Transition metal oxides are widely used in solar cells, batteries, transistors, memories, transparent conductive electrodes, photocatalysts, gas sensors, supercapacitors, and smart windows. In many of these applications, large surface areas and pore volumes can enhance molecular adsorption, facilitate ion transfer, and increase interfacial areas; the formation of complex oxides (mixed, doped, multimetallic oxides and oxide-based hybrids) can alter electronic band structures, modify/enhance charge carrier concentrations/separation, and introduce desired functionalities. A general synthetic approach to diverse mesoporous metal oxides is therefore very attractive. Here we describe a powerful aerosol-spray method for synthesizing various mesoporous metal oxides from low-cost nitrate salts. During spray, thermal heating of precursor droplets drives solvent evaporation and induces surfactant-directed formation of mesostructures, nitrate decomposition and oxide cross-linking. Thirteen types of monometallic oxides and four groups of complex ones are successfully produced, with mesoporous iron oxide microspheres demonstrated for photocatalytic oxygen evolution and gas sensing with superior performances.

Transition metal oxides have applications in a wide range of technologies^{1–10}. Many of their applications benefit from the formation of porous materials with large surface areas and pore volumes, as well as the formation of complex oxides, such as mixed, doped, multimetallic oxides and oxide-based hybrids. Continuous efforts have been made on the synthesis of mesoporous transition metal oxides since the 1990s owing to their wide uses in various important applications as mentioned above. Poly(alkylene oxide) block copolymers have predominantly been employed to direct the formation of mesoporous metal oxides through casting, film coating or aerosol spray. Two major types of metal-containing compounds have been utilized as metal oxide precursors. One is metal chlorides^{11–15}, and the other is metal alkoxides^{16–20}. Careful control of the hydrolysis and condensation rates of metal species in solutions has been found to be crucial for the formation of mesostructured oxides. Restrained hydrolysis and condensation have been realized through the inherent generation of strong hydrochloric acid for chloride precursors and the addition of strong acids for alkoxide precursors. Besides their separate uses, the two types of precursors are also often mixed together for better control of mesostructure formation and for the creation of mixed or multimetallic oxides^{21–24}. The involvement of strong acids makes the synthesis highly corrosive and environment-unfriendly. In addition, metal alkoxides are generally expensive and unstable.

We recently reported on the use of $\text{Fe}(\text{NO}_3)_3$ and $\text{Ni}(\text{NO}_3)_2$ as oxide precursors to prepare amorphous mixed iron-nickel oxides at varying compositions through aerosol spray for efficient electrochemical oxygen evolution reaction²⁵. Here we demonstrate the versatility and powerfulness of this cost-effective approach for the synthesis of a variety of mesoporous metal oxides ranging from monometallic to complex ones. The approach combines aerosol spray together with solvent evaporation-induced assembly. Low-cost metal nitrate salts are used as oxide precursors. The precursor solutions are composed only of metal nitrates, poly(alkylene oxide) block copolymer molecules, and ethanol. During the spray process, each droplet of the precursor solution acts as a microscale reactor. Solvent evaporation first induces mesostructure formation. The subsequent temperature increase after the solvent is completely evaporated causes the thermal decomposition of metal nitrates. This prevents precipitation and crystallization of oxides in the droplets and consequent phase separation between the inorganic and organic ingredients, a notably long-lasting problem in the synthesis of mesoporous transition metal oxides with chlorides and alkoxides as oxide precursors^{11–24}. The separation of the mesostructure formation and the thermal decomposition of metal nitrates avoids the use of strong acids in the preparation. Our method is therefore easy to handle, and can potentially be upgraded for continuous and large-scale production of various mesoporous metal

oxides. Thirteen types of monometallic oxides and four groups of complex ones have been successfully produced, with mesoporous iron oxide microspheres demonstrated for photocatalytic oxygen evolution and gas sensing with superior performances.

