AN EXPERIMENTAL STUDY OF DYNAMIC STALL ON ADVANCED AIRFOIL SECTIONS

VOLUME 1. SUMMARY OF THE EXPERIMENT

W. J. McCroskey, K. W. McAlister, L. W. Carr, and S. L. Pucci

U.S. Army Aeromechanics Laboratory (AVRADCOM), Ames Research Center

SUMMARY

The static and dynamic characteristics of seven helicopter sections and a fixedwing supercritical airfoil were investigated over a wide range of nominally twodimensional flow conditions, at Mach numbers up to 0.30 and Reynolds numbers up to 4×10^6 . Details of the experiment, estimates of measurement accuracy, and test conditions are described in this volume (the first of three volumes). Representative results are also presented and comparisons are made with data from other sources. The complete results for pressure distributions, forces, pitching moments, and boundary-layer separation and reattachment characteristics are available in graphical form in volumes 2 and 3.

The results of the experiment show important differences between airfoils, which would otherwise tend to be masked by differences in wind tunnels, particularly in steady cases. All of the airfoils tested provide significant advantages over the conventional NACA 0012 profile. In general, however, the parameters of the unsteady motion appear to be more important than airfoil shape in determining the dynamicstall airloads.

1. INTRODUCTION

Retreating-blade stall limits the high-speed performance of most modern helicopters. In the past decade, numerous new airfoils have been designed in attempts to improve the stall characteristics of rotors without compromising the advancing-blade performance. Only a few of these have been tested under unsteady conditions, and some have not been tested at all. Furthermore, there is almost no overlap between the existing data sets with regard to the important parameters of oscillatory motion.

The motivation of the present experimental investigation was the obvious need for a standard data base for a series of modern rotor-blade sections. The primary objective was to measure the unsteady airloads, over an extensive matrix of test conditions, on the eight profiles shown in figure 1. Other investigations were also overlapped as much as possible. The NACA 0012 served primarily as a standard reference section; the six modern helicopter sections were chosen as representative of contemporary designs from several different companies and research organizations. A modern fixed-wing supercritical profile was also included to extend the range of leading-edge geometries and to provide a basis for comparison with oscillating-airfoil results obtained in other wind tunnels.

Secondary objectives were to investigate the type of stall and boundary-layer separation characteristics for each profile, to provide guidelines for estimating the dynamic-stall characteristics of new airfoils in the future, to supplement the conventional lift and pitching-moment measurements with unsteady drag data and stall-flutter boundaries, and to determine the effects of leading-edge roughness that is comparable to the erosion of blades in service or in incipient icing conditions.

Dynamic stall depends on a large number of parameters. Consequently, a very large number of unsteady test points (more than 600) plus 44 sets of static data were required to fulfill the objectives of this investigation. As a result, the complete report consists of three volumes. The present volume summarizes the experiment and some of the principal results, including comparisons with data from other sources. It also contains a comprehensive index of the individual unsteady data points. Volume 2 (Pressure and Force Data) contains the pressure, force, and moment data in graphical form. These data are also available upon request on digital computer tapes, one tape for each airfoil, as explained in volume 2. In addition, there is a single tape containing only the 10 test cases that were discussed in reference 1 for the NACA 0012, Vertol VR-7, and NLR-7301 airfoils. Boundary-layer transition, flow reversal, and reattachment results appear in volume 3 (Hot-Wire and Hot-Film Measurements).

This report is primarily intended to assist the users of the data; therefore, the results are not discussed at length. The provide the second published in references 1 and 2.

2. DESCRIPTION OF THE CRIMENT

Test Apparatus

The experiment was performed in the 2- by 3-m atmospheric-pressure, solid-wall Wind Tunnel at the U.S. Army Aeromechanics Laboratory. The tests were conducted in essentially the same manner as those in a previous experiment (refs. 3,4), except that the free-stream Mach number was extended to 0.3, the model chord c was reduced to 0.61 m (except for the Hughes HH-02 airfoil, c = 0.69 m), the frequency of oscillation was extended to 11 Hz, and the data processing was refined considerably. The models spanned the 2.13-m vertical dimension of the wind tunnel, as indicated in figure 2, and were oscillated sinusoidally in pitch about the quarter chord. A gap of approximately 2 mm existed between the ends of the model and the wind-tunnel walls.

The drive mechanism used (fig. 3) was the same one described in references 3 and 4, with some notable improvements. In some cases, the connecting push rod was fitted with a remotely controlled jackscrew mechanism that allowed the mean angle, α_0 , to be varied continuously while the tunnel was operating. Discrete amplitudes of oscillation of 2°, 5°, 6°, 8°, 10°, or 14° could be set between runs. The motion of the airfoils was given by $\alpha \cong \alpha_0 + \alpha_1 \sin \omega t$, with maximum higher harmonic distortion approximately 2% of α_1 . Table 1 gives the harmonic content of the mechanism for various values of α_0 and α_1 . The frequency of oscillation could be varied between approximately 0.02 and 12 Hz.

The models of the eight airfoils (fig. 1) consisted of interchangeable shells constructed of wood and fiberglass. These shells surrounded a stainless steel spar that contained the instrumentation and wiring, as indicated schematically in figures 2 and 4. The shells contained special fittings for the pressure transducers and hot-wire or hot-film sensors (fig. 5) that facilitated model changes without disconnecting the instrumentation. Each set of shells was precision-machined, while mounted on the spar, to a design accuracy of ± 0.1 mm. However, measurements after the test revealed that the rms standard deviation of the coordinates from the design values was about 0.4 mm, or 0.06% of chord, and that the maximum error was about 0.8 mm. The nominal design coordinates of the airfoils are given in tables 2-5, referred to the standard coordinate system sketched in figure 6. The coordinates were taken originally from references 5-9 and from Amer (K. Amer, private communication, 1977).

