Abstract

Skin barrier disruption and dermal inflammation are key phenotypes of atopic dermatitis (AD). *Staphylococcus aureus* secretes extracellular vesicles (EVs), which are involved in AD pathogenesis. Here, we evaluated the role of EVs-associated α-hemolysin derived from *S. aureus* in AD pathogenesis. α-hemolysin production from *S. aureus* was detected using western blot analyses. The cytotoxic activity of α-hemolysin on HaCaT keratinocytes was evaluated by measuring cell viability after treating cells with soluble and EVs-associated α-hemolysin. To determine the type of cell death, HaCaT keratinocytes were stained with annexin V and 7-AAD. The *in vivo* effects of α-hemolysin were evaluated by application of soluble and EV-associated α-hemolysin on the mouse skin. The present study showed that increased α-hemolysin was produced by *S. aureus* colonized on AD patients compared to healthy subjects. α-hemolysin production was also related to AD severity. In addition, EV-associated α-hemolysin was more cytotoxic to HaCaT keratinocytes than soluble α-hemolysin, and α-hemolysin-negative EVs did not induce keratinocyte death. EV-associated α-hemolysin induced necrosis, but soluble α-hemolysin induced apoptosis of keratinocytes. *In vivo*, skin barrier disruption and epidermal hyperplasia were induced by soluble and EV-associated α-hemolysin. However, AD-like dermal inflammation was only caused by EV-associated α-hemolysin. Moreover, neither skin barrier disruption nor AD-like skin inflammation was induced by α-hemolysin-negative EVs. Taken together, α-Hemolysin secreted from *S. aureus*, particularly the EV-associated form, induces both skin barrier disruption and AD-like skin inflammation, suggesting that EV-associated α-hemolysin is a novel diagnostic and therapeutic target for the control of AD.

Introduction

Atopic dermatitis (AD) is a chronic inflammatory skin disease that is characterized by eczematous lesions with pruritus and xerosis [1]. AD skin lesions show distinct features, such as disrupted barrier function with epidermal hyperplasia and *Staphylococcus aureus* colonization. In particular, abnormal skin barrier function induced by the death of keratinocytes is one of the major causes in the etiology of AD [2,3,4]. Through the disrupted skin barrier, pathogen-associated antigens and allergens can penetrate the skin and subsequently affect host immune responses. Skin lesions of AD patients show increased keratinocyte cell death induced by immunologic mediators [5,6,7].

S. aureus is a gram-positive bacterium and notorious pathogen that can induce many human diseases [8]. Human skin and nasal anterior are well-known reservoirs of *S. aureus*, and it has been reported that carriage of *S. aureus* is related to allergic diseases. In particular, *S. aureus* is closely related to AD because it colonizes the skin lesions of most AD patients and augments disease severity [9,10]. *S. aureus* affects the host immune system by producing pathogenic molecules and toxins. For example, *S. aureus* produces staphylococcal enterotoxins that can induce excessive T-cell responses, as well as hemolysins, that cause cell death by forming heptameric membrane pores [8,11]. Among these, α-hemolysin (also called as α-toxin) is an important toxin, which kills many types of cells [8,12,13]. It has also been reported that α-hemolysin can target keratinocytes and is related to AD disease severity [14,15].

Recent evidence indicates that *S. aureus* secretes extracellular vesicles (EVs) as well as soluble toxins [16]. EVs derived from *S. aureus* are 20-200-nm vesicular structures that are membrane-enveloped spherical complexes and contain many proteins, DNA, RNA, and toxins. *S. aureus* EVs show potent immunogenicity and are related to AD pathogenesis [17]. Proteome analyses showed

that EVs harbor pathogenic toxins, including α-hemolysin [16]. Thus, we hypothesized that α-hemolysin, particularly the EV-associated form, is a key mediator of AD pathogenesis.

Results

### Comparison of α-hemolysin production between AD patients and healthy subjects

To evaluate the relationship between α-hemolysin production from S. aureus and AD, α-hemolysin levels were measured in culture media of S. aureus from AD patients and healthy controls. All bacteria were cultured under the same conditions and α-hemolysin levels in the culture media were measured by western blot. Although two of six samples of S. aureus from healthy controls produced α-hemolysin, most S. aureus from AD patients (seven of eight) produced it (**Fig. 1, A**). Furthermore, when α-hemolysin production was measured in S. aureus culture media from 90 AD patients, 91% of S. aureus from AD patients were positive for α-hemolysin compared to 33% of healthy controls (**Fig. 1, B and Table 1**). In terms of α-hemolysin production according to AD severity, α-hemolysin production was significantly higher from S. aureus from the severe group compared to S. aureus from the mild and moderate groups (**Fig. 1, C and Table 1**). These findings suggest that α-hemolysin from S. aureus is related to AD disease development and/or progression.