Results and discussion

Mesoporous monometallic metal oxides. Aerosol spray was performed on a home-built system, which was composed of a household ultrasonic humidifier, a tube furnace, and a sample collector (Fig. 1a and Supplementary Fig. 1). The precursor solution was prepared from metal nitrate, poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymer, and ethanol. It was nebulized with the humidifier. The generated mist was carried into the furnace with nitrogen. The furnace was maintained at a given temperature during spray. The residence time of the mist in the furnace under our spray conditions was 3–5 s. The production rate of mesoporous oxide products with our home-built system was estimated to be 0.1 g h^{-1} .

We first present the mesoporous monometallic oxide products. A total of 13 types of monometallic oxides was successfully produced. They were characterized with scanning/transmission electron microscopy (SEM/TEM, Fig. 1b–g and Supplementary Fig. 2), nitrogen sorption (Supplementary Figs 3 and 4), and powder X-ray diffraction (XRD, Supplementary Fig. 5). In Table 1 are provided the Brunauer-Emmett-Teller surface areas and pore volumes determined from the nitrogen sorption measurements, together with the furnace temperatures used during the spray process and the thermal decomposition temperatures of the metal nitrate salts found in the literature (Supplementary Table S1). The mesoporous oxide

products have a spherical shape, with diameters ranging from $\sim 200 \text{ nm}$ to $\sim 2 \mu\text{m}$, which are mainly determined by the droplet diameter and precursor concentration for a given material. For example, when 2 mmol of $\text{Al}(\text{NO}_3)_3$ or $\text{Fe}(\text{NO}_3)_3$ was used together with 0.25 g of the block copolymer surfactant, the average diameters of the obtained mesoporous Al_2O_3 and Fe_2O_3 spheres were $0.7 \pm 0.3 \mu\text{m}$ and $0.8 \pm 0.2 \mu\text{m}$, respectively. When the concentrations of the nitrate and surfactant in the precursor solutions were reduced by half, the products remained to be spherical, with the corresponding average diameters becoming $0.5 \pm 0.3 \mu\text{m}$ and $0.4 \pm 0.3 \mu\text{m}$. CuO microspheres are loosely packed. NiO and MgO microspheres are hollow, with folds appearing on their shells. The rest are densely packed. The loosely packed or hollow structures for the CuO , NiO and MgO products might result from the lower solubilities of the corresponding metal ions and thus their smaller diffusion rates in ethanol during the decomposition and condensation process in the furnace²⁶. The specific surface areas range from $\sim 20 \text{ m}^2 \text{ g}^{-1}$ to $\sim 200 \text{ m}^2 \text{ g}^{-1}$, and the pore volumes range from $\sim 0.05 \text{ cm}^3 \text{ g}^{-1}$ to $0.5 \text{ cm}^3 \text{ g}^{-1}$. The pores are generally disordered. Six types of mesoporous oxides, which are Fe_2O_3 , CeO_2 , Al_2O_3 , Cr_2O_3 , Ga_2O_3 and ZrO_2 , display narrow Barrett-Joyner-Halenda pore size distributions, with their pore sizes centered in the range of $\sim 5 \text{ nm}$ to $\sim 12 \text{ nm}$. The oxide products with narrow pore size distributions mostly have amorphous pore frameworks (Fe_2O_3 , Al_2O_3 , Ga_2O_3 and ZrO_2), except CeO_2 and Cr_2O_3 , which have narrow pore size distributions as well as crystalline pore frameworks. The others exhibit broad pore size distributions, which are caused by crystalline pore frameworks, loosely packed or hollow interiors.

Figure 1 | Aerosol spray system and representative monometallic oxide products. (a) Schematic illustrating the home-built setup and the processes associated with aerosol spray. The droplets of the precursor solution are carried into the furnace by nitrogen gas. Thermally-driven solvent evaporation and nitrate decomposition produce mesostructured oxide microspheres, which are collected with a filter. The top-right and bottom-left photographs show the precursor solution and the mesoporous microsphere product for Fe_2O_3 , respectively. (b–g) SEM images of mesoporous monometallic Mn_3O_4 , Fe_2O_3 , Co_3O_4 , NiO and CeO_2 products. (f) TEM image of a single hollow crumpled NiO microsphere. The shown mesoporous oxide products were all calcined.