A limited amount of static and dynamic data were obtained on each airfoil at $M_{\infty} = 0.185$ and 0.29 with a boundary-layer trip, consisting of a 3-mm-wide band of 0.10-mm-diam glass spheres glued to the leading edge. The purpose of the trip was to eliminate the laminar separation bubble that would normally form near the leading edge as the stall angle was approached. It also approximately simulated surface abrasion on helicopter blades operating under severe field conditions, as well as roughness caused by incipient icing conditions.

Instrumentation

The primary data were obtained from 26 Kulite differential pressure transducers, types YCQH-250-1 and YCQL-093-15. Those of the latter type were used in the leadingand trailing-edge regions, because of their smaller size. The locations of the transducers for each airfoil are given in table 6. The back side of each transducer was referenced to the total pressure of the wind tunnel; total pressure was measured about 1.5 m upstream of the model. The measuring side of the transducers mated with the fittings shown in figure 5, which had 0.79-mm-diam orifices. The transducers thus installed had flat amplitude versus frequency responses of 250 Hz or better and typical cavity resonance frequencies of about 850 Hz.

Special on-line analog computers that calculated and displayed the instantaneous normal force, pitching moment, pitch damping, and pressure distributions proved to be extremely valuable in assessing the dynamic-stall behavior, as well as the performance of the instrumentation, while the tests wire in progress. These devices also enabled the unsteady parameters to be adjusted until some desired result was obtained, such as the maximum lift condition in the absence of moment stall or neutral aerodynamic damping in pitch.

Boundary-layer transition, flow reversal, separation, and reattachment were studied with a variety of surface hot films and hot-wire sensors (single-, double-, and triple-element probes), using the techniques described in references 4, 10, and 11. Six sensors were used on the upper surface of each airfoil, at the locations given in table 6. In addition, a hot-wire probe protruding just outside the boundary layer was mounted near the leading edge of the NLR-1 profile to aid in diagnosing the local supersonic zone that was frequently inferred at high incidence.

The leading-edge region was also examined with a shadowgraph flow visualization system (fig. 7). The high-intensity strobe light was fired at selected phase angles during the oscillation, and the pattern that developed on the Scotchlite high-gain reflective sheeting on the floor of the tunnel was photographed by the pulse camera above the test section. A representative photograph is shown in figure 8.

Finally, a traversing pitot-static probe was used to survey the wake behind each airfoil under steady-flow conditions. The steady drag of the airfoils at $M_{\infty} = 0.30$ was derived from these measurements; these drag coefficients are listed in table 7.

Data Analysis and Measurement Accuracy

For quantitative purposes, the pressure transducer and hot-wire signals were amplified and recorded on a 32-channel analog tape recorder with 2500-Hz flat frequency response. In addition, the average free-stream dynamic pressure, the instantaneous angle of attack of the model, and 1/cycle and 200/cycle timing indicators were recorded simultaneously. Calibrations of the pressure transducers were recorded at the beginning and end of each analog tape. The unsteady data tapes were digitized and ensemble-averaged off line. At least 50 cycles of data were normally sampled 200 times per cycle; however, for the NACA 0012 airfoil at very low frequencies, that is, k < 0.002, only about 10 cycles were recorded. Reference and calibration signals and the steady pressure data were acquired with the same system and were digitally sampled 100 times over a 5-sec interval. The averaged pressure data were then processed and integrated numerically by trapezoidal rule to determine the unsteady lift, moment, and pressure drag.

End-to-end checks of the data acquisition and processing system indicated that the pressure signals were reproduced to within an rms error of approximately 70 N/m^2 (0.01 psi), and that the transducer calibrations were reliable to better than $\pm 150 \text{ N/m}^2$ (0.02 psi) or $\pm 3\%$ of the reading, whichever was greater, over the range of tunnel speeds and temperatures. The model temperature, measured inside the shells, was closely monitored and not allowed to vary more than 3°C between records of no-flow pressure readings. Transducer zero drift was normally controlled to within the greater value of either $\pm 150 \text{ N/m}^2$ (0.02 psi) or $\pm 5\%$ of free-stream dynamic pressure. However, some exceptions are noted later in this section.

The hot-wire and hot-film signals were recorded as consecutive, separate data frames, and individual cycles of the analog records were examined to determine the boundary-layer characteristics, as discussed in references 4, 10, and 11. For these data, the results from three to eight cycles were averaged to obtain the relative times within the cycle, ωt , at which the various boundary-layer events occurred.

The instantaneous angle of attack was measured with a potentiometer attached to the tubular portion of the model spar (fig. 3). The angle-of-attack signal was calibrated for each data point based on the value of α_1 , which was set by the oscillation linkage, and physical measurements of α_{max} and α_{min} that were obtained from the trailing-edge position relative to the centerline of the tunnel with the wind off. The maximum absolute error in α was estimated to be $\pm 0.2^{\circ}$, with a relative uncertainty of $\pm 0.05^{\circ}$ over the cycle. The maximum torsional deflection of the model at the centerline was calculated to be $\pm 0.3^{\circ}$. Table 1 gives the amplitude and phase of the second harmonic component of α for various nominal values of α_1 . The frequency of the oscillation was maintained and measured to an estimated accuracy of ± 0.03 Hz.