The effect of α-hemolysin on keratinocyte cell death

Numerous reports have shown that α-hemolysin can kill many types of cells, including epidermal keratinocytes [12,13,14]. Because α-hemolysin-producing S. aureus were more frequent in AD patients compared to healthy controls, we evaluated the effect of α-hemolysin on keratinocyte death by measuring cell viability after treatment with bacterial culture media. We found that HaCaT keratinocyte viability was decreased upon treatment with culture media of S. aureus from AD patients compared to healthy controls (**Fig. 1, D**). In addition, we evaluated the effect of S. aureus EVs on HaCaT keratinocyte death. The results indicate that keratinocyte viability was significantly decreased upon treatment with S. aureus EVs from AD patients (**Fig. 1, E**). These findings suggest that α-hemolysin in S. aureus EVs may be an important etiologic agent in AD pathogenesis.

The role of α-hemolysin in S. aureus EVs on keratinocyte cell death

Based on these data, we sought to determine whether S. aureus EVs harbor α-hemolysin, which induces keratinocyte cell death. For these experiments, we used the S. aureus 14458 strain, a reference strain used previously [16,17]. Our data show that α-hemolysin was present in both culture media and EVs from the S. aureus 14458 strain (**Fig. 2, A**). In terms of α-hemolysin hemolytic activity, we found that hemolysis was induced by S. aureus EVs in a dose-dependent manner, as well as by a soluble form of α-

Table 1. Demographic and clinical characteristics of atopic dermatitis patients.

		Mild	Moderate	Severe	Total
		n = 7	n = 37	n = 46	n = 90
Age, months		66.43	51	62	55
(range)		(36–145)	(4–163)	(2–510)	(2–510)
Sex (male: female)		01:02.5	01:01.2	1:01	01:01.1
MRSA (%)		42.8	43.2	28.6	38.9
α-hemolysin (%)[¶]	0	14.3	10.8	6.5	8.9
	1	28.6	48.7	26.1	35.5
	2	42.8	24.3	10.9	18.9
	3	14.3	16.2	56.5	36.7

Values shown are age in months (median), ratio of males versus females, percentage of methicillin-resistant *Staphylococcus aureus*, and percentage of patients colonized with α-hemolysin-producing *S. aureus*.
[¶]The percentage was determined by the amount of α-hemolysin produced by *S. aureus* isolated from the patients. The amount of α-hemolysin was measured by band intensity using Multi Gauge V3.1. Scores are as follows: 0: zero; 1: up to 6000 arbitrary units (AU); 2: from 6001 to 15,000 AU; and 3: over 15,001 AU.
doi:10.1371/journal.pone.0100499.t001

hemolysin (sHla) and the *S. aureus* culture media (**Fig. 2, B and Fig. S1, A**). Next, to evaluate the cytotoxic effect of α-hemolysin on keratinocytes, *S. aureus* EVs were added to HaCaT keratinocytes. Keratinocyte viability was significantly decreased upon treatment with *S. aureus* EVs, *S. aureus* culture media, and sHla compared to PBS alone (**Fig. 2, C**). *S. aureus* EVs and sHla also killed primary human keratinocytes (data not shown). To elucidate the role of α-hemolysin in EVs on keratinocyte cell death, we performed experiments using *S. aureus* strains that produce various amounts of α-hemolysin. We found that the amounts of α-hemolysin in *S. aureus* EVs were positively associated with keratinocyte death (**Fig. S1, B**). Next, to evaluate the effect of α-hemolysin deficiency on keratinocyte death, we isolated EVs from α-hemolysin-positive WT (Newman strain) and α-hemolysin-deficient mutant strains. Cell viability of HaCaT keratinocytes was significantly higher after treatment with *S. aureus* EVs from the α-hemolysin-positive strain compared to the α-hemolysin-negative strain. In addition, keratinocyte death was reversed by treatment with EVs isolated from the α-hemolysin-negative strain that complemented α-hemolysin using a plasmid (**Fig. 2, D**). Furthermore, the results indicate that EVs from α-hemolysin-negative *S. aureus* strains from either AD patients or healthy controls did not induce HaCaT keratinocyte death, whereas death was induced by α-hemolysin-positive *S. aureus* strains from AD patients (**Fig. 2, E**). Taken together, these findings suggest that α-hemolysin in *S. aureus* EVs are a key player in AD pathogenesis via keratinocyte death.

