily take on the s-shape prescribed by PT. All func-
431 tions mapped reward magnitudes onto utility values from 0 to 1 (i. e. 0% to 100% of normalized
432 utilities), and all but the 1-parameter power function could capture risk seeking and risk averse be-
433 haviour, as well as any inversion in the animals' risk attitudes within a reward distribution.

434 Because of the fractile method's reliance on aggregate, chained datapoints (Farquhar, 1984;
435 Machina, 1987), utility functions were also fit using a discrete choice model (DCM) applied to

436 individual, rather than aggregate, choices (Eq. 7). In line with the fractile-derived utilities, and be-
437 cause previous experiments with the same animals had identified negligible probability distortions
438 for $p = 0.5$ (Stauffer et al., 2015), choices in the model were then predicted based on the choices'
439 expected utilities (probabilities were treated as objective). The parameters that best described indi-
440 vidual choices in each model were estimated through maximizing the cumulative log likelihoods of
441 the DCMs defined on individual experimental sessions (Eq. 9; see methods).

442 To select the utility function that best described both the CEs and individual choices, we used the
443 Bayesian information criteria (BIC) from all fitted models; the model with the lowest median BIC
444 would thus represent the best fitting model. Of the five tested utility functions, the 2-parameter Pre-
445 lec proved most reliable in fitting both forms of data (Fig. 4a,b). Though the model is normally re-
446 served for probability distortion models, it presented the lowest BIC_{RSS} score as derived from the
447 residuals of fractile-derived utilities (significantly so, Friedman test; Monkey A: $F_r(4,240) =$
448 177.154 , $p = 3.046 \times 10^{-37}$; Monkey B: $F_r(4,168) = 140.780$, $p = 1.903 \times 10^{-29}$; Monkey C:
449 $F_r(4,220) = 120.800$, $p = 3.604 \times 10^{-25}$), and the lowest BIC_{LL} score as derived from the log likeli-
450 hoods of the discrete choice fits in 2 of 3 monkeys (Friedman test; Monkey A: $F_r(4,240) = 219.091$,
451 $p = 2.327 \times 10^{-45}$; Monkey B: $F_r(4,168) = 186.469$, $p = 2.221 \times 10^{-38}$; Monkey C: $F_r(4,220) =$
452 180.020 , $p = 5.298 \times 10^{-37}$). In Monkey A, the BIC_{LL} of the 2-parameter CDF of the two-sided
453 power distribution and the 2-parameter Prelec proved statistically indistinguishable. From these
454 BIC_{RSS} and BIC_{LL} measures, and because the behavioural predictions from each fitting method gen-
455 erally agreed (Fig. 4c), we selected the 2-parameter Prelec function for all further analyses.

456 **Risk preferences adapt to novel reward distributions**

457 Each fitted utility function provided a pair of parameters that could be compared to those elicited in
458 the same or different reward distributions. The curvature of these utility functions served as a direct
459 indicator of the animal's risk attitude for any given magnitude. Convexity reflected risk seeking be-
460 haviour; concavity signalled risk aversion. From these parametric functions, three predictions could
461 be made: utilities would either i) fully adapt to the novel reward distributions, ii) not adapt and re-
462 main constant (i. e. different parts of the same curve), or iii) utilities would partially adapt in a way
463 that did not solely rely on the current reward distribution. To test for these predictions, further anal-
464 yses were split into two sets of hypotheses. One set looked at utilities under the assumption that no
465 adaptation had occurred, the other assumed full utility adaptation between each of the reward distri-
466 butions. In the case of the no-adaptation assumption, the predictions from utilities on identical re-
467 ward magnitudes in the narrow distribution and full distribution were compared (Fig. 5a). For the
468 full adaptation assumption, the utilities from sequential reward distributions were normalized and
469 compared, looking at any differences with the previous distribution's pattern of risk attitude (Fig.
470 5b, c). If neither assumption proved accurate, then the assumption would be that neither full nor no
471 adaptation had taken place – that is, preferences would have partially adapted.

472 Starting with fractile-derived utilities, comparing the functional parameters elicited in the different
473 reward distributions provided us with a stringent test regarding the full adaptation assumption. In
474 the 2-parameter Prelec function, the α -parameter represented the temperature of the function, while
475 the β -parameter captured the relative height of the curve. If these were identical across conditions,
476 similar patterns of utility reflected preferences regardless of unique reward magnitudes in the differ-
477 ent reward distributions. One-way MANOVA analysis on the log-transformed parameters con-
478 firmed that this was not the case: there was a significant effect of reward distribution on the param-
479 eters elicited in each condition, for all animals (Monkey A: $F(2,59) = 34.913$, Wilks's $\lambda = 0.454$, $p =$
480 1.116×10^{-10} ; Monkey B, $F(2,41) = 13.695$, Wilks's $\lambda = 0.594$, $p = 2.946 \times 10^{-5}$; Monkey C: $F(1,$
481 $54) = 9.381$, Wilks's $\lambda = 0.739$, $p = 3.252 \times 10^{-4}$). Specifically, there was a significant difference be-
482 tween Monkey A and B's β -, or height-, parameters (Monkey A: $F(2,59) = 67.301$, $p =$
483 2.447×10^{-11} ; Monkey B, $F(2,41) = 13.695$, $p = 2.946 \times 10^{-5}$; Monkey C: $F(2,54) = 1.120$, $p =$
484 0.290), as well as a significant difference in Monkey C's α -, or temperature-, parameters (Monkey
485 A: $F(2,59) = 0.434$, $p = 0.513$; Monkey B, $F(2,41) = 2.583$, $p = 0.116$; Monkey C: $F(2,54) = 18.858$,

486 $p = 6.236 \times 10^{-5}$). The utilities, in terms of parameters, differed depending on the distribution from
487 which they were elicited (Fig. 6).

488 To explore how these parametric differences influenced utility patterns in a way that was directly
489 comparable between conditions, we compared the position of each utility function's inflection
490 points – the reward magnitude at which the behaviour predicted by the utility function flipped from
491 risk seeking to risk averse (or risk averse to risk -avskseeking depending on the temperature of the
492 utility function). The inflection crudely summarized choice predictions with a single metric – one
493 that had been previously used to signal animals' 'reference-points' (Chen et al., 2006;
494 Lakshminarayanan et al., 2011). Importantly, since this metric was tied to CE values; one could eas-
495 ily observe if inflection points fell on similar magnitudes depending on the distribution in which it
496 had been measured (Fig. 5a).

497 From these inflection points, the assumption of no adaptation was tested by comparing both within
498 and across-distribution inflections. If no adaptation had occurred, the inflections would be the same
499 within and across the different reward distributions. Testing for the former, i.e. Within distribution
500 differences in inflection points, no significant pattern of change could be identified – at least for
501 Monkeys A and B (linear regression analysis, Monkey A: $p_{\text{full-distribution}} = 0.160$, $p_{\text{high-distribution}} =$
502 0.472 ; Monkey B: $p_{\text{full-distribution}} = 0.270$, $p_{\text{high-distribution}} = 0.714$; Monkey C: $p_{\text{low-distribution}} = 0.009$).
503 And since Monkey C's low distribution had been tested over a year after changing distributions –
504 the fact that a significant positive slope was identified (the inflection slowly went up in value over
505 the days of testing) did little to indicate distribution-swap adaptation. Moving from within distribu-
506 tion to between distribution analyses, there were significant differences between the distribution-
507 specific inflections for all monkeys (Kruskal Wallis test; Monkey A: $H(2,58) = 44.281$, $p =$
508 2.424×10^{-10} ; Monkey B: $H(2,40) = 27.973$, $p = 8.429 \times 10^{-7}$; Monkey C: $H(1,54) = 28.397$, $p =$
509 9.881×10^{-8}), which translated into significant pairwise differences (Wilcoxon rank sum) for all
510 but Monkey B's high and full distribution inflection points (Fig. 6a). Simply put, the inflection
511 points fell on different reward magnitudes for each of the reward distributions. If preferences had
512 truly been non-adaptive, no significant difference across any of the conditions would have been ob-
513 served.