The tunnel dynamic pressure was measured with a conventional pitot-static probe mounted approximately 1.5 m upstream of the model and connected to a pressure transducer and amplifier system with a net accuracy of approximately $\pm 14 \text{ N/m}^2$ (0.002 psi) under steady conditions. The measured values ranged from 90 N/m² (0.013 psi) at $M_{\infty} = 0.04$ to 6200 N/m² (0.90 psi) at $M_{\infty} = 0.3$. The output of this transducer was recorded by hand and on the 32-channel analog tape recorder. An average of these two values, which rarely differed by more than 2%, was used to compute q_{∞} , except in a few cases in the early stages of the test program in which the tape-recorded value was obviously in error and was therefore ignored. The 25-mm-thick ground plane shown in figure 2 caused a 1% reduction in tunnel cross-sectional area between the pitotstatic tube and the model; this was ignored except as noted in connection with the steady lift results presented in section 4 under the heading Static Data.

4

3,

A detailed examination of the digitized data revealed that the 200/cycle sampling of the analog signals was not always synchronized perfectly with the 200/cycle timing indicators. That is, the effective time base of the digitized data was in error, the cumulative effect of which was either to leave a small gap in the data at the end of the cycle or to overlap the 200th sample of a given cycle with the first sample of the next cycle. Consequently, a corrected time base for the digital data arrays was obtained by least-squares curve-fitting a first- and second-harmonic sine wave to the angle-of-attack signal, α . All of the pressure data were then linearly interpolated onto the new time base at 200 even intervals per cycle and stored in new arrays, with the first data point in each array corresponding to $\omega t = 0$. The end result is that the final data appear at the desired times, but suffer an effective "smearing" that would be, at worst, equivalent to sampling at a rate of 100 points per cycle instead of 200 per cycle.

Experimental uncertainty of the airloads- For the purposes of comparing the static and dynamic-stall characteristics of the eight airfoil sections, the absolute accuracy of the measurements and the consequences of wind-tunnel blockage, circulation interference, and sidewall boundary-layer interference are less important than the random experimental errors outlined above. However, an attempt was made to assess all of these, as described below.

The total measurement uncertainty in the pressure, force, and moment coefficients depends on the operating conditions. For example, the probable error in C_p based on the instrumentation characteristics quoted above varies from less than ± 0.07 at $M_{\infty} = 0.3$ and $\alpha = 0$ to about ± 0.4 near the leading edge at $M_{\infty} = 0.11$ and α approaching the stall angle. For most of the static data at $M_{\infty} = 0.3$, the measurement uncertainty is estimated at ± 0.03 for $C_{L_{max}}$, ± 0.005 for C_M , and

 ± 0.0005 for C_D derived from the wake measurements. However, the uncertainty in the SC-1095 lift and moment data is thought to be at least twice as large, because of some unresolved difficulties with the pressure measurements. These values increase with decreasing Mach number, rising by a factor of about 5 in the extreme case $M_{\infty} = 0.035$, where the pressure signals were very small.

Some representative examples of static C_L and C_M versus α are given in figures 9-11, and the primary characteristics of each airfoil at $M_{\infty} = 0.30$ are presented in table 8. The symbols in the figures indicate the individual uncorrected data points, as presented in volume 2 of this report; the shaded bands denote the estimated bounds of the airfoil characteristics. The bounds of the airfoil characteristic include static wind-tunnel-wall corrections according to Allen and Vincenti (ref. 12) and a 1% correction due to the reduction in test-section area at the model caused by the steel plate on the floor of the tunnel (fig. 2). (This wall correction method is only valid below stall, where the corrections are about 1% for α and 1.5% for C_L .) These boundaries were derived based on the measurement uncertainties described above, on data that were obtained with the on-line analog computers, and on the dynamic data obtained at $k \leq 0.01$. It should be noted that the scatter in the data and the uncertainty bounds increase considerably for conditions above the stall angle. The last line in table 8 indicates the experimental uncertainties for the various quantities listed. The static data are discussed further in section 4.

A novel feature of the present experiment was the determination of unsteady pressure drag, $C_D = C_C \cos \alpha + C_N \sin \alpha$, where C_C and C_N are the chordwise and normal force coefficients derived from the upper and lower surface-pressure distributions. The two terms in this expression for C_D are approximately equal and opposite at high angles of attack below stall, so that the probable percentage errors of C_D are much greater than for C_C , C_N , C_L , or C_M . Figure 12 shows a typical static lift-drag polar based on pressure measurements and on the more accurate wake survey of the total drag (table 7). The measured pressure drag, which neglects the contribution due to skin friction, is less than the total drag at low lift coefficients, but it incorrectly exceeds the wake measurements by as much as 0.02 near the stall angle, that is, by as much as 100%. (It may be noted that Woodward (ref. 13) reported similar, unexplained discrepancies between measured pressure drag and C_D based on wake surveys.) However, the percentage errors are much less in the stall regime, where the magnitude of C_C decreases considerably and the maximum drag coefficient becomes of the order of C_L tan α (i.e., of the order of unity) for the deep-dynamic-stall cases studied.

The measurement uncertainty of the unsteady data is probably comparable to that of the static data, but fewer independent checks were available to assess the random experimental errors and the wind-tunnel interference, especially in the post-stall regime. Fromme and Golberg (ref. 14) have indicated that unsteady wall corrections can be greater than the corresponding static corrections, but it is not clear to what extent their potential flow analysis can be applied to the present measurements. Likewise, it is not possible to estimate reliably the post-stall tunnel sidewall effects nor how these vary from one airfoil to another, but tuft flow visualization and experience suggested that these problems became less important as the frequency of oscillation is increased. It is the authors' judgment that for $M_{\infty} \geq 0.2$, the unsteady data in the deep-dynamic-stall regime should be in error by no more than ± 0.2 for C_L , ± 0.05 for C_M , and ± 0.10 for C_D , except as noted in the next section. The results are thought to be about twice this accurate below stall and in light stall, whereas the accuracy was seriously degraded for $M_{\infty} < 0.1$ because of the small values of the pressure signals.