Table 1 | Preparation and pore structure parameters of the mesoporous monometallic oxides

Oxide	Precursor	Thermal decomposition temperature (°C)	Furnace temperature (°C)	Surface area (m ² g ⁻¹)	Pore volume (cm ³ g ⁻¹)
Al ₂ O ₃	Al(NO ₃) ₃ ·9H ₂ O	200	400	118	0.18
Cr ₂ O ₃	Cr(NO ₃) ₃ ·xH ₂ O	100	400	101	0.12
Mn ₃ O ₄	Mn(NO ₃) ₂ ·4H ₂ O	160–200	400	87	0.33
Fe ₂ O ₃	Fe(NO ₃) ₃ ·9H ₂ O	125	400	194	0.52
Co ₃ O ₄	Co(NO ₃) ₂ ·6H ₂ O	200–240	500	56	0.21
ZnO	Zn(NO ₃) ₂ ·6H ₂ O	350–380	500	38	0.18
Ga ₂ O ₃	Ga(NO ₃) ₃ ·4H ₂ O	200	400	135	0.25
ZrO ₂	ZrO(NO ₃) ₂ ·4H ₂ O	200	400	116	0.16
CeO ₂	Ce(NO ₃) ₃ ·9H ₂ O	200	400	147	0.19
MgO	Mg(NO ₃) ₂ ·6H ₂ O	300–330	500	39	0.19
NiO	Ni(NO ₃) ₂ ·6H ₂ O	270–310	500	50	0.17
CuO	Cu(NO ₃) ₂ ·3H ₂ O	155–160	400	19	0.10
WO ₃	H ₂ WO ₄		400	18	0.04

We found that it is essential to set the temperature of the furnace 200–300°C higher than the thermal decomposition temperature. If the furnace temperature is lower than ~300°C, the collected products are gel-like, suggesting that the solvent evaporation is incomplete. As the furnace temperature is increased, the products become dry. However, if the furnace temperature is less than ~200°C higher than the thermal decomposition temperature of the metal nitrate, the dry particles in the products fall apart by themselves. They are difficult to be processed further for characterization or use. Only if the furnace temperature is high enough, can the particles in the products be tight enough to maintain their integrity during further processing. During aerosol spray, each droplet acts as a microscale reactor. The spherical morphology of the product particles is determined by the shape of the liquid droplets. We surmise that in the droplets, solvated metal nitrate species interact mainly with the poly(ethylene oxide) part of the triblock copolymer molecules. Ethanol evaporation induces the formation of mesostructures, where the hydrophilic phase is composed of metal nitrate species and the poly(ethylene oxide) part of the copolymer, and the hydrophobic phase is composed of the poly(propylene oxide) part of the copolymer. If the furnace temperature is high enough, the temperature of the self-assembled microspheres will be further raised after ethanol is completely evaporated, which causes decomposition of metal nitrate species and subsequent condensation of the corresponding metal oxides. Our preparation method is also applicable for some metal oxides that do not have corresponding nitrate precursors but can be dissolved in ethanol, decomposed and condensed at raised temperatures. An example is WO₃, for which H₂WO₄ was used as the precursor.

The mesoporous monometallic oxides can be post-treated to yield different phases with desired properties. For example, calcination of the product sprayed from Fe(NO₃)₃·9H₂O at 400°C in air produced mesoporous Fe₂O₃ microspheres with an amorphous pore framework (Supplementary Fig. 5). Raising the calcination temperature to 500°C yielded mesoporous α-Fe₂O₃ microspheres (Supplementary Fig. 6). Thermally treatment of the α-Fe₂O₃ product at 400°C in a H₂–N₂ mixture gave Fe₃O₄. γ-Fe₂O₃ was obtained by thermally treating the Fe₃O₄ product at 400°C in air. Both of the Fe₃O₄ and γ-Fe₂O₃ products are ferromagnetic (Supplementary Fig. 7).

