We demonstrate the efficient coupling of THz pulses into and out of an adiabatically compressed parallel-plate metal waveguide. The plate separation of the 63.5-mm long, compressed waveguide was fixed at $103\ \mu\text{m}$ at the entrance and exit ends for efficient coupling, but could be reduced in the middle. The experimental results show strong transmission of the THz signal through the compressed waveguide for a minimum midpoint separation of only $8\ \mu\text{m}$. This technique can be used to achieve efficient coupling together with higher sensitivity for waveguide THz-TDS. © 2005 American Institute of Physics. [DOI: 10.1063/1.1863439]

THz waveguides have recently been developed with low loss and single-mode propagation.¹⁻⁵ Among the several types of waveguides studied, the parallel-plate metal waveguides are of special interest due to their associated low-loss and low-group velocity dispersion in the transverse-electromagnetic (TEM)-mode propagation.^{3,4} With these developments, planar THz quasioptics and interconnects have also been realized.^{5,6} THz waveguides can also be used for spectroscopy purposes.¹ Waveguide THz-TDS, using the parallel-plate metal waveguide, has demonstrated exceptional sensitivity by probing nanometer water layers.⁷ The sensitivity of waveguide THz-TDS is inversely proportional to the separation between the two plates forming the waveguide,^{1,7} so it is desirable to minimize the plate separation.

Currently, quasi-optic techniques incorporating cylindrical silicon lenses are used to couple the THz beam into and out of the waveguide. This coupling is strongly dependent on the plate separation of the waveguide; minimized plate separation will reduce the coupling. For example, if the same cylindrical lens pair is used, the amplitude coupled into a parallel-plate waveguide with $10\text{-}\mu\text{m}$ plate separation would be approximately 10% of that with $100\text{-}\mu\text{m}$ plate separation; the same logic holds for the output, giving a throughput of 1% for the waveguide with $10\text{-}\mu\text{m}$ separation compared with the throughput for $100\text{-}\mu\text{m}$ separation. This strongly reduced coupling will significantly reduce the signal-to-noise ratio in the spectroscopy, thereby defeating the gain in sensitivity achieved by reducing the plate separation.

Tapered transmission lines^{8,9} and tapered waveguides^{10,11} have long been used in the microwave region to match unequal waveguide impedances and to connect guiding devices with different cross sections. When the taper is properly designed, the reflection loss and mode conversion can be neglected for the guided electromagnetic wave. In this letter we demonstrate the coupling of THz pulses into and out of a compressed parallel-plate metal waveguide with an adiabatically varying plate separation, thereby enabling the efficient coupling of THz waves to a metal waveguide with a narrow plate separation. The standard confocal THz-TDS system¹² and the compressed waveguide structure used for

this experiment are shown in Fig. 1. The metal waveguide consists of two identical copper plates, with dimensions of $63.5\ \text{mm}(\text{length}) \times 27.9\ \text{mm}(\text{width}) \times 9.5\ \text{mm}(\text{thickness})$. The copper plates were hand-polished to a mirror finish with submicron flatness. The cylindrical silicon lenses used in this experiment, with dimensions of $15\ \text{mm}(\text{height}) \times 6.56\ \text{mm}(\text{thickness}) \times 5\ \text{mm}(\text{radius})$, are attached $50\ \mu\text{m}$ from the entrance and exit ends of the waveguide. The incoming THz beam is horizontally x -polarized, perpendicular to the waveguide opening and the cylindrical axes of the lenses. The entire waveguide structure is placed at the confocal THz beam waist midway between the two off-axis paraboloidal mirrors.⁶ The THz-TDS system and the waveguide structure are placed in an air-tight box purged with dry air to mitigate the absorption lines of water vapor.