<u>Special cases of questionable accuracy</u>- Despite efforts to monitor the performance of the pressure instrumentation during the test and to control and minimize the measurement uncertainties, various problems sometimes arose that only became evident during the post-test reduction and analysis of the data. In most cases, it was possible to correct these problems on an individual basis, using redundant information or by interpolating in time or space between neighboring values, without significantly compromising the accuracy of the results. In other instances, the measurements appeared to be qualitatively correct, but the experimental uncertainty was likely to have been outside the normal bounds discussed in the previous section. These cases are identified below by data-point or "frame" number.

Frame 10202 for the NACA 0012 airfoil had an unusually large number of random irregularities, a total of 44 in the 5,200 pressure data samples. These were eliminated by linearly interpolating between data at preceding and succeeding time increments. Because some of these irregularities occurred during rapid fluctuations of the flow, the time-histories of part of the pressure data for this particular frame may have been degraded. However, the effect on the integrated force and moment coefficients was probably small.

Table 9 lists the frames for which the "zero" drift of one or more of the transducers appeared to have exceeded by a significant amount the nominal values quoted in the previous section. Also included are the low Mach-number cases for which the no-flow pressure readings taken before and after recording data varied by more than 50% of free-stream dynamic pressure, even though this drift amounted to less than the nominal measurement uncertainty of 150 N/m^2 (0.02 psi). It should be mentioned that in all cases the differences between these pretest and post-test zeros were linearly interpolated with respect to elapsed time to obtain effective zeros for the individual

data frames. In principle, this should have reduced the effects of the transducer drift; however, the actual improvement in the measurement accuracy because of this technique remains unknown.

For the Hughes HH-O2 airfoil, the responses of pressure transducers No. 1 (leading edge) and No. 25 (x/c = 0.0081, lower surface) were rather sluggish, possibly because the orifices were partially clogged. Therefore, the unsteady data from these two transducers are suspect. In calculating the force and moment data for this airfoil, transducer No. 25 was ignored and the pressure integrals

$$C_{N} = -\oint C_{p} dx/c$$
 etc.

were replaced by

 $C_N = -2 \oint C_p \xi d\xi$ etc.

where $\xi = \sqrt{x/c}$, thereby eliminating the influence of transducer No. 1, since $C_{p_1}\sqrt{x_1} = 0$. Another problem with the HH-02 force and moment data is that the trailing-edge transducers were at x/c = 0.925 instead of 0.98, so that the error in extrapolating to x/c = 1.0 is greater for this airfoil. The net effect of these modifications is difficult to assess, but it probably increased the experimental uncertainties for the lift, pressure drag, and pitching moment data by no more than 50%.

The NLR-7301 airfoil had a large amount of concave curvature on the lower surface downstream of x/c = 0.5, which produced larger pressure gradients there than existed on the other airfoils. Therefore, the relatively sparse distribution of pressure transducers in that region may have led to larger errors in determining the forces and moments than the nominal values quoted in the preceding section.

The reduced data for the Sikorsky SC-1095 airfoil under static conditions and at low frequencies consistently exhibited values of maximum lift coefficient and lift-curve slope that appeared to be about 5% too large, based on comparisons with the other airfoils and with the results obtained from the special on-line analog computer described above under Instrumentation. In particular, the comparison with the present NACA 0012 data (fig. 13) contrasts significantly with the steady results of Noonam and Bingham (ref. 15) and Jepson (ref. 16), who found $C_{L_{\alpha}}$ to be approxi-

mately the same for both airfoils. A detailed examination of the present data and the transducer calibrations revealed somewhat erratic performance in a few cases, but no systematic behavior emerged that could explain the apparent problem. Therefore, the conclusion is that the SC-1095 results should be viewed with caution, even though they appear to be qualitatively correct.

Test Conditions

The primary reference conditions for the initial comparisons of the various airfoils were static and deep-dynamic stall at $M_{\infty} = 0.3$, with the nominal unsteady motion given by $\alpha = 10^{\circ} + 10^{\circ}$ sin ωt and $k = \omega c/2U_{\infty} = 0.10$. Limited but systematic variations in Mach number and the unsteady parameters were explored for all airfoils as indicated below and in section 3, where the specific test points are indexed and cross-referenced. 一日二日

ومداهدة والمديد فيراوا مرمه أدر اللاسا والالالا فاعاد

Static data- Pressure measurements were recorded at discrete values of α between -5° and 20° for $M_{\infty} = 0.11$, 0.185, 0.25, and 0.30 for all airfoils except the NACA 0012. In the latter case, static data were recorded only at $M_{\infty} = 0.30$; quasisteady data were obtained for a continuous range of $\alpha = \alpha_0 + 10^\circ$ sin ωt for $k \approx 0.001$ for nine values of M_{∞} between 0.035 and 0.30. A number of the static conditions were repeated with a boundary-layer trip at the leading edge. Wake surveys for static drag were obtained at $M_{\infty} = 0.3$ for α between -5° and the static stall angle.

<u>Unsteady data</u>- The parameters that were varied under dynamic-stall conditions were Mach number, reduced frequency, mean angle, and amplitude of the oscillation. The effect of Mach number was studied between $M_{\infty} = 0.035$ and 0.30, primarily in the deep-stall regime for $\alpha = 15^{\circ} + 10^{\circ} \sin \omega t$ and k = 0.10. In these cases, the Reynolds number also varied, proportional to Mach number, according to the relation Re $\cong 14 \times 10^{6} M_{\infty}$.