514 Since none of the results corroborated the no-adaptation hypothesis, the next step was to test for full
515 adaptation. Rather than comparing the absolute position of the utilities' inflection points, testing for
516 full adaptation required predicting where inflection points from a past distribution would map onto
517 the next distribution: the assumption being that if the same utility function simply shifted to a new
518 distribution (i. e. fully adapted), the relative position of the inflection should be the same. An inflec-
519 tion at 0.3 ml in the low distribution, for example, would be placed at 0.15 ml in the full distribu-
520 tion, and vice versa. However, since an inflection of 0.3 in the low distribution would result in a
521 negative magnitude when compared with the high distribution, inflections $<$ minimum reward were
522 set at the minimum, and inflections $>$ maximum reward were set to the maximum. There were sig-
523 nificant differences between all consecutive comparisons in Monkeys A and C, and none for Mon-
524 key B (Fig. 6a; Wilcoxon rank sum test). From a full adaptation perspective, this suggested that,
525 while Monkeys A and C had not fully shifted their reference to accommodate the new distributions,
526 Monkey B's preferences seemed to follow the same relative pattern across all rewards distributions.

527 From the inflection points, the picture that emerged was one of (at least) partial adaptation. That is,
528 the significant differences between the inflection points corroborated neither the idea of fully- or
529 non-adaptative preferences. Nevertheless, because inflection points carried no information about the
530 risk attitude that followed or preceded them, the inflection points could be similar even if the ani-
531 mals' choices were not. To counter this, the previous comparisons were repeated using the area un-
532 der each utility curve – a direct indicator of the convexity/concavity patterns within single utilities.
533 Rather than representing a single point, the area under each curve reflected the order and intensity
534 of risk seeking or risk averse behaviour throughout the reward distribution. Hereafter defined as
535 curvature ratios (CRs, see methods), the areas calculated in each distribution were compared

536 through Kruskal Wallis test (followed by pairwise Wilcoxon rank sum post-hoc tests). The results
537 validated the earlier findings from the inflection comparisons: sequentially, there were significant
538 differences across distributions for Monkey A and B (Monkey A: $H(2,58) = 27.973$, $p =$
539 8.428×10^{-7} ; Monkey B: $H(2,40) = 12.124$, $p = 0.002$), but there were no statistical differences be-
540 tween monkey C's CRs across conditions (Fig. 6b; $H(1,54) = 1.872$, $p = 0.171$). In essence, while
541 the risk attitudes that Monkeys A and B exhibited differed between reward distributions, Monkey C
542 seemed to exhibit relatively similar behaviour in the two distributions (albeit with a slightly differ-
543 ent inflection).

544 To validate these fractile-based comparisons, we repeated the full/no-adaptation analyses using the
545 DCM-derived utilities. Both the inflection points and the CRs of Monkey A reliably mimicked ear-
546 lier findings: significant differences between the distributions meant inflection points were some-
547 what adaptive (Fig. 7a; Kruskal Wallis, $H(2,58) = 44.504$, $p = 2.167 \times 10^{-10}$), but differences in se-
548 quential predictions also meant that inflections were not fully-adaptive (Fig. 6a; Wilcoxon rank
549 sum, $Z(45)_{\text{full-distribution}} = -5.761$, $p = 8.351 \times 10^{-9}$; $Z(40)_{\text{high-distribution}} = -4.790$, $p = 1.661 \times 10^{-6}$). Corrob-
550 orating the latter, CRs were again found to be significantly different across all distribution condi-
551 tions (Fig. 7b; $H(2,58) = 51.342$, $p = 7.100 \times 10^{-12}$). For Monkey B, the DCM-derived inflection
552 points also behaved like those estimated from fractile utilities: there were significant differences be-
553 tween all but the high and full-distributions ($H(2,40) = 31.103$, $p = 1.762 \times 10^{-7}$), suggesting that
554 inflections were not fixed, which was validated by the finding that there were no significant differ-
555 ences between all consecutive predictions ($Z(29)_{\text{high-distribution}} = 1.103$, $p = 0.270$; $Z(20)_{\text{full-distribution}} =$
556 1.941 , $p = 0.052$). In terms of curvature ratios, i.e. Test of no adaptation, there again was a differ-
557 ence between the CRs gathered in different reward distributions ($H(2,40) = 7.470$, $p = 0.024$), but
558 this time none of the post-hoc pairwise comparisons reached significance once corrected for multi-
559 ple comparisons (Wilcoxon rank sum; Fig. 6b). This meant that Monkey B's preferences were much
560 closer to being fully adaptive than not. Finally, Monkey C's results, like Monkey A, were consistent
561 across elicitation methods. Inflection points were significantly different between the two distribu-
562 tions tested ($H(1,54) = 30.524$, $p = 3.297 \times 10^{-8}$), consecutive inflection predictions were also signif-
563 icantly different ($Z(55)_{\text{low-distribution}} = 2.076$, $p = 0.03$), and CRs were not ($Z(55)_{\text{low-distribution}} = 0.0178$,
564 $p = 0.897$). Inflections differed, but risk attitudes did not.

565 Taken together, these results suggest that while no animal (except perhaps Monkey B) demonstrated
566 full adaptation, some form of partial adaptation had occurred across every distribution in every ani-
567 mal. More specifically, while not fully adapted, Monkey A and C's utilities did shift following
568 changes in the task's reward statistics. Their inflection points moved, but not to the degree predicted
569 by a full shift of the previous distribution's inflections. Where the two animals differed, however,
570 was in the fact that Monkey C had maintained a very similar CR across conditions – likely due to
571 the time elapsed between the different tests. Monkey B, on the other hand, maintained the relative
572 inflection predicted across conditions and a similar (though different in fractile-estimates) utility
573 shape.

574 **Predicting distribution-specific preferences from adapting utilities**

575 While the fractile- and DCM-fits generally agreed on the inflection of utility functions (Figs. 6a;
576 7a), variations in parameter estimates and concavity/convexity patterns (particularly in Monkey B;
577 see Table. 1) highlighted the need to select the most reliable fitting procedure if quantification of
578 adaptation was the goal.

579 To address this concern, we compared the risk attitudes predicted by the utilities of each method to
580 real risk attitudes measured in different, out-of-sample choices (i. e. validation sequences). The CEs
581 of equiprobable and equivariant gambles were recorded in each of the reward distributions, and the
582 differences between these CEs and the gambles' EVs ($CE - EV$) were used to indicate the animals'
583 risk attitudes. Every gamble had a magnitude spread equivalent to 30% of the respective reward dis-
584 tribution, and their EV were anchored at 25%, 45%, 65%, and 85% of the testing distribution's
585 magnitudes (Fig. 2c). If the difference between a gamble's CE and its EV ($CE - EV$) was positive, it

586 reflected a risk seeking attitude towards the gamble; if, on the other hand, this value was negative,
587 the animal was said to be risk averse. These ‘validation’ measurements were gathered in two of our
588 three animals (namely Monkeys A and B).

589 The CE - EV attitude predictions were compared to the risk attitude predictions from the fractile
590 and DCM utility estimates. If the S-shaped pattern of utilities elicited for each animal were accu-
591 rate, choices involving magnitudes that fell below the utility’s inflection point should have been
592 risk-prone, while choices above it should have been risk averse (also validating the S-shape utilities
593 as more than just an effect of the Prelec functional form). We found that this was indeed the case
594 and that CEs in all distributions reflected both risk seeking and risk averse behaviour depending on
595 the relative magnitudes involved (Fig. 8a). Then, to identify the best-fitting utility estimation proce-
596 dure, the CE – EV values were regressed onto the gamble’s relative distance from the median in-
597 flections in each distribution (the distance in EV terms; see Eq. 10). In both animals, positioning CE
598 – EV values relative the DCM-derived inflection resulted in a better regression fit than using the
599 fractile-derived inflections (Fig. 8b, c) – the DCM-derived utilities were therefore chosen for further
600 quantification as they represented a more accurate depiction of the animals’ behaviour.