Comparison between soluble and EV-associated α-hemolysin on keratinocyte cell death

Although sHla was reported to act on the plasma membrane of keratinocytes [14], the working mechanism of *S. aureus* EVs on keratinocyte death remains unknown. First, we evaluated the cellular localization of EVs. When fluorescence-labeled EVs were added to HaCaT keratinocytes, EVs were internalized into the cytoplasm (**Fig. 3, A**). In our measurements, EVs contained approximately 0.6 µg of α-hemolysin after treatment with 10 µg of EVs (quantified by total protein amount) (**Fig. S2**). When HaCaT keratinocytes were treated with equal amounts of soluble and EVs forms of α-hemolysin, α-hemolysin in EVs was more effectively delivered into the keratinocytes (**Fig. 3, B**). Furthermore, to compare the cytotoxic effects of EV-associated α-hemolysin and

sHla, HaCaT keratinocytes were treated with equal amounts of α-hemolysin in the soluble and EV forms. This study showed that cytotoxicity was enhanced after treatment with EV-associated α-hemolysin compared to sHla (**Fig. 3, C**). Keratinocyte death was induced faster by EV-associated α-hemolysin versus sHla (**Fig. 3, D**). Together, these findings suggest that compared to sHla, EV-associated α-hemolysin potently induces keratinocyte death.

α-hemolysin localization in *S. aureus* EVs

Generally, secreted soluble toxins are neutralized and lose their activity by engaging the host immune system [18,19,20]. Compared to soluble toxins, EVs may protect toxins by enveloping them with cell membrane. Our data show that EV-associated α-hemolysin remained intact after proteinase K treatment; however, after EVs were disrupted by lysis buffer, EV-associated α-hemolysin was degraded by proteinase K (**Fig. 3, E**). This finding suggests that α-hemolysin is localized in the EV lumen, not on the EV surface. Moreover, when both soluble and EV-associated α-hemolysin were treated with the anti-α-hemolysin antibody, keratinocyte cell death induced by EV-associated α-hemolysin was unaffected, whereas the cytotoxicity induced by sHla was reversed (**Fig. 3, F**). Collectively, these findings suggest that α-hemolysin in the EV lumen enhances killing of keratinocytes and evasion of host immune defenses.

Comparison of cell death mechanisms between EV-associated and soluble α-hemolysin

Although several reports have suggested that sHla induces host cell apoptosis [12,21,22], the exact mechanism of EV-associated α-hemolysin in keratinocyte death is unknown. We found that the morphology of cell death differed between soluble and EV-associated α-hemolysin; HaCaT keratinocytes were rounded and many cells were floating upon sHla treatment, which is indicative of apoptotic cell death; whereas cells underwent cell rupture upon EVs treatment, suggestive of necrosis (**Fig. 4, A**). In accordance with the observed cell morphology, LDH release, a marker of necrosis or cell rupture, was significantly increased after EVs treatment (**Fig. 4, B**). In addition, high-mobility group box (HMGB)-1, another marker for necrosis [23] was detected in culture media of EV-treated HaCaT keratinocytes, but not from that of sHla-treated cells (**Fig. 4, C**). Flow cytometry also showed that the number of 7-AAD-positive cells (necrotic cells) increased
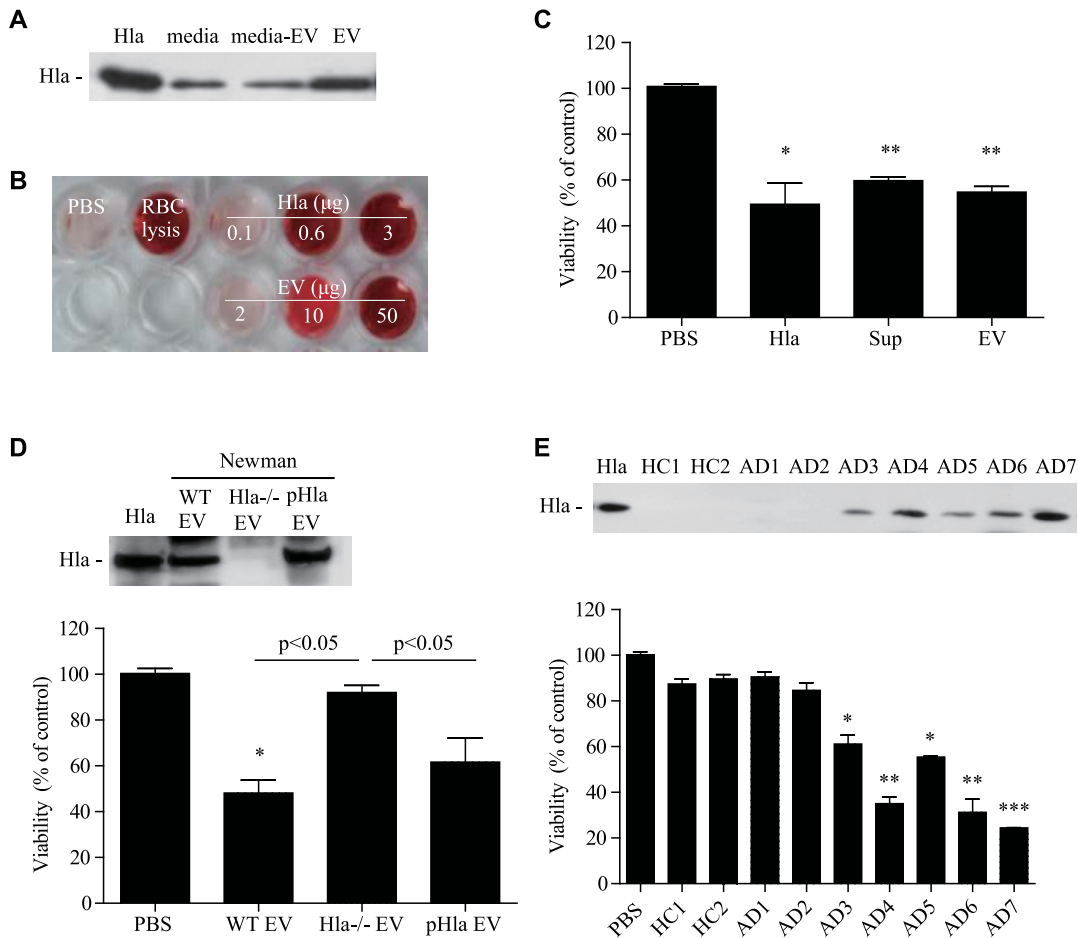