The principal ranges of reduced frequency, mean angle, and amplitude were $0.01 \le k \le 0.20$, $\alpha_0 = 10^\circ$ and 15°, and $\alpha_1 = 2^\circ$, 5°, and 10°, respectively; the effects of these parameters were studied primarily at $M_\infty = 0.30$. Additional variations in k and α_0 were effected to achieve specific dynamic effects, such as no stall, stall onset, stall suppression because of unsteady effects, and neutral aero-dynamic damping in pitch.

Finally, additional test points were selected that duplicated some of the conditions of references 3 and 17-19 as closely as possible. A complete list of the unsteady test conditions and descriptions of the parametric variations are given in the following section.

3. GUIDE TO THE DATA

A very large data base was generated in this investigation. As mentioned in the Introduction, summary graphs of the pressure, force, and moment coefficients and selected results from the boundary-layer studies are contained in separate volumes. The airloads data are also stored on digital computer tapes, one for each airfoil, as explained in volume 2. This section describes briefly the data presentations to be found in the subsequent volumes and indicates by test point, or "frame number," the various types of data that are available.

Figure 14 illustrates the format of volume 2 for the unsteady pressure, force, and moment coefficient data, that is, C_L , C_M , and C_D versus α and ωt , and the upper-surface pressure distributions throughout the cycle. Additional information is listed at the top of the graphs. Following the airfoil name is the identification number for each test point. As explained in volume 2, these frame numbers comprise data at a single angle of attack for the steady data, and data at 200 evenly spaced time intervals throughout the cycle for the unsteady cases. The quantities A0 and A1 are the mean value and the first-harmonic amplitude, respectively, of the instantaneous angle of attack, α ; M_{max} is the estimated maximum value of the local Mach number at any time in the cycle, calculated from the classical gas-dynamic equations for steady isen ropic flow and the measured pressure coefficient, $-C_{p_{min}}$

(cf. ref. 2); $\alpha_{L_{max}}$, $\alpha_{C_{min}}$, and $\alpha_{M_{max}}$ are the angles of attack corresponding to maximum lift, minimum chord force (cf. ref. 3), and M_{max} , respectively; and ζ is

.

the aerodynamic damping in pitch. The asterisk on the ordinate of the pressurecoefficient graph represents sonic conditions.

The dotted line in the C_L vs α curve in figure 14 is an approximation to the quasi-static lift behavior for this flow condition, according to the relation

$$C_{L} = A + \frac{B\alpha}{\sqrt{1 - M_{m}^{2}}}$$

where α is in degrees and A and B were obtained from the relevant steady and very low-frequency data, that is, for $k \leq 0.01$. The values of A and B are given in table 10. Finally, it should be mentioned that in contrast to the data in table 8 and the static results presented in section 4 under the heading Static Data, windtunnel wall corrections have not been applied to A and B, to the data in volume 2, nor to the numerical data tapes.

Figure 15 shows two representative examples of the boundary-layer "flow reversal" information contained in volume 3. The abscissa in the figures show the position on the airfoil where the surface instrumentation first indicated a breakdown of the attached boundary-layer flow at the beginning of dynamic stall, as explained and discussed in volume 3 and in references 4, 10, and 11. This event either signifies or is closely associated with the separation that accompanies the beginning stages of dynamic stall. The ordinate indicates the nondimensional time in the cycle, ωt , at which this event occurred.

Tables 11-24 provide a comprehensive summary and index of the entire experimental program. Table 11 lists the frame numbers of all the pressure data, in the sequence in which they appear on the data tapes. The airfoil and pertinent test conditions are also listed, and the conditions for which boundary-layer data were recorded are indicated in the last column. The letter "Y" in the "TRIP" column indicates the use of the boundary-layer trip; "N" denotes the standard smooth condition. The notations "ST" and "US" denote steady and unsteady data, respectively, and the frequency of oscillation in Hertz is given in the column labeled "FREQ."

Table 12 is an index of the steady-data sets, arranged by airfoil and Mach number. The use of a boundary-layer trip is indicated by the letter "T." The notation "Quasi-steady" indicates the data that were acquired on the NACA 0012 airfoil as unsteady data, but at very low frequency, $k \leq 0.002$.

A cross-reference index that groups the unsteady data by types for each of the eight airfoils is given in tables 13-24. There are some duplicate entries in these tables, in order to facilitate the identification of data sets with variations in the individual parameters of the unsteady motion. There are also blank entries, since not all conditions were recorded for all airfoils. The principal types of unsteady conditions are outlined below.

<u>Variations in Mach number</u> – Table 13 lists the test points concerned with the effect of Mach number on deep dynamic stall, for $\alpha = 15^{\circ} + 10^{\circ}$ sin ωt and k = 0.10. Although the NLR-7301 airfoil was only tested at three values of M_{∞} with $\alpha_0 = 15^{\circ}$, it was also tested with $\alpha_0 = 10^{\circ}$ at $M_{\infty} = 0.11$, 0.18, 0.22, and 0.30; these frames are given in table 24. Stall-suppression conditions, tables 19 and 20, and the effects of leading-edge trips, table 23, were studied at $M_{\infty} = 0.18$ and 0.30 for various values of α_0 and k. As stated in section 2 under Test Conditions, the variation of Reynolds number with Mach number was Re $\approx 14 \times 10^{6} M_{\infty}$.

「「「「「「」」」」

<u>Reduced frequency sweeps</u> The test points concerned with the effect of frequency on dynamic stall are given in tables 14-17. These data cover the range $0.01 \le k \le 0.20$ at $M_{\infty} = 0.3$, with mean angles of 10° and 15° and amplitudes of 5° and 10°. In addition, the NACA 0012 airfoil was tested over an extensive range of other values of α_0 (table 24).

