Abstract

We discuss two inverse free, highly parallel, spectral divide and conquer algorithms: one for computing an invariant subspace of a nonsymmetric matrix and another one for computing left and right deflating subspaces of a regular matrix pencil $A - \lambda B$. These two closely related algorithms are based on earlier ones of Bulgakov, Godunov and Malyshev, but improve on them in several ways. These algorithms only use easily parallelizable linear algebra building blocks: matrix multiplication and QR decomposition. The existing parallel algorithms for the nonsymmetric eigenproblem use the matrix sign function, which is faster but can be less stable than the new algorithm.

1 Introduction

We are concerned with the following two computational problems.

1. For a given $n \times n$ nonsymmetric matrix A , we want to find an invariant subspace \mathcal{R} (i.e. $A\mathcal{R} \subseteq \mathcal{R}$) corresponding to the eigenvalues of A in a specified region \mathcal{D} of the complex plane. In other words, we want to find a unitary matrix $Q = (Q_1, Q_2)$ with $\mathcal{R} = \text{span}\{Q_1\}$ such that

$$Q^H A Q = \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix}, \quad (1.1)$$

where the eigenvalues of A_{11} are the eigenvalues of A in \mathcal{D} . We shall call this problem an *(ordinary) spectral divide and conquer (SDC) problem*.

2. A *regular* matrix pencil $A - \lambda B$ is a square pencil such that $\det(A - \lambda B)$ is not identically zero. Given such an n by n nonsymmetric pencil, we want to find a pair of left and right deflating subspaces \mathcal{L} and \mathcal{R} (i.e. $A\mathcal{R} \subseteq \mathcal{L}$ and $B\mathcal{R} \subseteq \mathcal{L}$) corresponding to the eigenvalues of the pair $A - \lambda B$ in a specified region \mathcal{D} on complex plane. In other words, we want to find a unitary matrix $Q_L = (Q_{L1}, Q_{L2})$ with $\mathcal{L} = \text{span}\{Q_{L1}\}$ and a unitary matrix $Q_R = (Q_{R1}, Q_{R2})$ with $\mathcal{R} = \text{span}\{Q_{R1}\}$, such that

$$Q_L^H A Q_R = \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix} \quad \text{and} \quad Q_L^H B Q_R = \begin{pmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{pmatrix}, \quad (1.2)$$

where the eigenvalues of $A_{11} - \lambda B_{11}$ are the eigenvalues of $A - \lambda B$ in the region \mathcal{D} . We shall call this problem a *generalized spectral divide and conquer (SDC) problem*.

The region \mathcal{D} in the above problems will initially just be the interior (or exterior) of the unit disk. By employing Möbius transformations $((\alpha A + \beta B)(\gamma A + \delta B)^{-1})$ and divide-and-conquer, \mathcal{D} can be the union of intersections of arbitrary half planes and (complemented) disks, and so a rather general region. We will assume that the given matrix A or matrix pencil $A - \lambda B$ has no eigenvalues on the boundary \mathcal{D} (in practice this means we might enlarge or shrink \mathcal{D} slightly if we fail to converge).

The nonsymmetric eigenproblem and its generalized counterpart are important problems in numerical linear algebra, and have until recently resisted attempts at effective parallelization. The standard serial algorithm for the spectral divide and conquer problem is to use the QR algorithm (or the QZ algorithm in the generalized case) to reduce the matrix (or pencil) to Schur form, and then to reorder the eigenvalues on the diagonal of the Schur form to put the eigenvalues in \mathcal{D} in the upper left corner, as shown in (1.1) and (1.2) (see [7] and the references therein). The approach is numerically stable, although in some extremely ill-conditioned cases, the swapping process may fail¹. However the approach seems to be too fine grain to parallelize successfully [22].