Figure 2. α-Hemolysin in *S. aureus* EVs is a key factor for EVs cytotoxicity. doi:10.1371/journal.pone.0100499.g002

after EVs treatment, whereas annexin V-positive cells (apoptotic cells) increased after sHla treatment (**Fig. 4, D**). To sum up, these findings suggest that EV-associated α-hemolysin induces necrotic cell death by carrying α-hemolysin into the cytoplasm of keratinocytes, whereas sHla induces keratinocyte death via apoptosis.

In vivo effects of EV-associated and soluble α-hemolysin on skin barrier disruption

Because keratinocytes are major constituents of the skin barrier, keratinocyte death is a key contributor of skin barrier disruption in AD pathogenesis [2,5]. To examine the *in vivo* effects of EV-associated α-hemolysin on skin barrier disruption, EVs from α-hemolysin-positive and -negative *S. aureus* strains, as well as sHla, were applied to the back skin of mice. Evans blue dye penetration was enhanced by α-hemolysin-positive EVs or sHla treatment compared to PBS or α-hemolysin-negative EVs treatment (**Fig. 5, A**). Next, we aimed to evaluate the *in vivo* effects of skin barrier disruption on the penetration of high-molecular-weight allergens. Therefore, fluorescein-labeled ovalbumin (OVA) was administered to EV- and sHla-treated skin, and OVA levels were measured in

excised skins by quantification of fluorescein. We found that OVA-fluorescein levels were increased in mice treated with α-hemolysin-positive EVs or sHla compared to α-hemolysin-negative EVs or PBS treatment (**Fig. 5, B**). Together, these findings suggest that both EV-associated and soluble α-hemolysin induce skin barrier disruption via keratinocyte cell death and consequently enhance penetration of high-molecular-weight allergens.

Effects of EV-associated and soluble α-hemolysin on pro-inflammatory mediator production by keratinocytes