<u>Stall onset</u>- This condition, defined in references 1 and 2 as obtaining the maximum possible lift without moment stall occurring at any time throughout the cycle of oscillation, was studied at $M_{\infty} = 0.30$, k = 0.10, $\alpha_1 = 10^\circ$, and variable mean angle, as indicated in table 18.

<u>Stall suppression caused by unsteady effects</u>- With α_1 fixed at 10°, α_0 was varied so that α_{max} was slightly greater than the static-stall angle. Data were then recorded (tables 19 and 20) at various reduced frequencies to study whether stall would diminish or increase with increasing k.

<u>Pitch damping boundaries</u>- Stall conditions relevant to small-amplitude flutter boundaries are listed in table 21, at $\alpha_1 = 2^{\circ}$ and $M_{\infty} = 0.30$. Mean angle and reduced frequency were varied to obtain approximate boundaries of neutral aerodynamic damping in pitch and to obtain the maximum negative value of pitch damping, $-\zeta_{\min}$. However, no data of this type were recorded for the NACA 0012 airfoil.

<u>No separation</u> A limited number of test points were recorded at $M_{\infty} = 0.30$ and $\alpha = 5^{\circ} + 5^{\circ} \sin \omega t$, as indicated in table 22. Some additional conditions for the NLR-1 and NLR-7301 profiles without separation are given in table 24.

<u>Boundary-layer trip</u> Data with the leading-edge trip were obtained statically for α between 0° and 20° and dynamically for $\alpha = 15° + 10°$ sin ωt at two values of Mach number, 0.18 and 0.30. The values of k for the dynamic data are given in table 23; the static data with trip are so indicated in table 12. An exception was the NLR-7301 section at $M_{\infty} = 0.30$, for which $\alpha = 10° + 5°$ sin ωt (table 24). In addition, the NLR-1 section with trip was studied with $\alpha_0 = 2.5°$ (table 24).

<u>Miscellaneous</u>- These test points are included in table 24. In addition to the cases mentioned above, the unsteady test conditions of references 3 and 17 for the NACA 0012, of reference 18 for the Sikorsky SC-1095, and of reference 19 for the NLR-1 airfoil were reproduced insofar as possible. Also, for the Vertol VR-7 airfoil, k was varied from 0.01 to 0.25 at $M_{\infty} = 0.18$ with $\alpha_0 = 10^{\circ}$ and 15° and $\alpha_1 = 10^{\circ}$. Finally, dynamic stall on the NLR-1 profile at negative incidence was studied at $M_{\infty} = 0.30$ for $\alpha = -2^{\circ} + 10^{\circ} \sin \omega t$ and $0.01 \le k \le 0.10$.

<u>Selected test cases</u> Finally, table 25 lists the unsteady data that were proposed in reference 1 as specific test cases for evaluating unsteady viscous flow theories and computational methods. These data were obtained on the NACA 0012, Vertol VR-7, and NLR-7301 airfoils. They include conditions of no-stall, stall-onset, light-stall, and deep-dynamic-stall, all at $M_m = 0.3$.

4. RESULTS AND DISCUSSION

Static Data

The measurements performed under steady or quasi-static flow conditions provide a frame of reference for the dynamic-stall results and a basis for comparison with data from other wind tunnels. Some of the highlights of the static data are presented below, with particular reference to the force and moment coefficients at $M_{\infty} = 0.3$. With the exception of the drag data listed in table 7, wind-tunnel-wall corrections have been applied to all of the static results presented in this section, using the formulae of reference 12.

As noted earlier, table 8 gives a summary of the primary static characteristics of each airfoil at $M_{\infty} = 0.30$, and figures 16-23 show the basic variations of lift, pitching moment, and drag coefficients for the eight sections. The dashed lines in the "a" parts of figures 17-23 represent curve-fits of the lift data in the linear $C_L - \alpha$ regime. The drag data derived from the wake surveys are listed in table 7. In the following discussions, some comparisons are made for each airfoil between the present measurements and data obtained elsewhere.

<u>NACA 0012 airfoil</u>- This profile has been tested by many investigators, with a wide range of results. Figure 24 shows the variation in $C_{L_{max}}$ with Mach number, including results reported or summarized in references 3, 5, 15-17, and 20-24 over a wide range of Reynolds numbers. The present values of $C_{L_{max}}$ increase with increasing Mach number for $M_{\infty} < 0.22$, probably because of the effects of increasing Reynolds number, whereas compressibility effects are thought to be responsible for the decrease in $C_{L_{max}}$ for $M_{\infty} > 0.22$. The boundary-layer trip was found to be relatively unimportant for this airfoil at the Mach and Reynolds numbers of the test.

The present $C_{L_{max}}$ data tend to lie near the upper range of the values from other sources. The same is true for the lift-curve slopes in the linear regime, $C_{L_{\alpha}}$, which is not shown.

<u>Ames A-01 airfoil</u>- Figure 25 compares the data from the present test with measurements made in a transonic wind tunnel at somewhat lower Reynolds numbers (ref. 6) for the A-01 airfoil. Although the lift-curve slopes for $C_{\rm L} < 1.0$ were not significantly different in the two tests, the airfoil stalled at lower angles of attack in the transonic tunnel. Consequently, lower values of maximum lift coefficient were measured and reported in reference 6 at $M_{\infty} = 0.2$ and 0.3, which was near the lower operating limit of that facility.