There are two highly parallel algorithms for the spectral divide and conquer problem, those based on the *matrix sign function* (which we describe in section 3), and *inverse free methods* based on original algorithms of Bulgakov, Godunov and Malyshev [30, 14, 41, 42, 43], which are the main topic of this paper. Both kinds of algorithms are easy to parallelize because they require only large matrix operations which have been successfully parallelized on most existing machines:

¹Recently Bojanczyk and Van Dooren [11] have found a way to eliminate this possibility, although the theoretical possibility of nonconvergence of the QR algorithm remains [8].

matrix-matrix multiplication, QR decomposition and (for the sign function) matrix inversion. The price paid for the easy parallelization of these algorithms is potential loss of stability compared to the QR or QZ algorithms; they can fail to converge in a number of circumstances in which the QR and QZ algorithms succeed. Fortunately, it is usually easy to detect and compensate for this loss of stability, by choosing to divide and conquer the spectrum in a slightly different location.

In brief, the difference between the sign-function and inverse-free methods is as follows. The sign-function method is significantly faster than inverse-free when it converges, but there are some very difficult problems where the inverse-free algorithm gives a more accurate answer than the sign-function. This leads us to propose the following 3-step algorithm [21, 24]:

1. Try to use the matrix sign-function to split the spectrum. If it succeeds, stop.
2. Otherwise, if the sign-function fails, try to split the spectrum using the inverse-free algorithm. If it succeeds, stop.
3. Otherwise, if the inverse-free methods fails, use the QR (or QZ) algorithm.

This 3-step approach can work by trying the fastest but least stable method first, falling back to slower but more stable methods only if necessary.

This paper is primarily concerned with the algorithms based on the pioneering work of Godunov, Bulgakov and Malyshev [30, 14, 41], in particular on the work of Malyshev [42, 43]. We have made the following improvements on their work:

- We have eliminated the need for matrix exponentials, thus making their algorithms truly practical. By expressing the algorithms for computing the ordinary and generalized spectral divide and conquer decompositions in a single framework, we in fact show it is equally easy to divide the complex plane along arbitrary circles and lines with the same amount of work.
- Our error analysis is simpler and tighter. In particular, our condition number can be as small as the square root of the condition number in [42], and is precisely the square of the reciprocal of the distance from $A - \lambda B$ to a natural set of ill-posed problems, those pencils which have an eigenvalue on the unit circle.
- We have simplified their algorithms by eliminating all inversions and related factorizations.
- We propose a realistic and inexpensive stopping criterion for the inner loop iteration.

Many simplifications in these algorithms are possible in case the matrix A is symmetric. The PRISM project, with which this work is associated, is also producing algorithms for the symmetric case; see [10, 9, 37, 5, 40] for more details.

The rest of this paper is organized as follows. In section 2 we present our two algorithms for the ordinary and generalized spectral divide and conquer problems, discuss some implementation details and options, and show how to divide the spectrum along arbitrary circles and lines in the complex plane. In section 3, we compare the cost of the new algorithms with the matrix sign function based algorithms. In section 4, we explain why the new algorithms work, using a simpler explanation than in [42]. Section 5 derives a condition number, and section 6 uses it to analyze convergence of the new algorithms. Section 7 does error analysis, and section 8 contrasts our bounds to those

of Malyshev [42]. Section 9 discusses the stopping criterion of the new algorithms. Section 10 presents numerical examples, section 11 lists open problems, and section 12 draws conclusions.

Throughout this paper we shall use the notational conventions in [31]: Matrices are denoted by upper case italic and Greek letters, vectors by lower-case italic letters, and scalars by lower-case Greek letters or lower-case italic if there is no confusion. The matrix A^T is the transpose of A , and A^H is the complex conjugate transpose of A . $\|\cdot\|$, $\|\cdot\|_F$, and $\|\cdot\|_1$ are the spectral norm, Frobenius norm, and 1-norm of a vector or matrix, respectively. The condition number $\|A\| \cdot \|A^{-1}\|$ will be denoted $\kappa(A)$. $\lambda(A)$ and $\lambda(A, B)$ denote the sets of eigenvalues of the matrix A and the matrix pencil $A - \lambda B$, respectively. $\text{span}\{X\}$ is a subspace spanned by the columns of the matrix X . $\det(A)$ is the determinant of matrix A . The lower-case italic letter i equals $\sqrt{-1}$ throughout. Machine precision is denoted by ε .