601 **Partial adaptation to reward distribution shapes risk preferences**

602 Two final metrics served to quantify the degree to which each animal’s DCM-utilities had adapted
603 between the different reward distributions: a sequential adaptation coefficient (or SAC; Eq. 11) and
604 a general adaptation coefficient (GAC; Eq. 12). The SAC served to quantify how the utilities
605 adapted sequentially as a function of the preceding reward distribution, the GAC served to position
606 utilities elicited in distributions with low and high means relative to adaptive or absolute utilities
607 elicited from the full distribution.

608 The SAC represents the percent change in the CRs (the normalized areas under each curve) of suc-
609 cessive utilities. It can be used to quantify differences in utilities within a single distribution, or, in
610 this case, between the median utilities of different distributions. Importantly, the SAC allowed us to
611 quantify utility adaptation on a normalized scale: if utility patterns were fully adapting (i. e. fixed
612 shape regardless of the distribution), the SAC would gravitate to 0. On the other hand, the SAC
613 would become negative if utilities became more convex (since the area under the utilities would be-
614 come smaller), and more positive if utilities became more concave. The other coefficient, the GAC,
615 compared the utility of the low- and high-distributions with the full reward distribution’s utility
616 function (Fig. 2b, dashed lines). Using the full-distribution utility as the ‘default’ utility shape, the
617 GAC measured how different narrow utilities were – ranging from no or 0% adaptation (i. e. narrow
618 utilities were but segments of an absolute full-distribution utility) to 100% adaptation (the utilities
619 had a fixed form that simply adapted to new distributions). We used DCM-derived utilities to calcu-
620 late these adaptation coefficients.

621 Using the SAC to quantify how median utilities changed between distributions, we found that the
622 differences between utilities of Monkey A amounted to SACs of 0.37 and 0.35 for the full- and
623 high-distributions, respectively; 0.11 and -0.14 for Monkey B’s high- and full-distribution, and 0.04
624 for Monkey C’s low distribution. In utility terms, this meant that Monkey A’s utilities predicted be-
625 haviour that was 37% and 35% more risk averse in consecutive distributions. Monkey B also be-
626 came more risk averse when going from the low distribution to the high distribution but became
627 more risk seeking again once choosing in the full distribution. The direction of these changes
628 seemed to reflect the ‘position’ of the tested distributions relative to the past distributions the ani-
629 mals had experienced. In line with this idea, Monkey C had no recent experience with the full-dis-
630 tribution when low-distribution utilities were estimated; the measured utilities were thus almost
631 identical.

632 The GACs calculated for each animal were also very informative in positioning low- and high-dis-
633 tribution utilities relative to the full distribution ones (see dotted lines in Fig. 7). Monkey A, for ex-
634 ample, had a GAC of 0.51 for the small distribution, and a GAC of 0.21 for the high distribution.

635 The high GAC essentially meant that the low-distribution utility was halfway between being only a
636 segment of a fixed full-distribution utility and being a fully rescaled versions of the full-distribution
637 utility; the low GAC suggested that high-distribution utilities were much closer to being segments
638 of a larger, absolute utility function. For Monkey B, low-distribution utilities matched a GAC of
639 1.14, i.e. The utilities of the low distribution had an almost identical shape to those in the full-distri-
640 bution, and the high-distribution utilities had a GAC of 0.69, a bit more than halfway between no-
641 and full- adaptation. Monkey C, corroborating earlier findings, had a GAC between low and full-
642 distributions of 0.87 – they were, for all intents and purposes, identical.

643 Finally, going back to the original idea that preferences are shaped by one’s expectations, we
644 looked at the shape of each DCM-utility relative to the task’s daily reward statistics. Though even
645 the initial distribution’s utility inflections never truly followed the task’s mean reward (one-sample
646 t-test; Monkey A: $t(20)_{\text{low-distribution}} = 3.849$, $p = 0.001$; Monkey B: $t(23)_{\text{full-distribution}} = 2.534$, $p =$
647 0.019 ; Monkey C: $t(13)_{\text{high-distribution}} = 4.267$, $p = 1.103 \times 10^{-4}$), the difference between mean rewards
648 and inflections became markedly larger for Monkeys A and B when they were introduced to new
649 reward distributions (Kruskal-Wallis test; Monkey A: $H(2,58) = 40.052$, $p = 2.008 \times 10^{-9}$; Monkey
650 B: $H(2,40) = 16.806$, $p = 2.242 \times 10^{-4}$). Importantly, the differences were always skewed towards
651 past distributions. As reward distributions changed, Monkey A and B’s references appeared to lag
652 in fully adapting to the new distributions. Monkey C, on the other hand, saw no differences between
653 its two reward distributions ($H(1,54) = 0.021$, $p = 0.884$) – presumably because of the 54-week gap
654 between the two sets of measurements.

655 To better understand and quantify the lag in fully adapting to current reward, we built a simple rein-
656 forcement-learning model that predicted the reward distributions most likely to have shaped ani-
657 mals’ utilities (Sutton & Barto, 2018). Assuming the ‘normal’ form and a simple Rescorla–Wagner
658 learning rule, the model then identified the distributions closest to the one captured by animal’s
659 daily utility measures (that is, seeing utilities as the cumulative representation of the reward distri-
660 bution the animals most expected). These distributions’ means and standard deviations (STD) were
661 given by the following rule:

$$662 \text{Expected mean}_i = \text{Expected mean}_{i-1} + \eta (\text{real mean}_i - \text{Expected mean}_{i-1}) \quad \text{Eq. 13}$$

$$663 \text{Expected STD}_i = \text{Expected STD}_{i-1} + \eta (\text{real STD}_i - \text{Expected STD}_{i-1}) \quad \text{Eq. 14}$$

664 where each day’s ‘expected’ distribution relied on predictions from the previous day ($i-1$), as well as
665 the learning rate (η) at which animals learn from the difference between these predictions ($ex-$
666 $pected_{i-1}$) and reality ($real_i$) – the prediction error. Importantly, the first *expected* parameters were
667 assumed to be the statistics that the animal first observed, because of this as η would get closer to 1,
668 it would indicate that predictions adapted instantly to new distributions; if η was closer to 0, it indi-
669 cated preferences had relied only on early observations (i. e. the first distribution of rewards that the
670 animal experience). The functions were fitted by minimizing the sums of square differences be-
671 tween the cumulative distribution function of these curves and the utility of the CEs that had been
672 previously measured using the fractile method.

673 This simple reinforcement model offers insight as to the role that expectations played in shaping the
674 animals’ preferences. Monkeys A, B, and C had learning rates of 0.62, 0.81, and 0.62, respectively;
675 that is, their preferences adapted quickly to new reward distributions, but not fully. The recent past
676 also played a role, albeit marginal, in shaping the relative value of rewards. Figure 9 illustrates both
677 these ‘expected’ distributions as well as the ‘true’ distributions (as measured by the first derivative
678 of the utility functions). Notice how the expected distributions spill over reward distribution
679 changes only for the first couple of days. If preferences are built around expectations, then the utili-
680 ties that best described these preferences point to these animals using mostly present but also past
681 information to shape them.

682 Discussion

683 The present study investigated the role of task-specific expectations in shaping the preferences of
684 macaque monkeys. In line with human research on reference-dependent preferences (Arkes et al.,
685 2008, 2010; Koszegi & Rabin, 2007), the animals' risk preferences shifted following changes to the
686 reward distribution they could expect from the task at hand. As the rewards that the task delivered
687 got higher, the reward magnitude at which their risk-attitudes shifted also became higher. Modelling
688 the utility functions that best captured the animals' behaviour, we found that changes in their risk-
689 preferences mimicked the changes predicted in models like Prospect Theory (Kahneman &
690 Tversky, 1979): the points at which utility shifted from convex to concave closely followed what
691 could be considered plausible expectations in the task.

692 Taking the position of S-shaped utilities as a proxy for the animal's expectations, our findings sug-
693 gest that the monkeys partially adapted their preferences to account for new reward distribution in a
694 task. While they readily adapted to novel rewards, they did not readily ignore (or forget) reward in-
695 formation that was no longer relevant to the task. Rather than relying solely on the current instal-
696 ment of the task to build their expectation, the monkeys appeared to also consider the distribution of
697 past rewards – particularly the extremes in a distribution - in shaping their preferences (i. e. their
698 utility curve). This led to partial, not full, adaptation.