The two copper plates are separated at the four corners by brass spacers with dimensions of $3\ \text{mm}$ (length, along the waveguide openings) $\times 2\ \text{mm}$ (width) $\times 103\ \mu\text{m}$ (thickness), determining the $103\text{-}\mu\text{m}$ plate separation at the entrance and exit ends of the waveguide. A stainless steel compressor is applied at the midpoint of the waveguide to vary the mid-

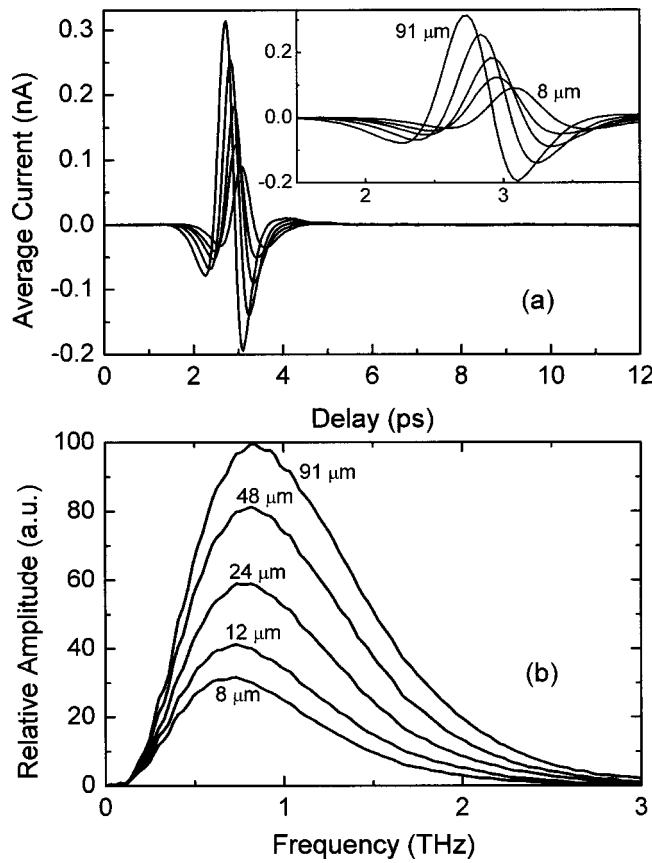

FIG. 2. (a) Output THz pulses from the compressed waveguide with midpoint separations of 91 (reference), 48, 24, 12, and 8 μm . The inset is the zoom-in view of the pulses. (b) The respective spectra.

point plate separation in the range from 0 to 103 μm . The compressor is composed of two identical hypercylindrical stainless steel plates with a radius of curvature of 38 mm. For reference, the waveguide is at minimal compression with the measured midpoint plate separation of 91 μm . The attached cylindrical lenses are carefully aligned to optimize the THz signal passed through the waveguide. After a reference scan is taken, the waveguide is compressed to change the midpoint plate separation. This compression is examined under a microscope to make sure that the separation is the same for both the top and bottom edges, and therefore is uniform along the mid-line between the plates.

Figure 2(a) shows the THz reference pulse transmitted through the waveguide with 91- μm midpoint separation and those taken with midpoint separations of 48, 24, 12, and 8 μm , with each separation having an uncertainty of $\pm 3 \mu\text{m}$. The respective spectra are presented in Fig. 2(b). From Fig. 2, it is seen that the transmitted THz pulse for the compressed waveguide with the minimal 8- μm midpoint separation is only reduced to 30% of that for the reference pulse with 91- μm midpoint separation. This result is fully explained by the increased absorption of the compressed waveguide; the coupling remains the same for the two cases.

The inset of Fig. 2(a) is the zoom-in view of the transmitted THz pulses, showing that as the midpoint plate separation is reduced, the attenuated THz pulse moves to later delays; the delay for the minimal 8- μm separation is 0.35 ps compared with the reference pulse. It is also seen that, the full-width at half-maximum of the pulse broadened slightly with compression, from 0.30 ps for the reference 91- μm

pulse to 0.33 ps for the 8- μm output pulse. In our case, the THz pulse propagates in the TEM mode of the parallel-plate waveguide.³ With perfect conductor plates, the TEM mode propagation would be free of group velocity dispersion and power absorption; hence the pulse delay and broadening should not be observed for the compressed waveguide. However, the finite conductivity of the metal plates causes the slight group velocity dispersion, the increase of the propagation constant, and the frequency-dependent absorption, resulting in the observed time delay, pulse amplitude reduction, and pulse broadening.