Complex mesoporous metal oxides. Our spray approach is also capable of facily producing complex mesoporous metal oxides beyond the monometallic ones, as demonstrated with doped, mixed, bimetallic oxides and oxide-based hybrids. Doping is a powerful means for adjusting the optical and electronic properties of metal oxide semiconductors. In our study, ZnO was taken as an example (Supplementary Fig. 8). Up to 10 mol% of Co, Mn, Ni, Cr and Fe could be readily doped in mesoporous ZnO, while the

crystalline structure of the ZnO host framework remained unchanged. Such heavy doping led to the increases in the absorption intensity below the bandgap energy of ZnO over the visible and near-infrared regions. As the dopant concentration was increased, the absorption in the below-bandgap spectral region became intensified. When the Co concentration was increased from 0 mol% to 10 mol%, the diffraction peak at $2\theta = 36.3^\circ$ shifted to the high-angle region by only ~0.05°, because the ionic radius of Co is slightly smaller than that of Zn. This observation confirms the maintenance of the crystalline structure of the ZnO host framework upon doping.

Mesoporous mixed and bimetallic oxides were made by judiciously choosing two different types of metal nitrates and simply adding them together in the precursor solutions. Our approach allowed for the compositions of the precursor solutions to be readily varied to obtain desired mesoporous oxide products. Figure 2a–i show the representative examples of such mesoporous mixed and bimetallic oxide microspheres. The products were carefully characterized by TEM, high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), energy-dispersive X-ray (EDX) analysis, elemental mapping and XRD. When Al(NO₃)₃·9H₂O and ZrO(NO₃)₂·4H₂O were co-added in the precursor solution, the obtained product was amorphous, with Al and Zr uniformly distributed within each microsphere (Fig. 2a–c). This type of mesoporous products is therefore made of two amorphous metal oxides. When Zn(NO₃)₂·6H₂O and Fe(NO₃)₃·9H₂O were co-used as the precursors, the crystalline phase of the obtained product was found to vary with the Zn-to-Fe molar ratio (Fig. 2d–f). When the Zn-to-Fe molar ratio was 9:1 and 2:1, the crystalline ZnO phase was the dominant component in the products. When the Zn-to-Fe molar ratio was changed to 1:2, the ferrite phase, ZnFe₂O₄, became dominant in the product. Its crystallinity could be increased by lengthening the calcination time. Other ferrites, such as MFe₂O₄ with M being Co, Cu and Ni, were also successfully made in a similar way, where the dominant crystalline ferrite phases were obtained by increasing the calcination temperature or time (Supplementary Fig. 9). When Al(NO₃)₃·9H₂O and Cu(NO₃)₂·3H₂O were mixed in the precursor solution, the product was composed of amorphous Al₂O₃ and crystalline CuO (Fig. 2g–i). The Al₂O₃ ingredient remained amorphous even though the calcination temperature was raised. Then formed CuO nanoparticles were dispersed in the Al₂O₃ host.

Besides the preparations of a variety of mesoporous monometallic and complex oxides by choosing proper metal nitrate precursors, nanoscale species of particular functionalities can also be readily introduced into the oxide products by either adding the proper precursors for making nanoscale species or pre-synthesized nanoparticles in the solutions for aerosol spray. The first route was exemplified