699 Monkeys A and B, for example, reliably shifted their reference point when possible rewards went
700 from lower to higher magnitudes. When looking at the utility function that best represented their
701 preferences, the animals' utilities appeared to scale instantly to represent the now broader realm of
702 possible rewards. Conversely, when possible rewards were restricted to high magnitudes only (i.e.
703 high-distribution), the animals did not adjust their preferences in a way that accounted for the un-
704 availability of lower magnitudes – even after many days. Where they had previously been flexible in
705 rescaling preferences, the animals' preferences in the high distribution (where low rewards were
706 never delivered) stubbornly reflected the higher-half of full-distribution utilities. And while the shift
707 from low to high distribution seemed to induce partial, almost full adaptation – the shift from full to
708 high distribution reflected a move along a fixed, absolute utility instead. The data from Monkey C,
709 where different reward distributions were tested 54 weeks apart, corroborated this expectation-
710 based interpretation by providing a window on the adaption of utilities after a year. While Monkeys
711 A and B experienced every distribution in the span of just a couple of months, the effects of past
712 high rewards on Monkey C would have been minimal. In that respect, it came as no surprise that
713 Monkey C's lower distribution utilities took the form of fully rescaled full-distribution ones. A sim-
714 ilar effect was seen in previous estimations with Monkey A's utilities (Genest et al., 2016).

715 The idea that preferences adapt to fit a given distribution is neither new nor unfounded (Brunswik,
716 1956; Gigerenzer et al., 1991; Glöckner et al., 2014; Weber & Johnson, 2008). Indeed, while pro-
717 spect theory rests on reference-dependence, several newer models mimic RDU in that they claim
718 that the values with which we imbue our options rely on the other options we have at our disposal
719 (Hunter & Gershman, 2018; Loomes & Sugden, 2006; Parducci, 2012; Steward et al., 2003; Yaari,
720 2006). Likewise, it has long been known in psychology and neuroscience that distribution-adapta-
721 tion is an inherent feature of the brain (Louie & De Martino, 2013). In sensory systems, for exam-
722 ple, neuron's maximize their efficiency by tuning their firing rates to match the distribution of sen-
723 sory signals (Carandini & Heeger, 2012; Laughlin, 1981) – the same is thought to occur, to varying
724 degrees, in the brain areas that encode value (Burke et al., 2016; Kobayashi et al., 2010; Louie et
725 al., 2015; Padoa-Schioppa, 2009; Tobler et al., 2005; Tremblay & Schultz, 1999). Specifically, and
726 supporting the idea of distribution-dependent utility, neurons in the primate prefrontal cortex have
727 recently been recorded adapting their firing rate to different reward distributions in a way similar to
728 our animals' utility curves. In a study by Conen and Padoa-Schioppa (2019), rhesus macaques only
729 partially rescaled the value of juice rewards relative to the other possibilities in a given block of
730 choices. When recording from neurons in monkey orbitofrontal cortex, the researchers found that
731 the neural code mimicked behavioural measurements in that it partially adapted to match the spe-
732 cific reward distributions of different blocks within the broader context of all past rewards. Cru-
733 cially, two processes seemed to drive this adaptation: the first, a slow and adaptive learning process

734 about the outcomes one can expect (e.g., reinforcement learning (Bavard et al., 2018; Rudebeck &
735 Murray, 2014; Wilson et al., 2014), which involves the orbitofrontal cortex and its interaction with
736 the dopaminergic system (for review, see Soltani & Izquierdo, 2019) and might explain the role of
737 experience in shaping current preferences. The second process involves a rapid weighing of rewards
738 relative the decision-maker's present context (e.g., the canonical process of divisive normalization,
739 whereby neurons tune their firing rates to match the distribution of available stimuli; Louie et al.,
740 2013; Hiroshi Yamada, Louie, Tymula, & Glimcher, 2018; Zimmermann et al., 2018).

741 Partial adaptation is likely to underlie the brain's ability to maximize 'local' decisions, all while
742 placing these decisions in a much broader context (i.e. relative past experiences; Conen & Padoa-
743 Schioppa, 2019; Fairhall, Lewen, Bialek, & De Ruyter van Steveninck, 2001; Rustichini, Conen,
744 Cai, & Padoa-Schioppa, 2017). When comparing similarly-priced wines, for example, we manage
745 to select our favourite from relatively narrow distributions (similar prices) while still placing our
746 selection relative to a much broader price distribution (our past experiences with wines). It has re-
747 cently been suggested that this ability to flexibly optimize 'local' decisions while keeping track of
748 past outcomes underlies the formation of cause-and-effect relationships in our thinking (Bavard et
749 al., 2018). If this is the case, then the changes observed in our animals' utility functions point to the
750 animals building complex expectations, or an internal model, about the rewards they could get in
751 the task at hand.

752 Overall, and in line with the current view from neuroeconomics, this study showed that the prefer-
753 ences of macaque monkeys' scale in a way that reflects both inherent properties (and indeed limita-
754 tions) of the brain and the statistics of the task at hand. Put most poetically by the economists Her-
755 bert Simon, our animals' decision appeared "... *shaped by scissors whose two blades are the struc-*
756 *ture of the task environments and the computational capabilities of the actor*" (Simon, 1990, p.7).
757 Perhaps it is long time we consider this in the models used to study choice.

904

905

906

907 **Figure 1. Experimental design and timescale.**

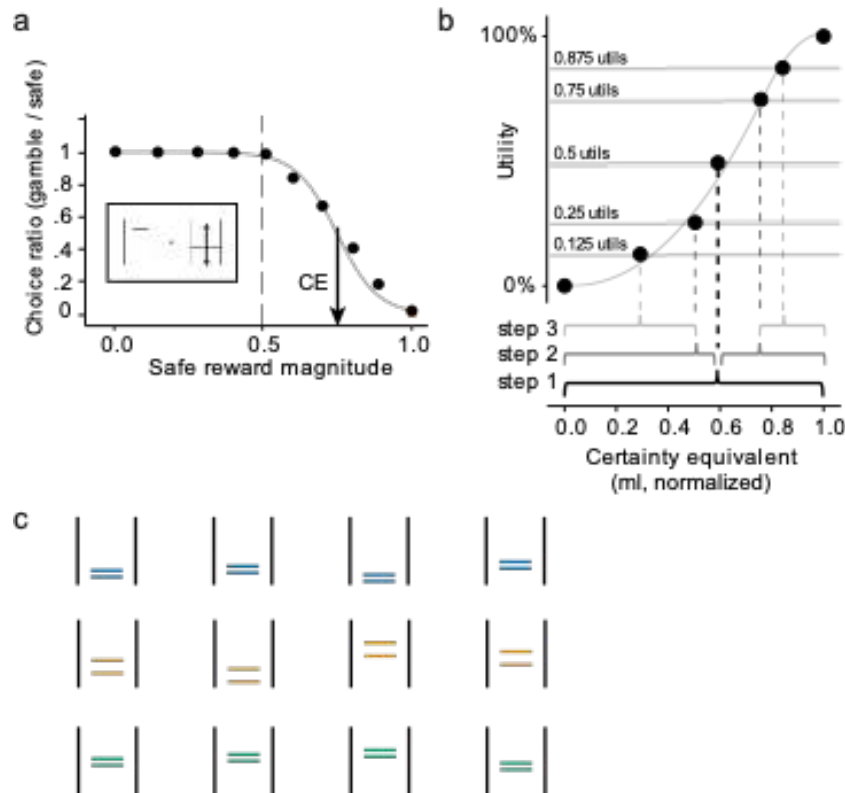

908 a) Binary choice task. The animals chose one of two gambles with a left-right motion joystick. They
909 received the blackcurrant juice reward associated with the chosen stimuli after each trial: the re-
910 ward's magnitude and probability of delivery were signalled by the vertical position and width of a
911 horizontal line as set between two vertical ones. Times, in seconds, indicate the duration of each of
912 the task's main events.