2 Algorithms

Algorithm 1 below computes an invariant subspace of a nonsymmetric matrix A corresponding to the eigenvalues inside (or outside) the unit disk, and Algorithm 2 computes left and right deflating subspaces of a matrix pencil $A - \lambda B$ corresponding to the eigenvalues in the same region. The algorithms are similar to the matrix sign function based algorithms in that they begin by computing orthogonal projectors onto the desired subspaces. Later, we will show how to divide into more general regions. Even though the algorithms are very similar, we will present them separately for ease of notation.

The algorithms presented in this section are for complex matrices. But if the given matrices are real, then the algorithms only require real arithmetic.

2.1 Algorithm for spectral division of A

Algorithm 1. Given an $n \times n$ matrix A , compute a unitary matrix Q such that

$$Q^H A Q = \begin{pmatrix} A_{11} & A_{12} \\ E_{21} & A_{22} \end{pmatrix},$$

and where in exact arithmetic we would have $\lambda(A_{11}) \subseteq \mathcal{D}$, $\lambda(A_{22}) \cap \mathcal{D} = \emptyset$, and $E_{21} = 0$. \mathcal{D} can be the interior (or exterior) of the open unit disk. We assume that no eigenvalues of A are on the unit circle. On return, the generally nonzero quantity $\|E_{21}\|_1 / \|A\|_1$ measures the stability of the computed decomposition.

1) Let $A_0 = A$ and $B_0 = I$.

2) For $j = 0, 1, 2, \dots$ until convergence or $j > \text{maxit}$

$$\begin{pmatrix} B_j \\ -A_j \end{pmatrix} = \begin{pmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{pmatrix} \begin{pmatrix} R_j \\ 0 \end{pmatrix}, \quad (\text{QR decomposition})$$

$$A_{j+1} = Q_{12}^H A_j;$$

$$B_{j+1} = Q_{22}^H B_j;$$

$$\text{if } \|R_j - R_{j-1}\|_1 \leq \tau \|R_{j-1}\|_1, \quad p = j + 1, \text{ exit};$$

End for

- 3) For the exterior of the unit disk, compute
 $(A_p + B_p)^{-1} A_p = QR\Pi$, (rank revealing QR decomposition)
 or for the interior of the unit disk, compute
 $(A_p + B_p)^{-1} B_p = QR\Pi$, (rank revealing QR decomposition)
- 4) $l = \text{rank}(R)$, (number of eigenvalues in the selected region)
- 5) Compute

$$Q^H A Q = \begin{matrix} & l & n-l \\ l & \begin{pmatrix} A_{11} & A_{12} \\ E_{21} & A_{22} \end{pmatrix} \\ n-l & \end{matrix}$$

and $\|E_{21}\|_1/\|A\|_1$.

Note that in step 2), we assume that the QR decomposition of $\begin{pmatrix} B_j \\ -A_j \end{pmatrix}$ is computed so that the diagonal elements of R_j are all positive, so the matrix R_j is uniquely defined. $\|E_{21}\|_1/\|A\|_1$ is an accurate measure of the backward stability of the algorithm, because setting E_{21} to zero introduces a backward error of precisely $\|E_{21}\|_1/\|A\|_1$ (measured relative to A and using the 1-norm).

In Algorithm 1, we need to choose a stopping criterion τ in the inner loop of step 2), as well as a limit *maxit* on the maximum number of iterations. So far we have used $\tau \approx n\varepsilon$ (where ε is the machine precision) and *maxit* = 60. In section 10 we shall discuss these issues again.

In the next subsection we will show how to compute Q in the $QR\Pi$ decomposition of $(A_p + B_p)^{-1} A_p$ or $(A_p + B_p)^{-1} B_p$ in step 3) without computing the explicit inverse $(A_p + B_p)^{-1}$ and subsequent products. This will yield the ultimate *inverse free* algorithm.