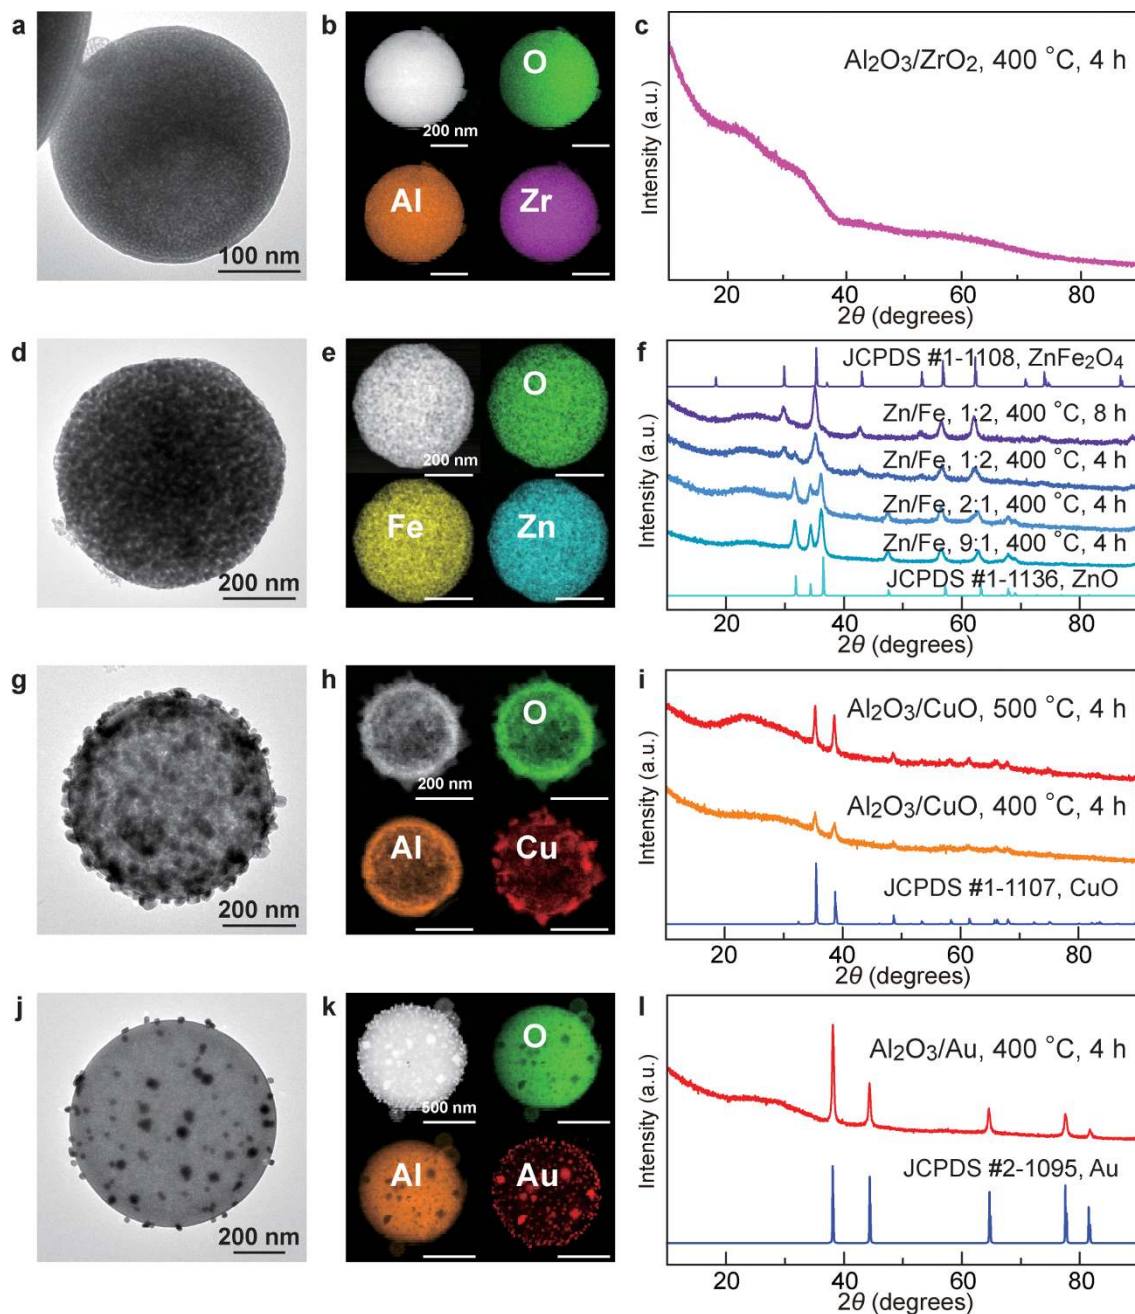

Figure 2 | Representative complex mesoporous metal oxide products. (a–c) Mixed Al₂O₃–ZrO₂ microspheres, where both oxides are amorphous. (d–f) Variation from Fe-doped ZnO microspheres to bimetallic ZnFe₂O₄ microspheres as the molar ratio between Zn and Fe is changed. (g–h) Mixed Al₂O₃–CuO microspheres, where Al₂O₃ is amorphous while CuO is crystalline. (j–l) Al₂O₃ microspheres loaded with Au nanoparticles. In the first column are the TEM images of the corresponding complex oxide microspheres. In the second column are the HAADF-STEM images (top-left corner) and elemental mappings of the corresponding products. The scale bars in the elemental mappings are the same as that in the HAADF-STEM image for each product. The images in (d) and (e) were acquired on the bimetallic ZnFe₂O₄ product with the Zn-to-Fe molar ratio being 1:2. The product was calcined at 400 °C for 4 h. In the third columns are the XRD patterns of the products. Some related standard JCPDS patterns are also shown for comparison.

by adding HAuCl₄ in the oxide precursor solution. Au nanoparticles were generated during the spray process and further enlarged by calcination. Figure 2j–l show the product prepared in this way, where Au nanoparticles were embedded in mesoporous Al₂O₃ microspheres. Besides the amorphous Al₂O₃ framework, mesoporous α-Fe₂O₃ (Supplementary Fig. 10) and CeO₂ (Supplementary Fig. 11) microspheres with crystalline walls could also be loaded with Au nanoparticles similarly. The amount of loaded Au nanoparticles could be facilely controlled by adjusting the amount of HAuCl₄ added in the precursor solution. The second route for the introduction of

functionalities was demonstrated by the addition of pre-synthesized nanoscale species. As an example, pre-synthesized ferrite Zn_xFe_{1-x}Fe₂O₄ nanoparticles were encapsulated in mesoporous Al₂O₃ microspheres, which were also co-loaded with Au nanoparticles through the first route (Supplementary Fig. 12). The product was superparamagnetic and could be collected with a small magnet. The superparamagnetic property was inherited from the ferrite nanoparticles.

Photocatalytic oxygen evolution and gas sensing. To demonstrate the wide potential applications of our aerosol-sprayed mesoporous

