Abstract

Empirical Bayes methods have, in recent years, been shown to be powerful data-analytic tools. The empirical Bayes model is much richer than either the classical model or the ordinary Bayes model, and often provides superior estimates of parameters. An introduction to some empirical Bayes methods is given, and these methods are illustrated with two examples.

## 1. Introduction

Empirical Bayes methods have been around for quite a long time. Their roots can be traced back to work by von Mises in the 1940's (see Maritz, 1970), but the first major work must be attributed to Robbins (1955), although his formulation is somewhat different from that used here. One might refer to Robbins' formulation as "non-parametric empirical Bayes", while the formulation discussed here can be referred to as "parametric empirical Bayes". The major difference is that the parametric approach specifies a parametric family of prior distributions, while the non-parametric approach leaves the prior completely unspecified. We will deal here only with parametric empirical Bayes methods, and will refer to them simply as "empirical Bayes methods".

Although the idea of a parametric empirical Bayes analysis is not new, the first major work in this area did not appear until the early 1970's, in a series of papers by Efron and Morris (1972, 1973, 1975), and one might rightfully say that they are the founders of modern empirical Bayes data analysis. Efron and Morris (1977) is an excellent, fairly non-technical account of the interrelationship of these methods and the "Stein-effect".

Empirical Bayes methods have become increasingly popular, and have been applied to many types of problems. Some examples are fire alarm probabilities (Carter and Rolph, 1974), revenue sharing (Fay and Herriot, 1979), quality assurance (Hoadley, 1981), and law school admissions (Rubin, 1981). More recently, Morris (1983), has formulated a theory of parametric empirical Bayes inference.

The purpose here is to give a simple introduction to empirical Bayes methods, and illustrate them with two examples.

## 2. Empirical Bayes Estimators for the Normal Case

Suppose we observe  $p$  random variables, each from a normal population with different means but the same known variance, i.e.,

$$X_i \sim n(\theta_i, \sigma^2) \quad i = 1, \dots, p. \quad (2.1)$$

(Think of a balanced one-way analysis of variance, with the  $X_i$  representing the cell means.) The cases of unknown variance, or different sample sizes per cell can also be handled, but here we will stay with this simple case.

The usual, or classical, estimator of  $\theta_i$  is  $X_i$ , the observation (or cell mean). This estimator has many optimality properties (best linear unbiased, maximum likelihood, minimax, etc.), but we can do better.

For the moment, make the Bayesian assumption

$$\theta_i \sim n(\mu, \tau^2) \quad i = 1, \dots, p. \quad (2.2)$$

The Bayes estimate for  $\theta_i$ ,  $\delta^B(X_i)$ , is given by

$$\delta^B(X_i) = \left( \frac{\sigma^2}{\sigma^2 + \tau^2} \right) \mu + \left( \frac{\tau^2}{\tau^2 + \sigma^2} \right) X_i. \quad (2.3)$$

Note that  $\delta^B(X_i)$  is a weighted average of  $\mu$ , the prior estimate, and  $X_i$ , the sample estimate. The weights used in the weighted average depend on the relative sizes of  $\tau^2$  (the prior variance) and  $\sigma^2$  (the sample variance). As  $\tau^2/\sigma^2$  gets smaller, more weight is put on  $\mu$ . Thus, the relative accuracy of the estimates  $X_i$  and  $\mu$  determines how much weight they receive in the weighted average.

$\delta^B(X_i)$  is the Bayes estimate because it is the mean of the posterior distribution, the distribution of  $\theta_i$  given  $X_i$ , denoted by  $\pi(\theta_i | X_i)$ . A standard calculation shows that

$$\pi(\theta_i | X_i) \sim n\left(\delta^B(X_i), \sigma^2 \tau^2 / (\sigma^2 + \tau^2)\right) \quad i = 1, \dots, p. \quad (2.4)$$