Our previous reports showed that *S. aureus* EVs induced pro-inflammatory cytokine production by dermal fibroblasts and airway epithelial cells [17,24]. To evaluate the effect of EV-associated and soluble α-hemolysin on the production of pro-inflammatory mediators from keratinocytes, we measured the production of pro-inflammatory cytokines from HaCaT keratinocytes after treatment with equal amounts of α-hemolysin in the EV and soluble forms. We found that the cytokine production profile differed between EV-associated and soluble α-hemolysin. IL-6 was enhanced by both EV-associated and soluble α-hemolysin, IL-1β was enhanced only by EV-associated α-hemolysin, and TNF-α
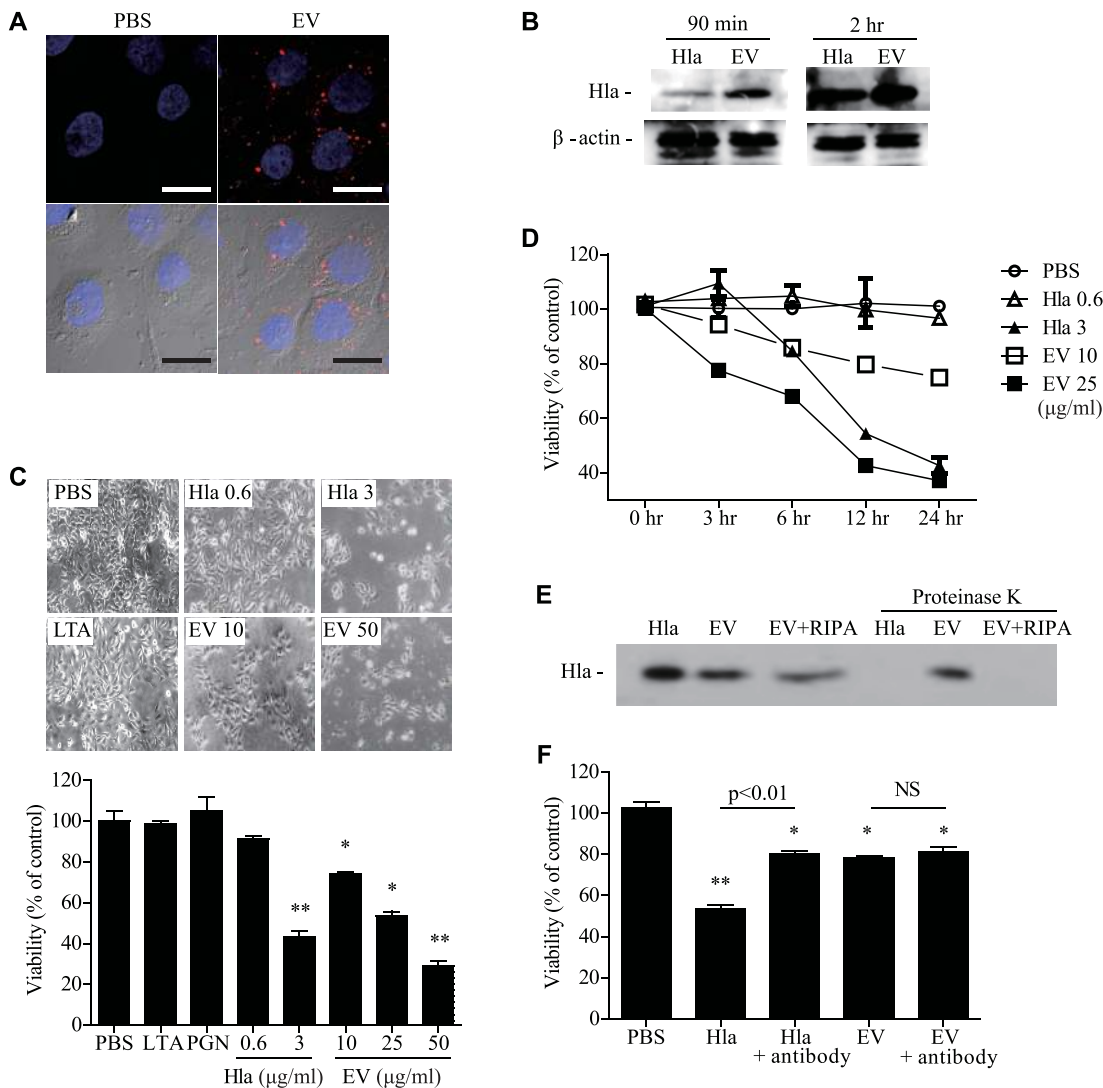

Figure 3. EVs are more potent mediators of keratinocyte death compared to soluble α-hemolysin. doi:10.1371/journal.pone.0100499.g003

was enhanced only by sHla (**Fig. 6, A**). Moreover, IL-1β and IL-6 production by keratinocytes was decreased after treatment with EVs derived from the α-hemolysin-negative *S. aureus* strain compared to the α-hemolysin-positive strain, whereas TNF-α production was enhanced in the former group versus the latter group (**Fig. 6, B**). Collectively, these findings suggest that EV-associated α-hemolysin induces IL-1β and IL-6 production from keratinocytes but may inhibit TNF-α production induced by *S. aureus* EVs or other signals.

Effects of EV-associated and soluble α-hemolysin on the development of AD-like skin inflammation

Finally, we evaluated *in vivo* effects of EV-associated and soluble α-hemolysin on the development of skin inflammation. To do this, the same amounts of α-hemolysin in the EV-associated and soluble forms were administered epicutaneously into the mouse skin and

histological alterations were evaluated. Dermal infiltration of inflammatory cells, particularly eosinophils, was enhanced by EV-associated α-hemolysin but not by sHla. However, both forms of α-hemolysin increased epidermal cell hyperplasia (**Fig. 7, A**). Furthermore, dermal infiltration of inflammatory cells, including eosinophils, and epidermal thickening were reduced in skin treated with repeated applications of α-hemolysin-negative EVs (**Fig. 7, B**). Taken together, our data show that α-hemolysin in *S. aureus* EVs are a key player for the development of AD phenotypes, including epidermal thickening and eosinophilic inflammation in the dermis.