2.2 Algorithm for spectral division of (A, B)

Algorithm 2. Given $n \times n$ matrices A and B , compute two unitary matrices Q_L and Q_R , such that

$$Q_L^H A Q_R = \begin{pmatrix} A_{11} & A_{12} \\ E_{21} & A_{22} \end{pmatrix}, \quad Q_L^H B Q_R = \begin{pmatrix} B_{11} & B_{12} \\ F_{21} & B_{22} \end{pmatrix},$$

and where in exact arithmetic we would have $\lambda(A_{11}, B_{11}) \subseteq \mathcal{D}$, $\lambda(A_{22}, B_{22}) \cap \mathcal{D} = \emptyset$, and $E_{21} = F_{21} = 0$. \mathcal{D} can be the interior (or exterior) of the unit disk. We assume that no eigenvalues of the pencil (A, B) are on the unit circle. On return, the generally nonzero quantities $\|E_{21}\|_1/\|A\|_1$ and $\|F_{21}\|_1/\|B\|_1$ measure the stability of the computed decomposition.

/ Compute the right deflating subspace */*

- 1) Let $A_0 = A$ and $B_0 = B$.
- 2) For $j = 0, 1, 2, \dots$ until convergence or $j > \text{maxit}$

$$\begin{pmatrix} B_j \\ -A_j \end{pmatrix} = \begin{pmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{pmatrix} \begin{pmatrix} R_j \\ 0 \end{pmatrix}, \quad (\text{QR decomposition})$$

$$A_{j+1} = Q_{12}^H A_j;$$

$$B_{j+1} = Q_{22}^H B_j;$$

if $\|R_j - R_{j-1}\|_1 \leq \tau \|R_{j-1}\|_1$, $p = j + 1$, exit;

End for

- 3) For the exterior of the unit disk, compute
 $(A_p + B_p)^{-1} A_p = Q_R R_R \Pi_R$, (rank revealing QR decomposition)
 or for the interior of the unit disk, compute
 $(A_p + B_p)^{-1} B_p = Q_R R_R \Pi_R$, (rank revealing QR decomposition)
- 4) $l_R = \text{rank}(R)$, (the number of eigenvalues in the selected region.)
/ Compute the left deflating subspace */*
- 5) Let $A_0 = A^H$ and $B_0 = B^H$.
- 6) For A_0 and B_0 do the loop 2).
- 7) For the outside of the unit disk, compute
 $A_p^H (A_p + B_p)^{-H} = Q_L R_L \Pi_L$, (rank revealing QR decomposition)
 or for the inside of the unit disk, compute
 $B_p^H (A_p + B_p)^{-H} = Q_L R_L \Pi_L$, (rank revealing QR decomposition)
- 8) $l_L = \text{rank}(R_L)$, (the number of eigenvalues in the selected region.)
- 9) If $l_R \neq l_L$, signal an error and quit, otherwise let $l = l_R = l_L$;
- 10) Compute

$$Q_L^H A Q_R = \begin{matrix} & l & n-l \\ \begin{matrix} l \\ n-l \end{matrix} & \begin{pmatrix} A_{11} & A_{12} \\ E_{21} & A_{22} \end{pmatrix} \end{matrix}, \quad Q_L^H A Q_R = \begin{matrix} & l & n-l \\ \begin{matrix} l \\ n-l \end{matrix} & \begin{pmatrix} B_{11} & B_{12} \\ F_{21} & B_{22} \end{pmatrix} \end{matrix}.$$

and $\|E_{21}\|_1/\|A\|_1$ and $\|F_{21}\|_1/\|B\|_1$.

As before, the iterations are not uniquely defined due to the non-uniqueness of the QR decompositions in step 2). But the R_j are uniquely determined. $\|E_{21}\|_1/\|A\|_1$ and $\|F_{21}\|_1/\|B\|_1$ are accurate measures of the backward stability of the algorithm because one proceeds by setting E_{21} and F_{21} to zero and continuing to divide and conquer.