The empirical Bayesian agrees with the Bayes model, but refuses to specify values for  $\mu$  and  $\tau^2$ . Instead, he estimates these parameters from the data. All the information about  $\mu$  and  $\tau^2$  is contained in the marginal distribution of  $X_i$  (unconditional on  $\theta_i$ ), and another standard calculation shows that this marginal distribution,  $f(X_i)$ , is given by

$$f(X_i) \sim n(\mu, \sigma^2 + \tau^2) \quad i = 1, \dots, p. \quad (2.5)$$

Thus, unconditionally, we can regard the  $X_i$ 's as coming from the same population. This assumption was already implicit in the Bayes model, since each  $\theta_i$  had the same prior distribution. In many cases this assumption is also quite reasonable - think of a one-way analysis of variance where the treatments are defined by levels of a particular factor. It is reasonable to assume that there is some distant, underlying similarity in the responses.

Using (2.5), we can construct estimates of the Bayes quantities in (2.3). In particular, we have

$$E(\bar{X}) = \mu, \quad E\left(\frac{(p-3)\sigma^2}{\Sigma(X_i - \bar{X})^2}\right) = \frac{\sigma^2}{\sigma^2 + \tau^2}, \quad (2.6)$$

where the expectation is taken over the marginal distribution of the  $X_i$ 's. From (2.6), we have unbiased estimators of the Bayes quantities in (2.3), and we can construct an empirical Bayes estimator of  $\theta_i$  by replacing these quantities by their estimates. Thus, an empirical Bayes estimator of  $\theta_i$ ,  $\delta_i^E(X)$ , is given by

$$\delta_i^E(X) = \left(\frac{(p-3)\sigma^2}{\Sigma(X_i - \bar{X})^2}\right)\bar{X} + \left(1 - \frac{(p-3)\sigma^2}{\Sigma(X_i - \bar{X})^2}\right)X_i. \quad (2.7)$$

Note that  $\delta_i^E$  uses information from all the  $X_i$ 's when estimating each  $\theta_i$ . This takes advantage of what has come to be known as the "Stein Effect" (see Stein (1981) or Berger (1982), for example). Simply put, the Stein Effect asserts that estimates can be improved by using information from all coordinates when estimating each coordinate.

The empirical Bayes estimator  $\delta_i^E(X)$  is quite a good estimator of  $\theta_i$ . We will see later how it performs on data, but it also has an extremely appealing theoretical property: on the average, it is always closer to  $\theta_i$  than  $X_i$ . We can measure the worth of an estimator  $\delta_i$  by considering  $\Sigma(\theta_i - \delta_i)^2$ , the sum of the

squared differences between the estimator and the parameter. If  $p \geq 3$ , it is true that

$$E\left(\sum_{i=1}^p (\theta_i - \delta_i^E(X))^2\right) < E\left(\sum_{i=1}^p \theta_i - X_i\right)^2, \text{ for all } \theta_i, \quad (2.8)$$

where, here, the expectation is over the distribution of  $X_i$  given  $\theta_i$ ,  $X_i \sim n(\theta_i, \sigma^2)$ . In this sense,  $\delta_i^E(X)$  is always closer to  $\theta_i$  than  $X_i$ . (For a rigorous proof of (2.8), see Efron and Morris, 1973.)

The quantities in (2.8) are called the Mean Squared Error (MSE) of the respective estimators, and are functions of  $\theta$  and  $\sigma^2$  only through the quantity  $\sum_{i=1}^p \theta_i^2 / \sigma^2$ . From Figure 1, it is fairly obvious that the empirical Bayes estimator has the most desirable MSE.

Figure 1: Mean squared error of the usual estimator,  $X$ , the Bayes estimator,  $\delta^B$ , and the empirical Bayes estimator,  $\delta^E$ .