Wortmann FX-098 airfoil- Maximum-lift data from several investigations (refs. 8, 24-26) are compared with the present data in figure 26 for the FX-098 airfoil. All of the data agree reasonably well over the Mach-number range of the present test. However, there are marked differences at higher Mach numbers.

<u>Sikorsky SC-1095 airfoil</u>- Steady results for this section are shown in figure 27, where the comparison is generally unfavorable. The suspicious nature of the present lift data was mentioned earlier in section 2 under Data Analysis and Measurement Accuracy; here the open circles indicate the present data analyzed in the normal way and the solid symbols represent what are thought to be the true values. The latter, somewhat lower, values are based primarily on the on-line measurements. It should be mentioned that the data of Noonan and Bingham (ref. 15) were obtained on a modified profile with a reflex training edge that reduced C_{M_o} to approximately zero,

compared with the present value of -0.027 at $M_{\infty} = 0.3$ (cf. table 8). Also, the data of Jepson (ref. 16) in figure 27 came from a slotted-wall tunnel with 12.5% porosity, which was thought to yield somewhat lower values of $C_{\rm L}$ than comparable tests in solid-wall tunnels. Furthermore, the Reynolds numbers in references 15 and 16 were

lower than those of the present tests. Nevertheless, the discrepancies in figure 27 seem to be noo large to be attributed to these factors or to measurement uncertainties. It will be shown later that dynamic data on the SC-1095 section are generally in better agreement.

Hughes HH-02 airfoil- Figure 28 shows the measured maximum lift coefficients for the present HH-02 airfoil, in comparison with tata from a section that is almost identical except for a slightly smaller leading-edge radius (ref. 27). Although the Mach number range does not overlap, the two sets of results seem consistent.

<u>Vertol VR-7 airfoil</u>- Results from four sources are plotted in figure 29 for the VR-7 profile. The present data are somewhat higher than those of Coulomb (ref. 28), primarily because the stall occurred at slightly higher angles of attack, but the lift-curve slopes (not shown) and the effect of a boundary-layer trip were approximately the same. The value of $C_{L_{max}}$ at $M_{\infty} = 0.3$ is slightly lower than that of Dadone (ref. 5), whose measurements at higher Mach numbers exceed considerably those of Bingham et al. (ref. 29).

<u>NLR-1 airfoil</u>- Figure 30 shows the good agreement of the present measurements with those of Dadone (ref. 19) for the NLR-1 airfoil. It should be mentioned, however, that the details of the pitching-moment behavior in the vicinity of $C_{L_{\text{max}}}$ (not shown) were somewhat different. As in the previous example, the data of Noonan and Bingham (ref. 24) for $C_{L_{\text{max}}}$ at $M_{\infty} \ge 0.35$ tend to be lower than the data of Dadone (ref. 19). This airfoil appears to be more sensitive to Mach number than any of the other modern helicopter sections.

<u>NLR-7301 airfoil</u>- As shown in figure 31, the maximum static lift for the NLR-7301 airfoil exceeded that of the other sections by a considerable margin; however, C_{M_O} was -0.083 (cf. table 8). The values of $C_{L_{max}}$ shown are also greater than those obtained at NLR under virtually identical conditions (ref. 30). This was obtained at a significantly larger stall angle, more than 1° larger at $M_{\infty} = 0.18$, than in the NLR experiments, apparently because of different boundary-layer separation characteristics and sidewall interferences.

Dynamic Data

Although the static data described above comprised an essential part of the investigation, the primary objective was to obtain a common data base of unsteady characteristics for helicopter applications. In this section some representative examples are presented and comparisons made with other investigations. More complete discussions of the basic phenomena and of the results obtained are given in references 1 and 2.

The unsteady stall-onset and dynamic-stall counterparts of the static $C_{L_{max}}$ results discussed above are shown in figures 32 and 33, reproduced from reference 2 with some minor corrections. The dashed lines in figure 33 indicate the estimated deep-stall $C_{L_{max}}$ for the NLR-7301 airfoil; data were not obtained for this condition for $M_{\infty} > 0.25$. These results have not been corrected for wind-tunnel-wall interference.

12

Figures 32 and 33 illustrate an important general result of the investigation: the parameters of the unsteady motion tend to be more important than the airfoil geometry. For example, the differences in the values of $C_{L_{max}}$ for the Wortmann,

Sikorsky, and Hughes airfoils can hardly be discerned within the experimental uncertainty, but the unsteady stall-onset and deep-stall results are much higher than the static values shown in figures 26-28 and 33. It is also interesting to note that at least for $M \leq 0.25$, the deep-stall $C_{L_{max}}$ values for the NLR-1 and NLR-7301 airfoils

are almost identical. In contrast, the static and unsteady stall-onset results for these two very different profiles are considerably different and represent the lower and upper bounds, respectively, of all the airfoils tested.

In view of the aforementioned scatter in the static results from different wind tunnels, it is logical to inquire how different sets of dynamic data might compare. Because of the large number of parameters that affect dynamic stall and the tendency for past investigators to select different combinations of these parameters, the possibilities for direct comparison of unsteady results are much more limited. However, some examples are given below.

<u>NACA 0012 airfoil</u>- The first comparison for this profile is shown in figures 34 and 35, where data from reference 3 were obtained in the same wind tunnel as the present results, but with a model whose chord was twice as large. Figure 34 shows that the large values of $C_{L_{max}}$ reported in reference 3 were not realized in the present

experiment. Figure 35 shows C_L versus α , where the two results are seen to differ by approximately 10% during the portion of the cycle when α is increasing but before dynamic stall begins. This is approximately the same as the difference in the liftcurve slopes for the corresponding static data, and it is consistent with the differences that would be predicted for static wind-tunnel-wall corrections (ref. 12) for the two chord-to-height ratios. However, it can be inferred from the differences in the peaks of the lift curves in figure 35 that the organized vortex-shedding phenomenon was more pronounced on the larger model after stall began. Also, reattachment of the boundary layer on the downstroke occurred earlier. These do not seem to be solely Reynolds-number effects; rather, it is suspected that in the earlier tests there was excessive interference between the boundary layers on the upper and lower walls of the tunnel and the unsteady viscous flow on the ends of the vertically mounted airfoil.