Parameters τ and *maxit* play the same role in Algorithm 2 as Algorithm 1. In finite precision arithmetic, it is possible that we might get two different numbers l_R and l_L of eigenvalues in region \mathcal{D} in steps 4) and 8). Therefore, we need an extra test step 9) in Algorithm 2. In our numerical experiments, l_R and l_L have always been equal. If they were not, we would handle it the same way we handle other convergence failures: the spectral decomposition based on \mathcal{D} is rejected, and a new region \mathcal{D} must be selected (see section 2.4).

In the next section we will show how to remove the apparent inverses in steps 3) and 7) in the same way as for Algorithm 1. This will make the algorithm *inverse free*. We also show how to potentially save half the work, at the cost of solving another linear system, which is potentially ill-conditioned.

2.3 Implementation details and options

We describe in more detail the implementation of Algorithms 1 and 2. The main costs are the matrix-matrix multiplications and the QR decomposition in the inner loop, and the rank-revealing QR following the inner loop.

There is a large literature on matrix-matrix multiplication, and it is usually one of the first algorithms to be implemented quickly on a high performance architecture [25, 2].

Regarding the QR decomposition in the inner loop, there is no need to form the entire $2n \times 2n$ unitary matrix Q in order to get the submatrices Q_{12} and Q_{22} . Instead, we can compute the QR decomposition of the $2n \times n$ matrix $(B_j^T, -A_j^T)^T$ (using SGEQRF from LAPACK if the matrices are real, for example), which leaves Q stored implicitly as Householder vectors in the lower triangular part of the matrix and another n dimensional array. We can then apply Q^T — without computing it — to the $2n \times n$ matrix $(0, I)^T$ to obtain the desired matrix Q_{12}^T and Q_{22}^T (using LAPACK routine SORMQR).

Another way to view the inner loop is as computing an orthonormal basis for the null space of $(B_j^T, -A_j^T)$. The QR decomposition is the simplest way, but there are other ways also. For example, we may extend an idea proposed in Kublanovskaya's AB-algorithm [39] for computing such null spaces, which cuts the arithmetic cost significantly but with the possible loss of block operations; more study is needed here.

Let us now discuss computing the rank-revealing QR decomposition of $C^{-1}D$ (or $D^H C^{-H}$) without computing the inverse or product explicitly. This is needed in step 3) of Algorithm 1 and steps 3) and 7) of Algorithm 2. For simplicity, let us use column pivoting to reveal rank, although more sophisticated rank-revealing schemes exist [19, 32, 35, 52]. Recall that for our purposes, we only need the unitary factor Q and the rank of $C^{-1}D$ (or $D^H C^{-H}$). It turns out that by using the generalized QR (GQR) decomposition technique developed in [45, 3], we can get the desired information without computing C^{-1} or C^{-H} . In fact, in order to compute the QR decomposition with pivoting of $C^{-1}D$, we first compute the QR decomposition with pivoting of the matrix D :

$$D = Q_1 R_1 \Pi, \quad (2.3)$$

and then we compute the RQ factorization of the matrix $Q_1^H C$:

$$Q_1^H C = R_2 Q_2. \quad (2.4)$$

From (2.3) and (2.4), we have $C^{-1}D = Q_2^H (R_2^{-1} R_1) \Pi$. The Q_2 is the desired unitary factor. The rank of R_1 is also the rank of the matrix $C^{-1}D$.

In order to compute the rank revealing QR decomposition of $D^H C^{-H}$, we first compute the QL decomposition of C :

$$C = Q_1 L_1 \quad (2.5)$$

and then compute the QR decomposition with pivoting of $D^H Q_1$:

$$D^H Q_1 = Q_2 R_2 \Pi. \quad (2.6)$$

From (2.5) and (2.6), we have $D^H C^{-H} = Q_2 (R_2 \Pi L_1^{-H} \Pi^H) \Pi$. This is not exactly a QR decomposition, but has the same effect, since Q_2 is the desired unitary factor, and the rank of R_2 is also the rank of the matrix $D^H C^{-H}$.