### 3. Some Empirical Bayes Intuition

There is a very nice intuitive justification of the empirical Bayes estimator of (2.7) in the one-way analysis of variance. Suppose that there are five treatments. Let  $X_1, \dots, X_5$  represent observed cell means, and  $\theta_1, \dots, \theta_5$  represent true cell means. The ANOVA F-test tests the hypotheses

$$H_0: \text{all } \theta_i \text{'s equal} \quad \text{vs.} \quad H_A: \text{not } H_0. \quad (3.1)$$

We can regard these hypotheses as two extremes: if  $H_0$  is true then we should estimate each  $\theta_i$  with  $\bar{X} = \Sigma X_i / 5$  (since all the  $\theta_i$ 's are equal), while if  $H_A$  is true we should estimate each  $\theta_i$  with  $X_i$ . The empirical Bayes estimator, given in (2.7), is a compromise between these two extremes, as seen in Figure 2.

Figure 2: The empirical Bayes estimator in the one-way ANOVA.

Note how the empirical Bayes estimator affects the extreme means ( $X_1$  and  $X_5$ ) much more than it affects the means that are close to  $\bar{X}$ . In most cases this type of shrinkage will improve the estimate of  $\theta_i$ : the extreme cell means are often overestimates or underestimates. One might say that the empirical Bayes estimator "anticipates regression to the mean".

The amount of shrinkage in the empirical Bayes estimator is directly related to the F-statistic that tests the ANOVA null hypothesis. If there are  $p$  treatments, the F-statistic is

$$F = \frac{\Sigma(X_i - \bar{X})^2 / (p - 1)}{\hat{\sigma}^2}, \quad (3.2)$$

where  $\hat{\sigma}^2$  estimates  $\sigma^2$ . Since here we are dealing with known  $\sigma^2$ , the ANOVA null hypothesis would be tested by

$$T = \frac{\Sigma(X_i - \bar{X})^2 / (p - 1)}{\sigma^2} \sim \chi_{p-1}^2, \quad (3.3)$$

and large values of  $T$  would lead to rejection of  $H_0$ : all  $\theta_i$ 's equal. Using (3.3), the empirical Bayes estimator of (2.7) can be written

$$\delta_i^E(X_i) = \left(\frac{p-3}{p-1}\right)T^{-1}\bar{X} + \left(1 - \left(\frac{p-3}{p-1}\right)T^{-1}\right)X_i. \quad (3.4)$$

As  $T$  gets large (and the data support  $H_A$ ),  $\delta_i^E(X_i)$  puts more weight on  $X_i$  and less on  $\bar{X}$ . Thus,  $\delta_i^E(X_i)$  puts more weight on the estimate ( $X_i$  or  $\bar{X}$ ) which seems most reasonable based on the evidence from all the data.

#### 4. Examples of Empirical Bayes Estimates

The following two examples were chosen because, in both cases, the parameter values were available. Thus, it is possible to directly assess the performance of the estimators.

Example 1: Estimating Batting Averages

Efron and Morris (1975) report the batting averages of 18 major league baseball players after their first 45 at bats. The problem is to estimate their final batting average. For simplicity, here we will only consider a subset of their data, consisting of seven players selected to be illustrative. (The highest, lowest, and five others at random were chosen.)

It is reasonable to assume that each time at bat is a binomial trial, with success probability equal to the player's true batting average. With 45 trials, the normal approximation seems reasonable. (Actually, the arcsin-square root transformation was performed on the data, and the data were then recentered to resemble batting averages. The variance attached to each player's observed average is  $(.0659)^2$ .)

Thus, we can model each observed batting average,  $X_i$ , by

$$X_i \sim n(\theta_i, \sigma^2) \tag{4.1}$$

where  $\theta_i$  = true batting average and  $\sigma^2 = (.0659)^2$ . We then use the Bayes prior,  $\theta_i \sim n(\mu, \sigma^2)$ , and construct the empirical Bayes estimator as indicated in Section 2. The data, calculations, and final batting averages (true  $\theta_i$ ) are given in Table 1.