913 b) Experimental reward distributions. Choices were made in one of three experimental reward dis-
914 tributions. In the low distribution, choice options had juice magnitudes set between 0 ml and 0.5 ml
915 during preference elicitation sequences. The high distribution involved juice magnitudes set be-
916 tween 0.5 ml and 1.0 ml during preference elicitation sequences (unique to Monkey A and B). The
917 full distribution was set between 0 ml and 1.0 ml for Monkeys A and B and set between 0.1 ml and
918 1.3 ml for Monkey C.

919 c) Monkeys' experienced specific reward distributions for consecutive days. Vertical lines represent
920 the daily experimental session, in their tested order; the height of these lines signals the reward dis-
921 tribution tested (blue, low distribution; yellow, full distribution; green high distribution). Black dots
922 indicate the mean magnitude of all rewards experienced on the day, the white dots represent the
923 standard deviation on the mean.

924

925

926

927 **Figure 2. Estimating certainty equivalents and utility functions.**

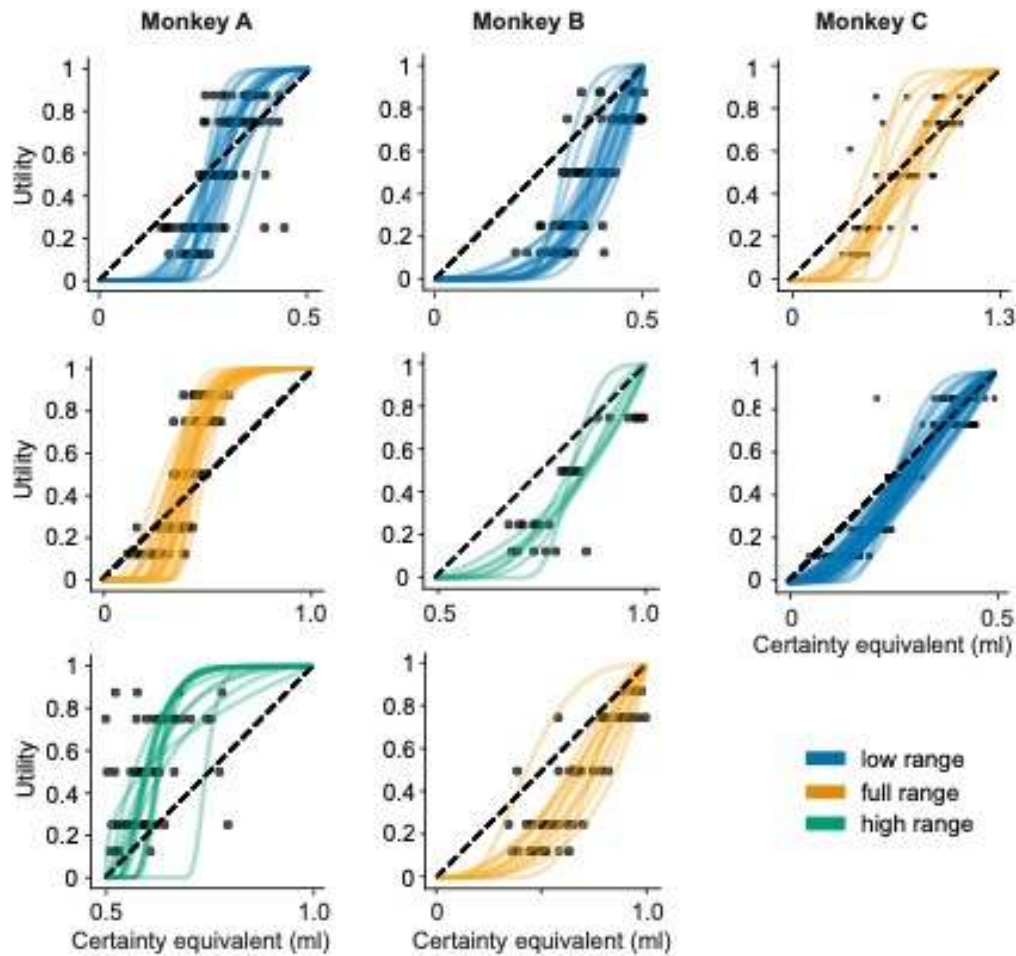

928 a) Basic choice behaviour and estimation of certainty equivalents. Animals chose between a safe
 929 reward and a gamble on each trial. The safe rewards alternated pseudorandom on every trial – never
 930 going above or below the highest and lowest magnitudes tested in the daily reward distribution.
 931 Each point is a measure of choice ratio: the animal’s probability of choosing the gamble option over
 932 various safe rewards. We fit psychometric softmax functions (Eq. 1) to these choice ratios, sepa-
 933 rately for each day, and recorded the certainty equivalent (CE) of individual gambles as the safe
 934 magnitude for which the probability of either choice would be 0.5 (black arrow). The dashed verti-
 935 cal line indicates the expected value (EV) of the gamble represented in the box.

936 b) Estimation of utility using the stepwise, fractile method. In step 1, the animals were presented
 937 with an equivariant gamble comprised of the maximum and minimum magnitudes in the tested re-
 938 ward distribution. the CE of the gamble was estimated and assigned a utility of 50%. In step 2, two
 939 new equivariant gambles were defined from the CE elicited in step 1. The CEs of these gambles
 940 were elicited and assigned a utility of 25% and 75%. Two more gambles are defined in step 3, from
 941 the CEs elicited in step 2. Their CEs were then assigned a utility of 12.5% and 87.5%. Parametric
 942 utility functions, anchored at 0 and 1, were fitted on these utility estimates (see *methods*).

943 c) Equivariant, equiprobable gambles presented in out-of-sample validation sequences. Sets of four
 944 gambles, unique to each reward distribution, were used to validate the risk attitudes predicted by the
 945 fractile-derived utilities. The CEs of these gambles were measured (see panel a) and the difference
 946 between CEs and the specific gambles’ EVs signalled the animals’ risk attitudes: if the difference
 947 was positive, the animals were risk seeking, if the difference was negative, the animals were risk
 948 averse.