Discussion

If the skin barrier is disrupted, pathogen-associated antigens and allergens can penetrate into the human body. Skin barrier disruption is considered one of the major causes of AD
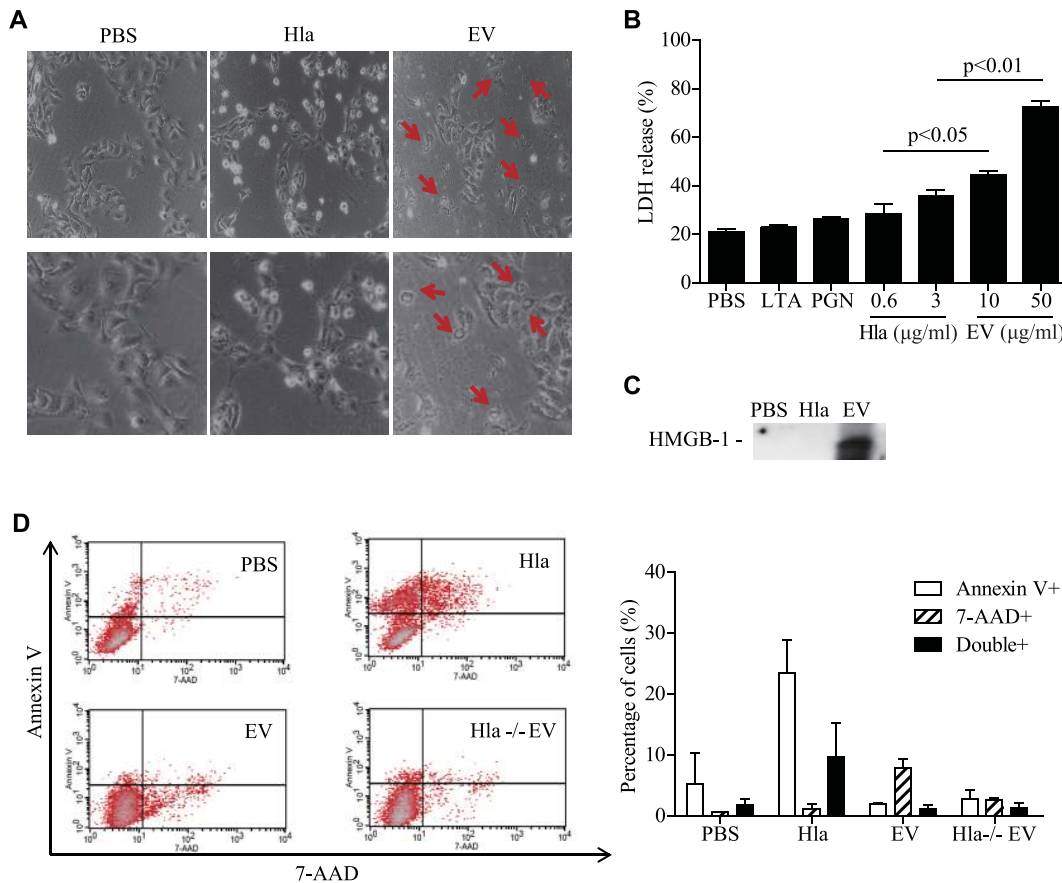

Figure 4. *S. aureus* EVs induces necrotic cell death, in contrast to soluble α-hemolysin. A, Micrographs of cell death by soluble α-hemolysin (3 μg/ml) and EVs (25 μg/ml). doi:10.1371/journal.pone.0100499.g004

exacerbation, but many studies have focused on intrinsic factors, such as host molecules that maintain the skin barrier [4,25]. Though it is known that staphylococcal toxins can affect skin barrier integrity for a long time, the role of α-hemolysin in skin barrier disruption via killing keratinocytes have been reported recently [26,27]. In the present study, we elucidated the role of extrinsic factor (α-hemolysin and EVs) on the development of skin barrier disruption and AD-like inflammation. The present data show that α-hemolysin-producing *S. aureus* had colonized AD patients, and that soluble and EV-associated α-hemolysin induce keratinocyte cell death, consequently enhancing skin penetration of high-molecular-weight allergens. However, EV-associated α-hemolysin was found to induce keratinocyte necrosis, whereas sHla induced keratinocyte apoptosis. Additionally, EV-associated α-hemolysin induced epidermal thickening and eosinophilic inflammation in the dermis, whereas the soluble form induced only epidermal thickening. This is the first report that α-hemolysin in EVs derived from *S. aureus* induces skin barrier disruption and AD-like skin inflammation, predominantly via keratinocyte necrosis and the production of pro-inflammatory mediators by keratinocytes.