St. Hilaire and Carta (ref. 17) have reported on dynamic-stall tests of the NACA 0012 airfoil at UTRC under conditions similar to those in the present experiment. Figure 36 compares some of the data from the two investigations. The format and choice of unsteady parameters is based on an extension of the observation in reference 2, that for sinusoidal pitching oscillations the values of α_{max} and the product $\alpha_1 k^2$ seem to be particularly important in determining the detailed time-history of the unsteady airloads during dynamic stall. In order to compare as many test points as possible, data were selected that satisfied the criterion $0.0014 < \alpha_1 k^2 < 0.0022$, where α_1 is in radians. The variations in $C_{L_{max}}$ and $C_{M_{min}}$ ir figure 36 are seen to correlate reasonably well on this basis, and the results from the two sources are in fairly good agreement. Some of the $C_{L_{max}}$ data from the UTRC wind tunnel are slightly higher than the present measurements.

<u>SC-1095 airfoil- Gangwani</u> (ref. 18) has reported data that were obtained on the SC-1095 section in the same facility that was used by St. Hilaire and Carta (ref. 17) to obtain the NACA 0012 data described in the preceding paragraph. The results are

compared with the present data in figure 37, following the same format as above. Fewer data points are available, but the degree of correlation is approximately comparable to that of the NACA 0012 results in figure 36. In contrast with that figure, however, the present values of $C_{L_{max}}$ tend to be slightly higher than the UTRC data (ref. 18). In any case, the discrepancies generally appear to be within the measurement uncertainty, and the agreement is better than for the static results (fig. 27).

<u>NLR-1 airfoil</u>- This profile was tested by Dadone (ref. 19) over a wide range of Mach numbers, mean angles, and amplitudes. Based on the considerations outlined above regarding α_{max} and $\alpha_1 k^2$, his results are compared with the present data in figure 38 as functions of $\alpha_1 k^2$ at a constant value $\alpha_{max} = 20^\circ$, where α_1 is also in degrees. The lift data are in better agreement than in the previous examples, but more scatter appears in the pitching-moment results than before.

No unsteady results from other sources are presently available from other sources for comparison with the data obtained on the Wortmann FX-098, Ames A-01, Hughes HH-02, Vertol VR-7, and NLR 7301 airfoils.

Comments on Wind-Tunnel Effects

It is well known that testing the same airfoil in different wind tunnels often gives different results, especially for the static-stall characteristics. This is borne out in figures 24-31. In fact, if the results from these eight figures were overlaid, the real differences between the individual airfoils would be almost completely obscured by the differences attributable to the test facilities.

Although more limited in scope, the comparisons of dynamic-stall data shown in figures 36-38 are more encouraging than the static results. Since all of these data came from tests with either high aspect-ratio models or sidewall boundary-layer control, this suggests that the present dynamic data may be relatively free of windtunnel-wall contamination and other three-dimensional effects. A detailed examination of the complete time-histories of the unsteady airloads and further studies on models of various aspect ratios would be required to confirm this speculation.

A special feature of the present experiment is that a large number of airfoils were studied over a wide range of unsteady flow conditions in the same facility. This provides the basis for meaningful comparisons, even though wind-tunnel interference effects were not completely negligible. However, as stated in reference 1, it is recommended that the wind-tunnel walls be included or considered in any quantitative uses of the data.

5. SUMMARY AND CONCLUSIONS

A large amount of steady and unsteady data has been obtained on eight airfoil sections over a wide range of test conditions, at Mach numbers up to 0.30. The details of the experimental arrangements, estimates of the measurement accuracy, and the test conditions are described in this volume. Some comparisons are also made with data from other sources. Volume 2 (Pressure and Force Data) presents the results in graphical form and describes the digital computer tapes that contain the extensive numerical data. Volume 3 (Hot-Wire and Hot-Film Measurements) describes the boundary-layer studies performed with surface-mounted hot wires and hot films. The results of the experiment show important differences between airfoils, differences that would otherwise tend to be masked by differences in wind tunnels, particularly in steady cases. All of the airfoils tested offer significant advantages over the standard NACA 0012 profile. In general, however, the parameters of the unsteady motion appear to be more important than airfoil shape in determining the dynamic-stall airloads.

16. Abstract The static and dynamic characteristics of seven helicopter sections and				
a fixed-wing supercritical airfoil were investigated over a wide range of				
nominallyo-dimensional flow conditions, at Mach numbers up to 0.30 and				
Reynolds numbers up to 4×10^6 . Details of the experiment, estimates of mea-				
surement accuracy, and test conditions are described in this volume (the				
first of three volumes). Representative results are also presented and com-				
parisons are made with data from other sources. The complete results for pressure distributions, forces, pitching moments, and boundary-layer separa-				
tion and reattachment characteristics are available in graphical form in				
volumes 2 and 3.				
The results of the experiment show important differences between air-				
foils, which would otherwise tend to be masked by differences in wind tun-				
nels, particularly in steady cases. All of the airfoils tested provide				
significant advantages over the conventional NACA 0012 profile. In general,				
however, the parameters of the unsteady motion appear to be more important				
than airfoil shape in determining the dynamic-stall airloads.