949

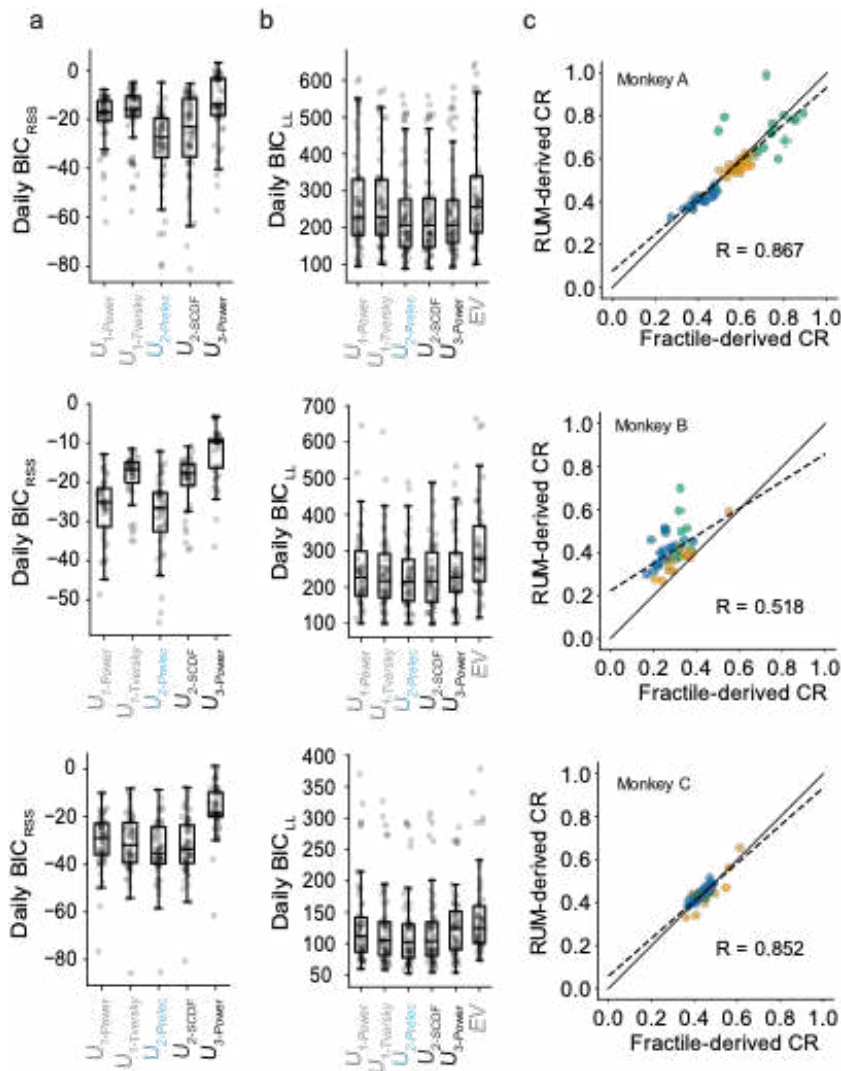

950

951

952 **Figure 3. Utility functions elicited from daily fractile procedures.** Order of distributions tested is
953 captured vertically. Black dots represent CE-utility pairings elicited in individual experimental ses-
954 sions using the fractile method; coloured lines are parametric fits ($U_{2-Prelec}$) to daily CE estimates
955 (blue, low narrow distribution; yellow, full distribution; green, high narrow-distribution). Utility fits
956 for Monkey A, from top to bottom, represent 20 days, 26 days, and 15 days. For Monkey B, we
957 have 23 days, 7 days, and 13 days. Finally, Monkey C has a total of 13 days for the top panel, and
958 43 days for the lower one. In all cases, convexity of the functional fit signals risk seeking behaviour,
959 concavity signals risk aversion.

960

961

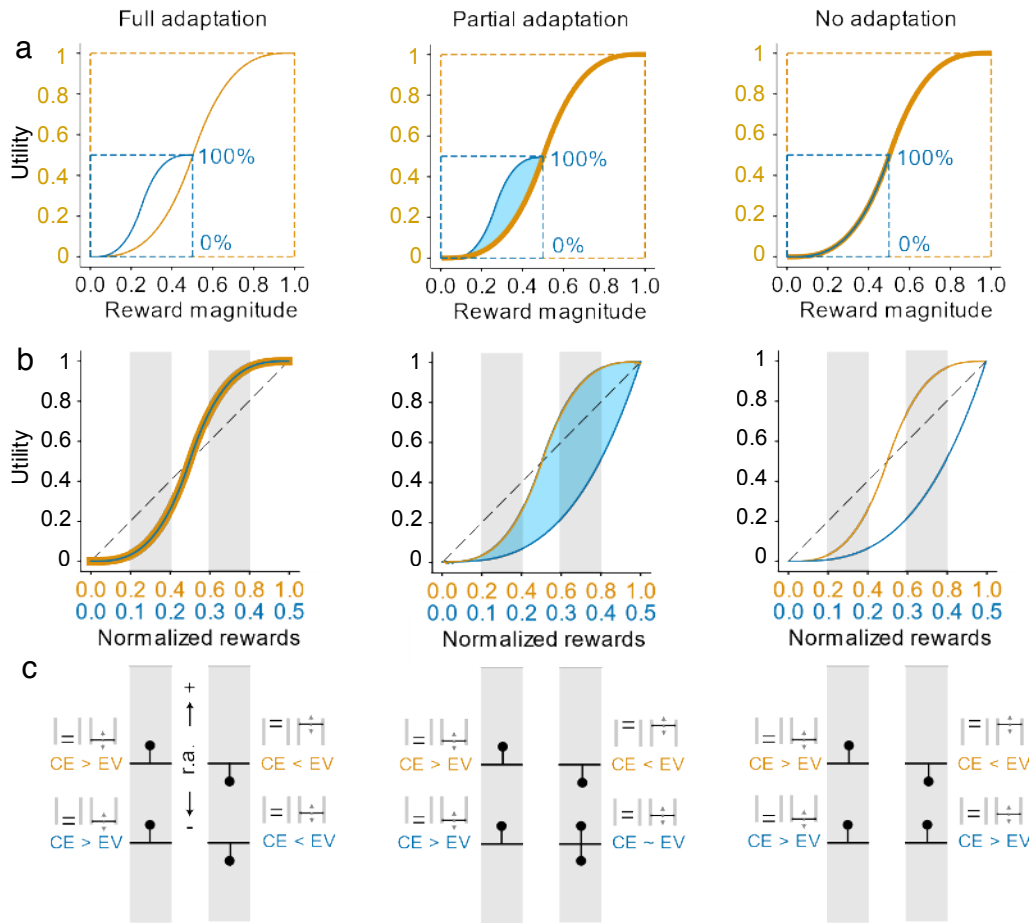

962 **Figure 4. Model comparisons within and across fitting procedures.**

963 a) Model selection for fractile-derived utilities. We calculated daily Bayesian information Criteria
 964 for each utility function using the orthogonal residuals on each fit (BIC_{RSS}). Lower BIC_{RSS} scores indicated a better fit to the CE-utility pairings, and the 2-parameter Prelec model that was used
 965 throughout this study appears in blue ($U_{2-Prelec}$).
 966

967 b) Model selection for discrete choice utilities. We again calculated daily BIC scores for each utility
 968 function, this time using the log-likelihoods estimated to fit each discrete choice models (BIC_{LL}).
 969 Lower BIC_{LL} scores indicated better fits between the discrete choice model (DCM) predictions and
 970 individual measured choices pairings. Again, the 2-parameter Prelec model that was used through-
 971 out this study appears in blue ($U_{2-Prelec}$), and, in contrast to the fractile-fits, we also compared the var-
 972 ious DCMs to predictions based on expected value (seeing if noise alone could explain choices).

973 c) Curvature ratios (CRs) from each fitting procedure correlate. We calculated CRs as the area un-
 974 der the curve of each utility function. Each point represents the CRs from fractile-derived utilities
 975 (x-axis) and DCM-derived utilities (y-axis); their colour captures the reward distribution from
 976 which they estimated (blue: low-distribution, green: high-distribution; yellow: full-distribution).
 977 Significant positive correlations between the fractile-derived CRs and DCM-derived CRs were
 978 found in each of the three animals, and we only observed clear differences between the two proce-
 979 dures in Monkey B.