Table 1: Baseball Data

	$X_i$ (Observed batting average)	$\theta_i$ (Final batting average)	$\delta_i^E(X)$ (Empirical Bayes estimate)
1	.395	.346	.341
2	.355	.279	.321
3	.313	.276	.300
4	.291	.266	.289
5	.247	.271	.266
6	.224	.266	.255
7	.175	.318	.230
MSE	1.084		.355

$$\bar{X} = .286 \qquad \Sigma(X_i - \bar{X})^2 = .035 \qquad \frac{4\sigma^2}{\Sigma(X_i - \bar{X})^2} = .495$$

$$\delta_i^E(X) = (.495)(.286) + .505X_i = .142 + .505X_i$$

The empirical Bayes estimators are closer to the  $\theta_i$ 's than the classical estimators, the  $X_i$ 's. The improvement in mean squared error is quite remarkable,  $.355/1.084 = .327$ , meaning a 67% reduction in mean squared error. (Here we have scaled the MSE, so, for example,  $1.084 = \Sigma(X_i - \theta_i)^2/7\sigma^2$ . Of course, this does not affect the comparisons with the empirical Bayes estimator.)

The empirical Bayes estimator performed well because it "anticipated regression toward the mean". The player who was batting .395 after 45 at bats was doing unusually well ("playing above his head"), and it would be unreasonable to expect him to continue at such a pace. Notice also that both  $X_i$  and  $\delta_i^E$  failed miserably on player 7, who had (for him) an unusually poor start. (An explanation for this failure may be the fact that player 7 was Thurmon Munson, and these data were taken in his rookie year. Munson went on to become a consistently excellent ball player.)

A graphical display, as in Figure 2, will serve to further support the claim that regression toward the mean is a very real effect. Examining Figure 3, and noting how close together the  $\theta_i$ 's are (compared to the  $X_i$ 's and even the  $\delta_i^E$ 's), shows that the empirical Bayes estimates are vastly superior to the usual ones.

#### Example 2: Assessing Consumer Intent

This example was not only chosen because the parameters were available, but also to illustrate the empirical Bayes technique for distributions other than the normal distribution. The data is taken from Juster (1966), and has also been analyzed by Morrison (1979), using techniques outlined by Sutherland *et al.* (1975). In fact, Morrison uses some highly sophisticated empirical Bayes techniques, and obtains even better estimates than those presented here.

The problem here is to estimate the probability that a consumer will purchase a given product, given his stated probability (intent) of such an event. Here we