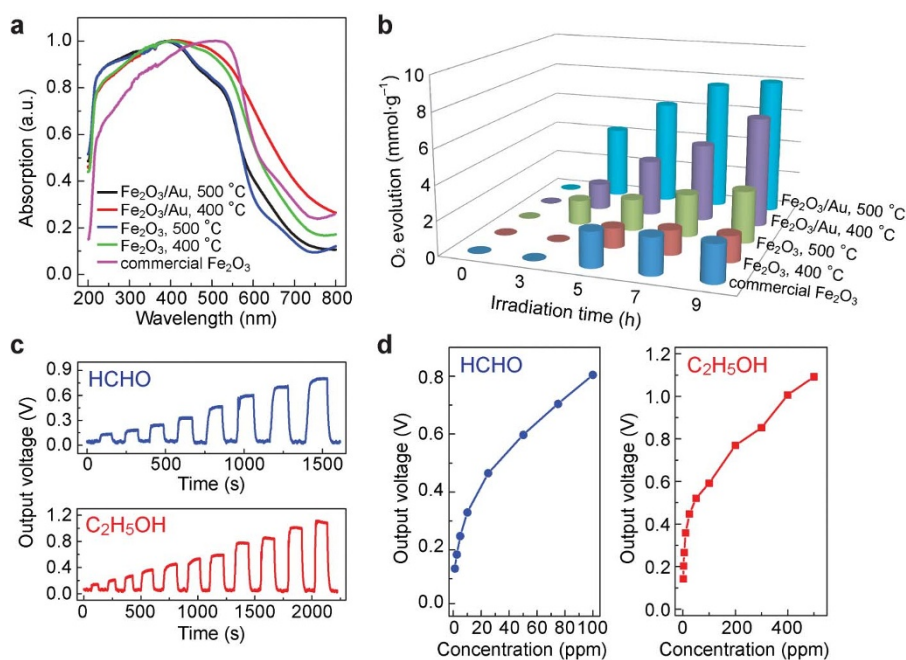

Figure 3 | Photocatalytic oxygen evolution and gas sensing performances. The tests were carried out with the different mesoporous Fe₂O₃-based products. (a) Normalized absorption spectra of the different Fe₂O₃-based products and a commercial Fe₂O₃ product. The absorption spectra were determined from UV-visible diffuse reflectance spectroscopy. (b) Oxygen evolution rates as functions of the irradiation time for the different Fe₂O₃-based samples. (c) Real-time sensing response curves of the mesoporous α -Fe₂O₃ microspheres for formaldehyde (top) and ethanol (bottom), where the concentrations of both types of gas molecules are gradually increased. (d) Output voltage signals as functions of the molecular concentrations for formaldehyde (left) and ethanol (right). The working temperature of the sensing device was 280 °C.

metal oxides, we studied the photocatalytic oxygen evolution and gas sensing performances of the mesoporous Fe₂O₃ products (Fig. 3). α -Fe₂O₃, due to its low cost, abundance, and bandgap energy in the visible region (Fig. 3a), has received wide attention for photocatalytic and photoelectrochemical water splitting^{27,28}. In our photocatalytic measurements, Ag⁺ ions were added to consume photogenerated electrons. When the product was calcined at 500 °C, the photocatalytic O₂ evolution reached 3.0 mmol g⁻¹ after 9-h reaction (Fig. 3b). This amount was twice that of the product calcined at 400 °C. In comparison, a commercial α -Fe₂O₃ product generated 2.2 mmol g⁻¹ of O₂ within 9 h. The differences in the photogenerated amounts of O₂ can be attributed to the joint effects of the crystallinity and specific surface area. Moreover, when Au nanoparticles were loaded in the mesoporous Fe₂O₃ microspheres, the O₂ evolution amounts were greatly increased. For the products calcined at 400 °C and 500 °C, 6.5 mmol g⁻¹ and 8.0 mmol g⁻¹ of O₂ were generated within 9-h reaction. The resultant largest O₂ evolution rate, 0.89 mmol h⁻¹ g⁻¹, is among the highest photocatalytic O₂ evolution rates that have been reported with various Fe₂O₃-based photocatalysts under visible light irradiation (Ref.²⁹ and Supplementary Table 2). The enhanced O₂ evolution rates upon the loading of Au nanoparticles are ascribed to the enhanced charge separation at the interface between the Au nanoparticles and the Fe₂O₃ host as well as plasmon-enhanced light absorption by the embedded Au nanoparticles, as have been discussed recently^{30,31}.

Gas sensing was performed by coating the mesoporous α -Fe₂O₃ microspheres on a ceramic tube and measuring the electrical conductance change upon exposure to gas molecules (Supplementary Fig. 13). The sensing signal was measured as a voltage on a sampling resistor. A higher measured voltage corresponded to a larger current, and therefore a smaller resistance, when an oxide was exposed to a particular molecular vapor. The mesoporous Fe₂O₃ product was very electrically sensitive to gas molecules owing to its large specific surface area (Fig. 3c&d). The detection limits for formaldehyde and ethanol were as low as 1 ppm by volume, with a signal-to-noise

ratio of 3. These detection limits are about one order of magnitude lower than those reported in many other studies^{32–34}. The response time, which is defined as the time required for the signal to reach 63% of its stable value, is only ~5 s. Many other types of gas molecules could also be detected with remarkable sensitivities (Supplementary Fig. 14). Meanwhile, the measured voltage signal was found to increase as the working temperature of the sensor was raised (Supplementary Fig. 15). In contrast, the commercial Fe₂O₃ product exhibited very poor performance in gas sensing. Almost no response could be recorded on our measurement setup. The high sensitivity of our mesoporous Fe₂O₃ product can be explained qualitatively. In general, gas sensing with oxide semiconductors is based on the resistance change upon adsorption of target gas molecules on the surface of the oxide semiconductor. Fe₂O₃ is typically an n-type semiconductor. If oxygen molecules are adsorbed on its surface due to exposure to ambient environment, its resistance is increased, because a fraction of electrons are transferred from the oxide to the adsorbed oxygen molecules. When the oxide is exposed to small organic molecules, for example, HCHO, the adsorbed oxygen molecules react with HCHO molecules, electrons are returned back to the oxide, and therefore the resistance is reduced. In our experiments, the Fe₂O₃ microspheres are mesoporous. They have a large specific surface area for interaction with gas molecules. Moreover, the pores allow for gas molecules to diffuse into the microspheres. As a result, the mesoporous Fe₂O₃ microspheres offer a high sensitivity for gas sensing.