980

981

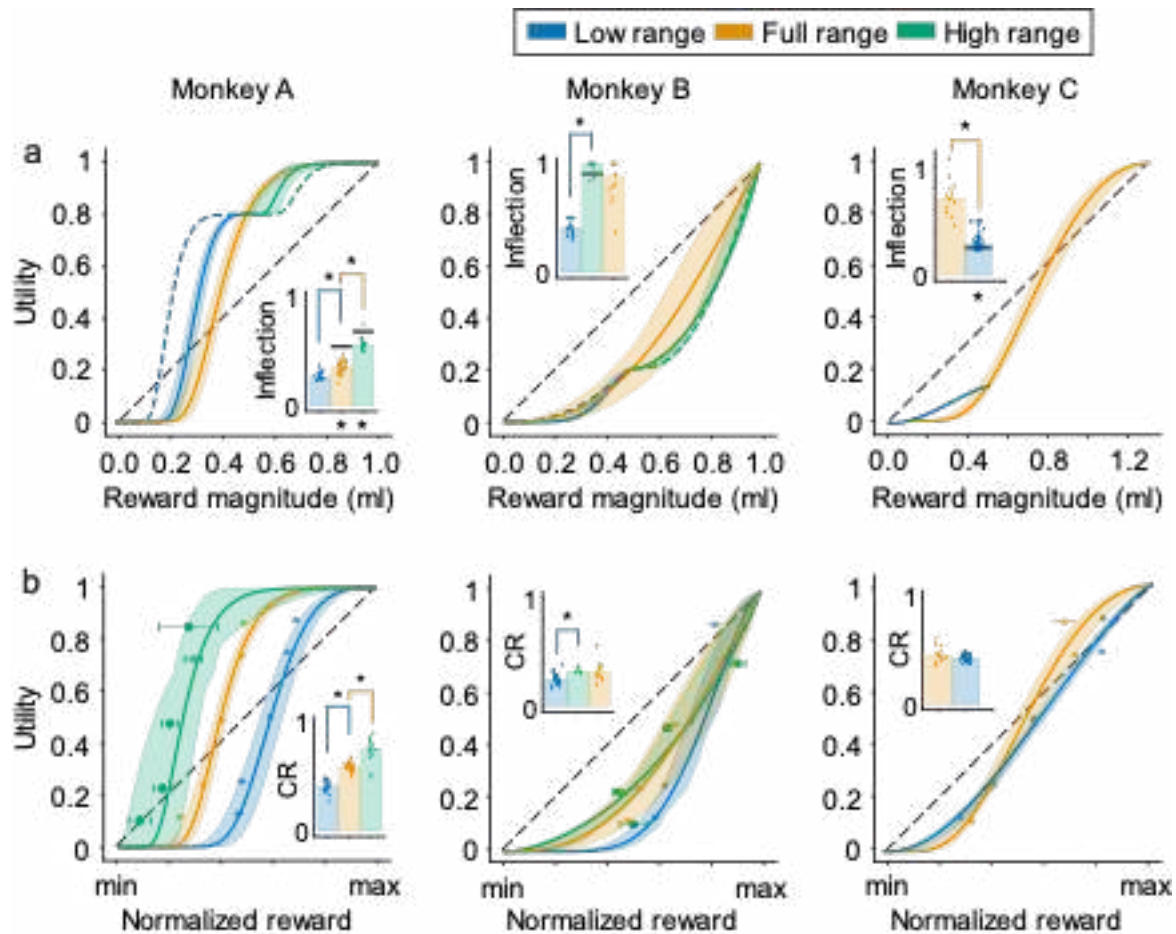

982 **Figure 5. Schematic representation of full-, partial-, and non-adapting utilities estimated in**
 983 **low- and full-distributions of rewards.**

984 a) Scaled, identical utility functions in different reward distributions: the utility value of a 0.5 ml
 985 reward in the small distribution (blue curve, 100% utility) is scaled to the utility value of 0.5 ml re-
 986 ward in the large distribution (yellow curve). From left to right, utilities reshape assuming full-, par-
 987 tial-, and no adaptation. The three possibilities differ mostly in terms of the risk-attitudes exhibited
 988 for rewards between 0 ml and 0.5 ml – under full adaptation they should differ, under no adaptation
 989 they should not.

990 b) Utilities normalised according to the reward distribution from which they were estimated. Utili-
 991 ties are set on the same scale by normalizing across the domains of each function. Curves should
 992 overlap if utilities adapt fully (left) and fail to do so if there is no adaptation (right). If functions fail
 993 to adapt the low distribution utility is predicted to be identical to the first half of the full distribution
 994 utility curve.

995 c) Predicting the direction of risk attitudes (r.a.) from utilities. For an equiprobable gamble made up
 996 of the two outcomes that fall at the edges of each grey shaded area, the horizontal black line depicts
 997 the expected value (EV) and the black dot above or below signals the direction in which we expect
 998 the certainty equivalent (CE). A black dot above the horizontal line signals risk seeking behaviour
 999 (or positive r.a.) and a CE of higher value than the EV, and a dot below the line signals risk averse
 1000 behaviour (negative r.a.). From left to right we again have predictions of r.a. given full-, partial-, or
 1001 non-adaptive preferences.

1002

1003

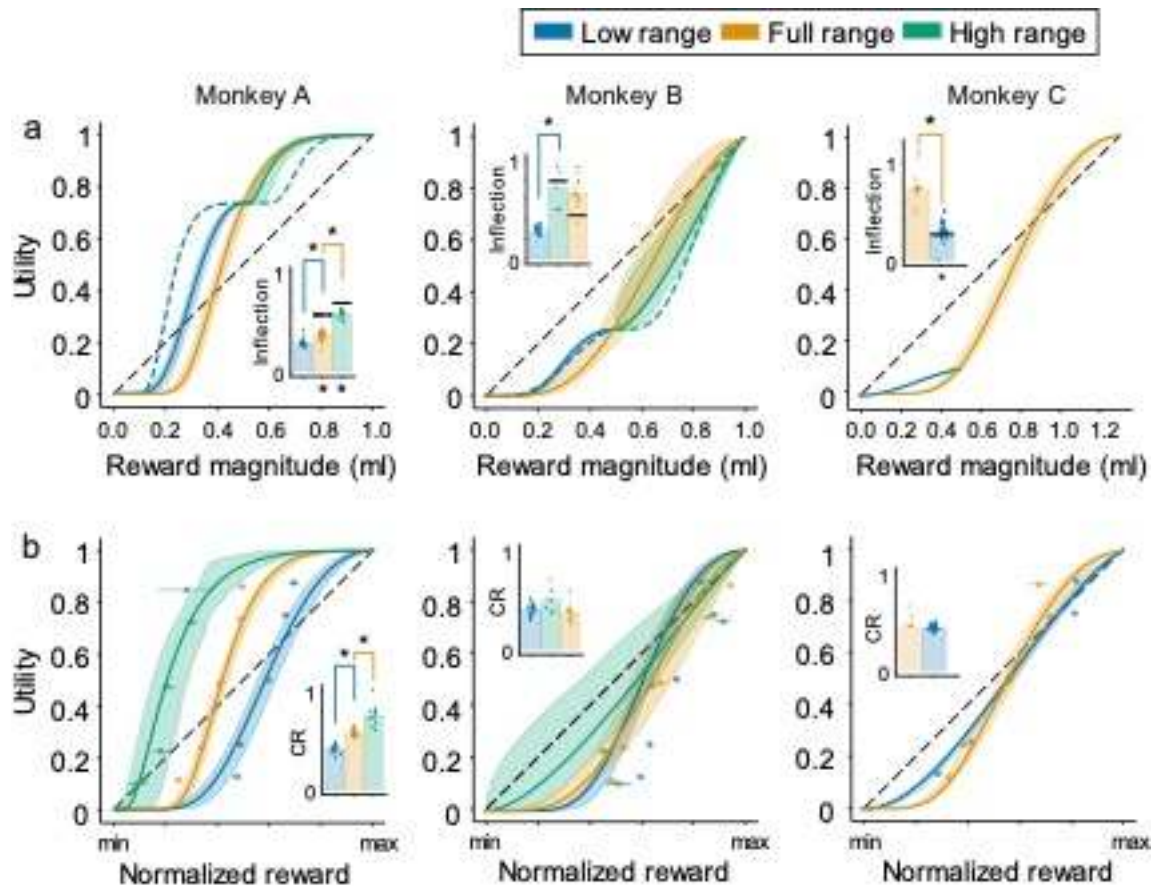

1004 **Figure 6. Fractile-derived utilities reflect adaption to different reward distributions.**

1005 a) Scaled utilities estimated from fractile-derived CE-utility pairings. Each curve represents the
 1006 median of daily, distribution-specific parameter estimates; 95% Confidence intervals were
 1007 estimated via bootstrapping said parameters (random sampling with replacement, n=10000). Dotted
 1008 blue lines represent predictions full-distribution utilities predicted to fully-adapt to low-
 1009 distributions. The dotted green lines represent similar full-adaptation predictions in the high
 1010 distribution. Bar graphs represent the median inflection point, i.e., the reward magntiude at which
 1011 the curve goes from convex to concave – points are daily inflection points. Upper asterisks (*)
 1012 indicate differences between daily inflection estimates in two sequential distributions (Wilcoxon
 1013 rank sum test, $p < 0.05$); Lower asterisks (*) indicate significant difference between the median
 1014 predicted inflection from the previous tested distribution and the true inflection estimates of the next
 1015 distribution (Wilcoxon rank sum, $p < 0.05$).

1016 b) Normalized utilities estimated from fractile-derived CE-utility pairings. Each curve is the median
 1017 of daily, distribution-specific parameter estimates normalized according to the minimum and
 1018 maximum rewards in the tested distribution. Again, 95% confidence intervals were estimated via
 1019 bootstrapping. Points represent mean normalized certainty equivalents \pm SEMs for each of the
 1020 tested distribution. Bar graphs represent median curvature ratios (CRs) for each distribution; the
 1021 relative concavity of each utility (concave > 0.5 ; convex < 0.5) – individual points are daily CRs.
 1022 Upper asterisks (*) indicate significant differences between CRs estimated in sequential
 1023 distributions (Wilcoxon rank sum, $p < 0.05$). For each panel, blue comes from low-distribution
 1024 utilities, yellow from full-distribution, and green from high-distribution.