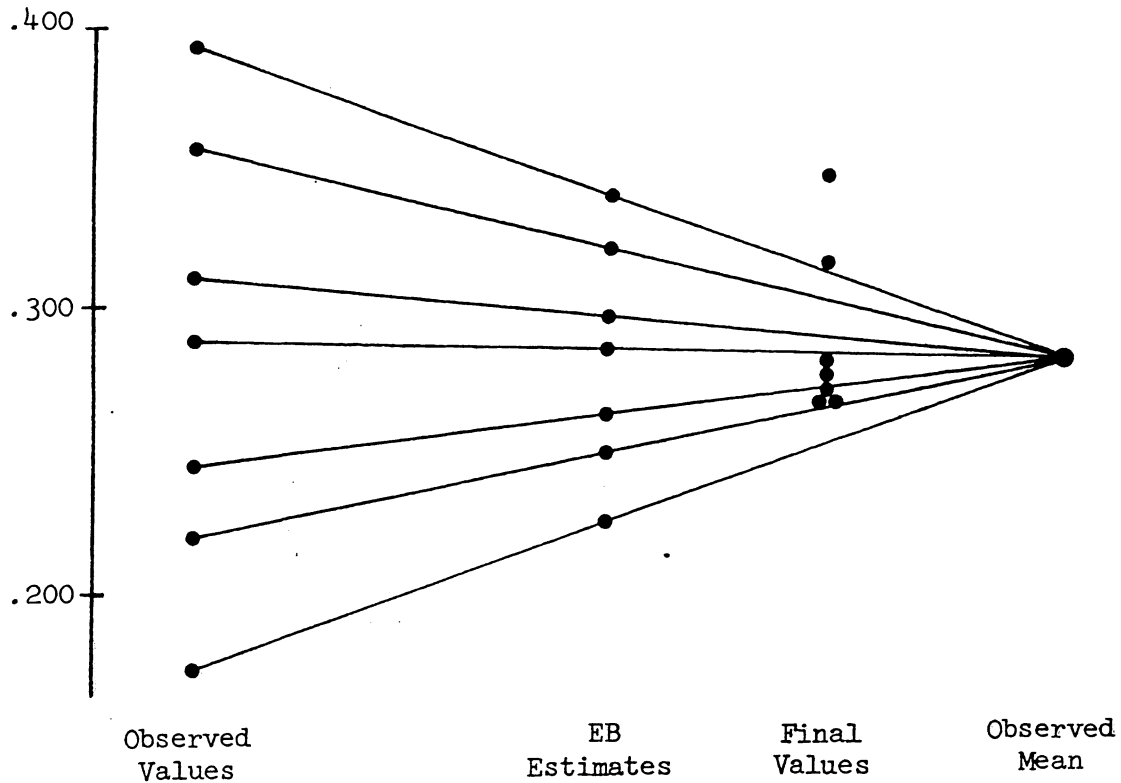

Figure 3: Graphical Display of the Baseball Data.

will concentrate only on a portion of Juster's data, where 447 randomly selected people were asked the question:

Taking everything into account, what are the prospects that you or some member of your family will buy a car sometime during the next 12 months?

Certain	(10 in 10)
Almost Sure	(9 in 10)
Very Probably	(8 in 10)
⋮	
Very Slight Possibility	(1 in 10)
No Chance	(0 in 10)

The distribution of responses is given in Table 2.

Table 2: Consumer Intent Data

	Intent										
	0	.1	.2	.3	.4	.5	.6	.7	.8	.9	1
#Responses	293	26	21	21	10	9	12	13	11	10	21
		.19			.51			.79			

The data were grouped by Juster (as indicated in Table 2) in order to increase the sample sizes. The weighted average of these groups is also given in Table 2. This grouping was also used by Morrison, and will be used here. Thus, we are dealing with five intent groups.

Before proceeding to a formal model, it should be noticed that these data should almost certainly be shrunk toward their mean. It is quite unreasonable to assume that none of the 293 people in the zero intent group will buy a car; thus, 0 is certainly an underestimate of the intent. The same type of argument applies to group with intent = 1.

The model for these data, used by Morrison and others, is that  $I_i^S$ , the stated intent of person  $i$ , can be modeled as a binomial random variable with  $n = 10$  and  $p = I_i^T$ , the true intent. That is,

$$I_i^S \sim \text{binomial}(10, I_i^T) . \tag{4.2}$$

The justification for this model is that an individual with true intent  $I^T$  responds 0 or 1 in an independent fashion to each point on the intent scale with probabilities  $I^T$  and  $1 - I^T$ , respectively. The stated intention is then the sum of these 0,1 responses.

While this model may sound strange, it has been widely used, and justified, in both marketing and psychology literature (Morrison, 1979). From a practical

point of view, it also seems to work rather well.

There is a minor problem with scaling, in that the stated intention is on a 0-1 scale, and the modeled intention is on a 0-10 scale. This can, of course, be handled rather easily, and here we will not go into such details.

The empirical Bayes model also specifies that

$$I_i^T \sim \text{Beta}(\alpha, \beta), \quad (4.3)$$

i.e., the true intentions are drawn from a Beta distribution with parameters  $\alpha$  and  $\beta$ . Note that the  $I_i^T$ 's are specified to have a common distribution, which will, to a certain extent, take into account the fact that the stated intentions are somewhat related.

Under the model (4.2) and (4.3), the Bayes estimate of  $I_i^T$  is given by

$$\hat{I}_i^T = \left( \frac{\alpha}{\alpha + \beta} \right) \left( \frac{\alpha + \beta}{\alpha + \beta + 1} \right) + \left( 1 - \frac{\alpha + \beta}{\alpha + \beta + 1} \right) I_i^S, \quad (4.4)$$

where, here and hereafter,  $I_i^S$  will be taken to be on the 0-1 scale. The marginal distribution of  $I_i^S$  (unconditional on  $I_i^T$ ) is the negative hypergeometric distribution, sometimes called the Beta-Binomial. The exact form is not important here, because we will only use the facts that, unconditionally,

$$\begin{aligned} E(I_i^S) &= \frac{\alpha}{\alpha + \beta} \\ \text{Var}(I_i^S) &= \frac{1}{10} \left( \frac{\alpha}{\alpha + \beta} \right) \left( 1 - \frac{\alpha}{\alpha + \beta} \right) \left( \frac{\alpha + \beta + 10}{\alpha + \beta + 1} \right). \end{aligned} \quad (4.5)$$