S. aureus secretes toxins, including α-hemolysin, as both soluble and EV-associated forms. EV-associated toxins have some advantages in intercellular communication compared to soluble forms. Toxins in the EV lumen, such as EV-associated α-hemolysin, can be protected from clearance by host defense systems, including antibody-mediated neutralization and protease-mediated destruction, enabling toxins to retain their function and travel long distances without interference [28]. In addition, because EVs are membrane-enveloped complexes, they can deliver their contents easily into the cytoplasm by fusing with the host cell membrane or by endocytosis after interaction between ligands on EVs and receptors on host cells [18,29]. Indeed, the present data show that *S. aureus* EVs were internalized into the cytoplasm of keratinocytes and that EVs efficiently delivered α-hemolysin to the cytoplasm. Collectively, these findings suggest that EVs-associated toxins are key molecules in disease pathogenesis.

EVs derived from several bacteria kill host cells by transferring cytotoxic factors [29,30,31]. It was reported that *S. aureus* EVs can induce death of human epidermoid cancer cells [32]. Additionally, recent data indicate that α-hemolysin associated with *S. aureus* EVs can induce death of cervical cancer cells [33]. In addition, the present data showed that EV-associated α-hemolysin can also induce keratinocyte necrosis, whereas the soluble form induces apoptosis. This difference can be partly attributed to the differences in delivery efficacy between EV-associated and soluble α-hemolysin. We can speculate that α-hemolysin can be efficiently delivered by EVs and that a high α-hemolysin concentration in the cytoplasm attacks cell membranes and/or cytoplasm organelles, thereby initiating necrosis pathways.

doi:10.1371/journal.pone.0100499.g007

Cell death via necrosis or apoptosis can result in immunologically distinct consequences [22]. The present data showed that EV-associated α-hemolysin up-regulateed the production of IL-6, a key mediator of Th17 polarization, which is associated with keratinocyte necrosis. In contrast, sHla enhanced the production of TNF-α, but not of IL-6. Our previous data demonstrated that skin exposure to *S. aureus* EVs induced a Th17-cell response in regional lymph nodes and ultimately resulted in AD-like skin inflammation [17]. Together, these findings suggest that *S. aureus* EVs induce skin barrier disruption and Th17-associated inflammation in the dermis via effective delivery of α-hemolysin into keratinocytes.

The expression of toxins from *S. aureus* can be regulated by environmental stress, and also host factors, such as filaggrin production [11,34,35,36]. In the present study, most of *S. aureus* isolated from the skin of AD patients was found to produce α-hemolysin, as soluble and EV-associated forms, which can induce skin barrier disruption. In contrast, we can hardly detect the production of α-hemolysin from *S. aureus* isolated from healthy control subjects. Moreover, the levels of α-hemolysin in lavage fluids from the AD patient skin were found to be positively correlated with AD severity. Because EVs are produced via shedding of bacterial membrane and contain many pathogenic molecules [16,18], it is hard to define the effect of EVs by deleting or adding specific molecules. We can assume that many proteins interact with other proteins and the relationship between various proteins can affect overall characteristics of EVs. Nevertheless, out present findings suggest that α-hemolysin, especially EV-associated form, is a good biomarker for the diagnosis and therapy of AD.

In summary, the present study showed that α-hemolysin, present in the EV lumen, induces skin barrier disruption and AD-like skin inflammation via keratinocyte necrosis and/or up-regulation of pro-inflammatory mediator production from keratinocytes. Moreover, *S. aureus* colonized on AD patient skin secretes α-hemolysin, which is significantly related to AD severity. These findings indicate that α-hemolysin, particularly the EV-associated form, is a novel target for diagnosis and treatment of AD.

Materials and Methods

Ethics statement

This study was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institute of Health. The experimental protocols were approved by the Institutional Animal Care and Use Committee at POSTECH, Pohang, Republic of Korea (Permit Number: 2011-01-0027). All animal experiments were planned in order to minimize mice suffering. The study protocol for human samples was approved by the Ethics Committee of Seoul Suncheonhyang Hospital (Permit Number: 2010-01-0016). Participants provided their written informed consent to participate in the present study.

Mice

SKH-HR1 hairless mice were purchased from Charles River Laboratories Japan, Inc. (Yokohama, Japan) and were bred in a specific-pathogen-free facility at Pohang University of Science and Technology (POSTECH; Pohang, Republic of Korea).