For the TEM mode propagation of a parallel-plate waveguide, the amplitude absorption coefficient caused by the finite conductivity of the metal is determined by $\alpha(\omega) = R_s/\eta_0 b$,¹³ where ω is the angular frequency, $\eta_0 = 377 \Omega$ is the intrinsic impedance of free space, b is the plate separation of the waveguide, $R_s = \sqrt{\omega \mu_0/2\sigma}$, μ_0 is the free-space permeability, and σ is the conductivity. We use $\sigma = 5.8 \times 10^7 \Omega^{-1} \text{m}^{-1}$ for copper. In general for a waveguide with cross-sectional change, the attenuation is caused by both the absorption due to the finite conductivity and the reflection due to the cross-sectional change. However, if the cross-sectional change is made adiabatically (slowly) over a length of many wavelengths, the reflection is negligible.^{9,10} In our case, the cross-sectional change is made in a length of 30 mm, 100 times the wavelength at 1 THz, thus the reflection can be neglected. The absorption coefficient is therefore only a function of plate separation, i.e., $\alpha(\omega, z) = \alpha_0(\omega)b_0/b(z)$, where b_0 is the plate separation at the ends, and $\alpha_0(\omega) = R_s/\eta_0 b_0$. For a straight waveguide with length L and uniform plate separation b_0 , the total amplitude attenuation due to the finite conductivity of the metal plates would be $A_0(\omega) = \exp[-\alpha_0(\omega)L]$. For the compressed waveguide, the total amplitude attenuation can be calculated correspondingly as

$$A_c(\omega) = \exp\left[-\int_{-L/2}^{L/2} \alpha(\omega, z) dz\right] = \exp[-\alpha_0(\omega)L(b_0/b_E)], \quad (1)$$

where

$$b_0/b_E = (b_0/L) \int_{-L/2}^{L/2} [1/b(z)] dz. \quad (2)$$

It is quite important to notice that the effect of the adiabatic waveguide compression as displayed in Eqs. (1) and (2) does not change the frequency dependence of $\alpha_0(\omega)$ but only changes the absorption strength by the compression factor (b_0/b_E). This feature can enable very precise determinations of the frequency dependence of $\alpha_0(\omega)$ using waveguide THz-TDS with adiabatic compression.

For a simply supported elastic beam of length L , when pressed in the middle, the cross section deflection curve takes the form of $x \propto z'(3L^2 - 4z'^2)$,¹⁴ where $z' = L/2 - |z|$ and $-L/2 \leq z \leq L/2$. In our case, we can assume that the ends of copper plates move freely when compressed, so that the compressed waveguide plates can be treated as simply supported beams. The plate separation of the compressed waveguide can therefore be written as $b(z) = b_0 - pz'(3L^2 - 4z'^2)$, where $p = (b_0 - b_m)/L^3$, and b_m is the midpoint plate separation. Note that $z = 0$ at the midpoint of the waveguide. To test this prediction, we measured the plate separation across the

compressed waveguide for an 8- μm midpoint separation. The measured results and the calculated results based on the simply supported beam assumption are compared in Fig. 3. It can be seen that, the measurement and the calculation agree reasonably well; the difference between measurement and calculation is less than 5 μm for most of the data points.

With the above analysis we can now compare the amplitude absorption for the reference guide with the compressed guide. Since the cylindrical lenses and the plate separation at the ends are fixed, the coupling between the cylindrical lenses and the waveguide is considered to be the same for the reference guide and the compressed guides. Thus, the pulse and spectrum changes are solely caused by the different absorption of the compressed guides. We can therefore compare the scan from the reference guide with individual scans from the compressed guides in terms of the amplitude spectral ratio, which gives the relative absorption information. Figure 4 shows the amplitude spectral ratios between scans from the compressed waveguides and the reference guide. Using Eq. (2), the compression factors (b_0/b_E) are calculated to be 1.08, 1.59, 2.38, 3.50, and 4.37 for the midpoint separations of 91, 48, 24, 12, and 8 μm , respectively. The calculated spectral ratios (solid lines) match the experimental values (dotted lines) reasonably well for all the cases.

The experimental results and the simple analysis demonstrate and explain the efficient coupling of THz pulses into and out of an adiabatically compressed parallel-plate metal waveguide. Using this technique, it is possible to achieve

both high sensitivity and good coupling to significantly improve the sensitivity of waveguide THz-TDS. Because adiabatic compression does not change the frequency dependence of the absorption coefficient, this technique can determine this dependence with increased sensitivity and accuracy.