(See Kendall and Stuart, Vol. 1, 1977, for more information on the Beta-Binomial distribution.)

Using (4.5) and the method of moments,  $\alpha$  and  $\beta$  can be estimated. From the full data set in Table 2, we have  $\bar{I}^S = .172$ ,  $\widehat{\text{Var}}(I^S) = .091$ . Equating these to the expressions in (4.5), we can solve for  $\alpha$  and  $\beta$ , and get  $\hat{\alpha} = .25$ ,  $\hat{\beta} = .43$ . These yield the empirical Bayes estimate

$$\hat{I}_i^T = (.172)(.405) + (.595)I_i^S, \quad (4.6)$$

which can be seen, once again, to be a weighted average of the grand mean (.172) and the individual intention.

The 447 people in the sample were contacted after the time period, and it was found out whether or not a car had been purchased. Thus, the parameter values are known. These values, together with the usual estimates (observed intent) and empirical Bayes estimates, are given in Table 3.

Table 3: Consumer Intent Estimates and Parameters

<u>Intent Group</u>	<u>Observed Intent</u>	<u>True Intent</u>	<u>Empirical Bayes Estimate</u>
0	0	.07	.07
.1 - .3	.19	.19	.18
.4 - .6	.51	.41	.37
.7 - .9	.79	.48	.54
1	1	.53	.67
MSE	.729		.055

(MSE scaled by  $\hat{\sigma}^2 = .091$ )

As expected, the empirical Bayes estimates are far superior to the observed intent, yielding a 93% improvement in mean squared error. Notice how the parameter values are much closer together than the observed intent, the phenomenon anticipated by the empirical Bayes estimates. In fact, the regression toward the mean was even more pronounced than predicted by the empirical Bayes estimates.

Table 3 shows that the empirical Bayes estimates perform remarkably well but, seen in another light, their performance is quite startling. From (4.4) and (4.6) it can be seen that we are using estimates of  $I_i^T$  which are linear functions of  $I_i^S$ . Since we now have the parameter values, we can see what the best linear predictor is (in practice, this can never be done). A linear regression of the true intent on the stated intent yields the line  $.10 + .47I_i^S$  as the best possible

linear predictor. Compare this to the empirical Bayes line  $.07 + .595X$ , and it can be seen that the empirical Bayes line is incredibly close to the best possible (but always unattainable) line. Imagine doing a regression of  $y$  on  $x$  without any  $y$  values! Figure 4 illustrates this graphically.

Figure 4: Comparison of the Empirical Bayes Line with the Best Possible Line.

Finally, the empirical Bayes method can tell us something about the prior distribution, and such information can be useful, particularly if future studies are to be done. Recall that our estimates of  $\alpha$  and  $\beta$ , the prior parameters, were .25 and .43, respectively. Figure 5 is a graph of the Beta distribution with these parameter values. As one can see, the greatest concentration of mass is

Figure 5: The Beta density function,  $\alpha = .25$ ,  $\beta = .43$ .

near the ends of the intervals, with the distribution being fairly flat in the middle. Since the Beta distribution can have virtually any shape (U-shape, bell-shape, symmetric or asymmetric), it is interesting that the empirical prior is an asymmetric U-shaped distribution. Since the empirical Bayes estimator produced such good estimates, it is reasonable to infer that this U-shaped prior is a reasonable approximation to the true prior distribution. Thus, one would expect a population's true intents to be clustered near 0 or 1, with a small portion (approximately 30%) uniformly distributed between .2 and .8.