Keratinocytes and bacteria

Immortalized human epidermal keratinocytes (HaCaT cells) were kindly donated by Jeung-Hoon Lee (Chungnam National University, Daejeon, Korea). Primary human epidermal keratinocytes (HEK cells) were purchased from ScienCell (Carlsbad, CA). HaCaT cells were maintained in DMEM (Hyclone Laboratories, South Logan, UT) containing fetal bovine serum (Gibco) and antibiotics (Hyclone Laboratories). ATCC14458 *S. aureus* strain was purchased from ATCC. The Newman strain, α-hemolysin deficient strain, and α-hemolysin complemented strain were kindly provided by Juliane Bubeck Wardenburg (University of Chicago, IL).

S. aureus isolation from human samples

S. aureus was collected from the skin lesions of 90 AD patients visiting the Pediatric Clinic of Seoul Suncheonhyang Hospital (Seoul, Republic of Korea). *S. aureus* from healthy controls was isolated from the skin of the upper limbs and subungual spaces from 36 volunteers who had no AD symptoms.

Isolation of *S. aureus* EVs

S. aureus EVs were obtained as described previously [17]. Briefly, *S. aureus* was cultured in nutrient broth or tryptic soybean broth (Difco, Sparks, MD) at 37°C to an optical density (OD) of 1.5 at 600 nm. Bacteria were removed by centrifugation and filtration. The filtrate was concentrated and the resulting concentrate was filtered and ultracentrifuged at 150,000×g for 3 h. The pellet was resuspended in PBS. *S. aureus*-derived EVs protein concentrations were measured using BCA assays (Thermo Scientific, Rockford, IL). Hereafter, the dose of *S. aureus* EVs refers to the quantity of *S. aureus*-derived EVs proteins.

Cytotoxicity measurements

Keratinocyte viability was measured at 24 h after treatment using thiazolyl blue tetrazolium bromide (MTT) purchased from Sigma Aldrich (St. Louis, MO). The PBS control group was used as 100% viability. Lactate dehydrogenase (LDH) activity in the culture supernatant was measured using the LDH cytotoxicity detection kit purchased from Takara Bio Inc. (Otsu, Japan) according to the manufacturer's instructions.

Hemolysis measurements

Red blood cells (RBCs) were isolated from mouse whole blood. α-Hemolysin (Sigma-Aldrich, USA) and *S. aureus* EVs were added to RBCs and incubated at 37°C. After 1 h, the remaining RBCs were removed by centrifugation and the optical density at 540 nm of the supernatant was measured. RBC lysis buffer was used as a positive control.

Flow cytometry analyses of cell death

Annexin V (BD biosciences) and 7-AAD (Biolegend) were used detect cell death using flow cytometry. Cells were treated with *S. aureus* EVs or α-hemolysin, and cells in the culture supernatant and remaining cells were collected. Cells were processed according to the manufacturer's instructions. Processed cells were analyzed using FACSCalibur (Becton Dickinson, USA).

In vivo assays

For Evans blue dye assays and fluorescein-labeled OVA penetration, gauze soaked with 100-μl PBS containing *S. aureus* EVs or α-hemolysin was placed and secured on mildly tape-stripped skin. Mice were treated five times in 1 week with *S. aureus* EVs and α-hemolysin. Dorsal skin was serially fixed with 30, 50, 70, and 100% methanol. After fixation, 0.1% Evans blue was added for 10 min, followed by washing with PBS. Skin was excised, immersed in formamide, and incubated at 60°C. After 6 h, the optical density at 620 nm was measured. For OVA-fluorescein penetration, 50 μg of fluorescein-conjugated OVA were added twice to *S. aureus* EVs- or α-hemolysin-treated skin. Next, the skin was excised and homogenized. Fluorescence was measured using a Wallac 1420 Victor luminometer (American Instrument Exchange, Inc., Harverville, MA). Skin alterations were evaluated after *S. aureus* EVs and α-hemolysin treatment three times per week for 3 weeks, as reported previously [17].

Statistical analyses

For multiple comparisons, one-way analysis of variance (ANOVA) was used first. If significant differences were found, individual t-tests or Wilcoxon's rank-sum tests were performed between pairs of groups. Differences were considered statistically significant if $P < 0.05$.

Supporting Information

Figure S1 A, Hemolytic activity of EVs and culture media from the ATCC14458 strain and α-hemolysin-deficient EVs strain. Hemolysis mediated by RBC lysis buffer is used as 100%. **B,** The amount of α-hemolysin on EVs from different strains (left panels) and cytotoxicity of EVs on keratinocytes (right panel). ** $P < 0.01$ versus the PBS group.
(EPS)

Figure S2 Quantification of α-hemolysin in EVs. Western blotting showed that 0.6 μg of α-hemolysin was present in 10 μg of EVs protein from the ATCC14458 strain and 0.25 μg of α-hemolysin was present in 10 μg of EVs protein from the Newman strain.