Conclusion

In summary, our experiments show that the use of low-cost, versatile metal nitrate salts as precursors in conjunction with aerosol spray-induced, block copolymer-directed assembly offers a facile yet powerful means for the preparation of a variety of mesoporous monometallic, multimetallic, and complex metal oxides. Our method allows for easy doping and formation of oxide mixtures, multimetallic oxides, as well as introduction of additional functional nanoscale species. Such modifications are often resorted to for

changing or improving the optical and electronic properties of metal oxides, but they are often difficult to be realized with conventional wet-chemistry or solid-state preparation methods. Our method is expected to bring many advances and improvements in the performances of enormous materials and devices based on metal oxides.

Methods

Mesoporous metal oxide preparation. To prepare the precursor solution, (ethylene oxide)₂₀-(propylene oxide)₇₀-(ethylene oxide)₂₀ (Pluronic P123) or (ethylene oxide)₁₀₆-(propylene oxide)₇₀-(ethylene oxide)₁₀₆ (Pluronic F127) triblock copolymer was first dissolved in absolute ethanol by stirring. After the copolymer was completely dissolved, a metal nitrate salt was added in the solution, followed by vigorous stirring for 10 min. The resultant transparent solution was then transferred to a household ultrasonic humidifier for aerosol generation. The liquid droplets were carried by nitrogen into a tube furnace that was set at a particular temperature. The product was collected through filtration. To prepare complex oxides or oxide-based hybrids, multiple metal nitrates at controlled molar ratios, dissolvable molecular precursors for non-oxides, and/or dispersible pre-synthesized nanoscale species were added together in the ethanolic solution of the copolymer. The collected products were calcined in air to remove the copolymer surfactant. More preparation details are provided in Supplementary methods.

Characterization. The sprayed products were examined by powder XRD (SmartLab Diffractometer, 40 kV, 40 mA), SEM (FEI QF400, attached with an EDX analysis system), TEM (FEI TS12, 120 kV), high-resolution TEM (FEI TF20, 200 kV), UV-visible diffuse reflectance spectroscopy (UV-2450, Shimadzu), and HAADF-STEM imaging and elemental mapping (FEI TF20, 200 kV). Nitrogen sorption isotherms were measured on a Micromeritics TriStar 3000 system at the liquid-nitrogen temperature. The specific surface area and pore size distribution were analyzed according to the Brunauer–Emmett–Teller and Barrett–Joyner–Halenda model, respectively.

Photocatalytic and gas sensing measurements. Photocatalytic water oxidation was performed in an aqueous AgNO₃ solution in a photocatalytic water-splitting system, where AgNO₃ functioned as a sacrificial agent. The reaction was under visible light illumination ($\lambda > 420$ nm). The sensing device was made of a ceramic tube with two printed gold electrodes. The mesoporous oxide powders were coated on the tube at a thickness of several ten micrometers. The working temperature of the sensing tube was controlled with a resistance heater. The sensing measurements were carried out in a home-designed chamber with an electrical measurement system. The gas vapor was injected into the chamber with a syringe and mixed automatically with air. The concentration of the gas vapor was estimated by taking into account the saturated vapor pressure of the gas at a given temperature, the injected vapor volume, and the chamber volume. More details for the photocatalytic and sensing measurements are provided in Supplementary methods.

Acknowledgments

This work was supported by the Research Grants Council of Hong Kong under the Theme-Based Research Scheme (T23-407-13-N) and National Natural Science Foundation of China (21229101).

Author contributions

J.F.W., T.M. and B.Y.G. conceived the project. L.K., T.M. and J.X.W. performed the experiments. C.H.F. contributed to the TEM characterizations. Z.H.S. performed the nitrogen sorption measurements. L.K., J.X.W. and J.F.W. wrote the paper.