1025

1026

1027

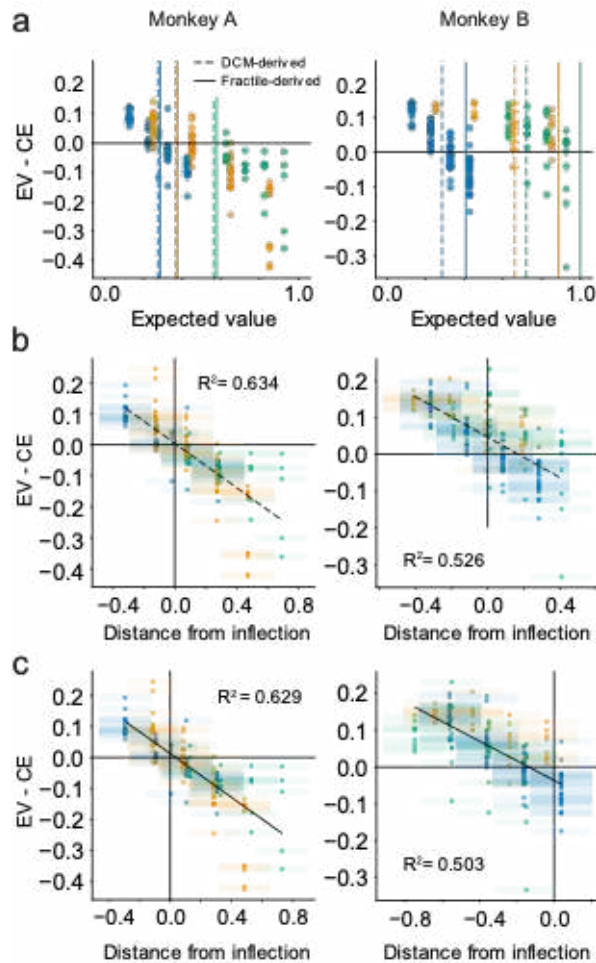

1028 **Figure 7. Discrete choice utilities reflect partial adaption to reward distributions.**

1029 a) Scaled utilities estimated from discrete choice models (DCM). Each curve represents the median
 1030 of daily, distribution-specific parameter estimates; 95% Confidence intervals were estimated via
 1031 bootstrapping said parameters (random sampling with replacement, n=10000). Dotted blue lines
 1032 represent predictions full-distribution utilities predicted to fully-adapt to low-distributions. The
 1033 dotted green lines represent similar full-adaptation predictions in the high distribution. Bar graphs
 1034 represent the median inflection point, i.e., the reward magnitude at which the curve goes from
 1035 convex to concave – points are daily inflection points. Upper asterisks (*) indicate differences
 1036 between daily inflection estimates in two sequential distributions (Wilcoxon rank sum test); Lower
 1037 asterisks (*) indicate significant difference between the median predicted inflection from the
 1038 previous tested distribution and the true inflection estimates of the next distribution (Wilcoxon rank
 1039 sum).

1040 b) Normalized utilities estimated from DCMs. Each curve is the median of daily, distribution-
 1041 specific parameter estimates normalized according to the minimum and maximum rewards in the
 1042 tested distribution. Again, 95% confidence intervals were estimated via bootstrapping (random
 1043 sampling with replacement, n=10000). Points represent mean normalized certainty equivalents \pm
 1044 SEMs for each of the tested distribution. Bar graphs represent median curvature ratios (CRs) for
 1045 each distribution; the relative concavity of each utility (concave > 0.5; convex < 0.5) – individual
 1046 points are daily CRs. Upper asterisks (*) indicate significant differences between CRs estimated in
 1047 sequential distributions (Wilcoxon rank sum). For each panel, blue comes from low-distribution
 1048 utilities, yellow from full-distribution, and green from high-distribution.

1049

1050

1051

1052 **Figure 8. Discrete choice utilities better predict out-of-sample risk attitudes.**

1053 a) Differences between the certainty equivalent (CEs) and expected value (EV) of out-of-sample,
1054 equivariant gambles reflects the risk attitudes predicted by utilities. Each point represents a CE –
1055 EV measure from individual CE estimates. For CE-EV measures above 0 reflect risk seeking be-
1056 haviour, points below 0 reflect risk averse behaviour. The transition from risk seeking to risk averse
1057 behaviour should correlate with the inflection points predicted from utility functions: full lines rep-
1058 resent the median inflection as predicted from daily fractile-derived utilities; dotted lines represent
1059 the median inflection from DCM-derived utilities.

1060 b) Discrete choice (DCM) derived inflections (better) predict risk attitudes as measured in out-of-
1061 sample gambles. CE – EV metrics positioned as a function of a gamble’s EV position relative the
1062 median fractile-derived inflection for each distribution. The x-axis captures the relative difference
1063 between the distribution’s inflection point (in ml) and a gamble’s EV (in ml). Dotted lines represent
1064 linear regression lines across all CE – EV measurements (Monkey A: $p=1.77 \times 10^{-35}$; Monkey B:
1065 $p=1.90 \times 10^{-31}$).

1066 c) Fractile-derived inflections predict risk attitudes as measured in out-of-sample gambles. CE – EV
1067 metrics positioned as a function of a gamble’s EV position relative the median fractile-derived in-
1068 flection of each distribution. The x-axis captures the relative difference between the distribution’s
1069 inflection point (in ml) and a gamble’s EV (in ml). Dotted lines represent linear regression lines
1070 across all CE – EV measurements (Monkey A: $p=5.43 \times 10^{-35}$; Monkey B: $p=1.43 \times 10^{-29}$).

1071

1072

1073

1074 **Figure 9. Daily inflections in utilities reflect recently experienced reward distributions.** Each
1075 experimental session is represented by a set of horizontal black lines; the first derivatives of fitted
1076 utilities appear as the coloured ‘violin plots’ on the horizontal lines. Black vertical lines indicate the
1077 true mean of the rewards experienced by the animals on individual days – smaller black lines indi-
1078 cate the STD on these means. Grey ‘violin plots’ reflect the expected distributions of rewards that
1079 the animals ‘learned’ over past experimental sessions, based on reinforcement learning predictions
1080 (Eqs. 13; 14). They are the distributions that best fit utilities, as allowed by a Rescorla-Wagner
1081 learning rule. Of note, the grey normal distributions are not restricted by reward distributions in the
1082 way that utilities are.

Table 1 | Height and temperature parameters from fractile-derived and DCM-derived utilities

		Utility elicitation method			
		Fractile-derived		DCM-derived	
Reward range (ml)	N	Median temperature	Median height	Median temperature	Median height
Monkey A 0 - 0.5	20	2.973	4.798	2.036	2.399
		95% CIs [2.508, 3.614]	95% CIs [3.017, 7.387]	95% CIs [1.820, 2.321]	95% CIs [2.036, 3.238]
		4.104 [3.412, 4.572]	0.965 [0.747, 1.256]	3.503 [3.092, 3.588]	1.075 [0.917, 1.287]
0.5 - 1.0	26	4.606	0.155	2.961	0.167
0.5 - 1.0	15	[2.170, 9.994]	[0.015, 0.412]	[2.364, 6.094]	[0.044, 0.339]
Monkey B 0 - 0.5	23	1.432	5.073	2.038	2.850
		[1.312, 1.877]	[3.975, 6.595]	[1.875, 2.235]	[2.689, 3.989]
		0.925 [0.843, 1.423]	1.964 [1.923, 2.410]	1.119 [0.867, 1.592]	1.377 [0.687, 1.807]
0.5 - 1.0	7	1.103	2.344	1.5174	2.33
0 - 1.0	13	[0.943, 1.499]	[1.878, 3.055]	[1.159, 1.988]	[1.843, 2.647]
Monkey C 0.1 - 1.3	13	1.897	1.620	1.880	1.908
		[1.551, 2.043]	[1.392, 1.751]	[1.601, 2.060]	[1.581, 2.161]