Note that the above GQR decomposition will not necessarily always reveal the numerical rank, even though it works much of the time. In particular, the permutation Π should really depend on both C and D . Another way to compute a *rank-revealing GQR decomposition* is to explicitly form $C^{-1}D$, compute its rank revealing QR, take the resulting permutation Π , and use this Π in decomposition (2.3). This costs quite a bit more, and Π is still not guaranteed to be correct if

$C^{-1}D$ is computed sufficient inaccurately. However, a more sophisticated implementation of this later idea can indeed reveal the numerical rank of $C^{-1}D$; this work will appear elsewhere.

GQR decomposition is always backward stable in the following sense. The computed Q_2 is nearly the exact orthogonal factor for matrices $C + \delta C$ and $D + \delta D$, where $\|\delta C\| = O(\varepsilon)\|C\|$ and $\|\delta D\| = O(\varepsilon)\|D\|$.

Here is another implementation option for Algorithm 2, which reintroduces inversion of a particular matrix, with the payoff of eliminating half the work of the algorithm. It will be justified at the end of section 4. Let

$$\begin{pmatrix} A^H \\ B^H \end{pmatrix} = Q \cdot \begin{pmatrix} R \\ 0 \end{pmatrix}$$

be the QR decomposition. Let $P_{R,|z|>1} \equiv (A_p + B_p)^{-1}A_p$ be the matrix computed in step 3) of Algorithm 2 (the notation will be justified in section 4), and $P_{L,|z|>1} \equiv A_p^H(A_p + B_p)^{-H}$ be the matrix computed in step 7) of Algorithm 2. We may compute $P_{L,|z|>1}$ directly from $P_{R,|z|>1}$, eliminating the work of step 6), by using the formula

$$P_{L,|z|>1} = (AP_{R,|z|>1}, BP_{R,|z|>1})Q \begin{pmatrix} I \\ 0 \end{pmatrix} R^{-H}.$$

The condition number of R is the same as the condition number of the $n \times 2n$ matrix $[A, B]$. If $[A, B]$ is nearly singular, this means the pencil $A - \lambda B$ is nearly singular, which means its eigenvalues are all very ill-conditioned, among other things [23]. We discuss this further in section 5.

Finally, we note that in some applications, we may only want the eigenvalues of the reduced matrix A_{11} or of the matrix pencil (A_{11}, B_{11}) or their subblocks. In this case, we do not need to compute the blocks A_{12} , A_{22} , B_{12} or B_{22} in step 5) of Algorithm 1 and step 10) of Algorithm 2, and so we can save some computations.

2.4 Other kinds of regions

Although the algorithms presented in sections 2.1 and 2.2 only divide the spectrum along the unit circle, we can use Möbius and other simple transformations of the input matrix A or matrix pair (A, B) to divide along other curves (treat A as the pair (A, I)). By transforming the eigenproblem $Az = \lambda Bz$ to

$$(\alpha A + \beta B)z = \frac{\alpha\lambda + \beta}{\gamma\lambda + \delta}(\gamma A + \delta B)z \quad \text{or} \quad A_0 z = \lambda_0 B_0 z$$

and applying Algorithm 2 to (A_0, B_0) , we see that we can split along the curve where $|\lambda_0| = |\frac{\alpha\lambda + \beta}{\gamma\lambda + \delta}| = 1$. This is a major attraction of this algorithm: it can handle an arbitrary Möbius transformation just by setting A_0 and B_0 to appropriate linear combinations of A and B . In contrast, applying the matrix sign function to an arbitrary Möbius transformation will generally require a matrix inversion. Here are some simple examples.

- (a) Transform the eigenproblem $Az = \lambda Bz$ to

$$(A - \mu B)z = \left(\frac{\lambda - \mu}{r} \right) (rB)z$$

where $r > 0$. Let $A_0 = A - \mu B$ and $B_0 = rB$ in Algorithm 2. Then Algorithm 2 will split the spectrum of $A - \lambda B$ along a circle centered at μ with radius r . If A and B are real, and we choose μ to be real, then all arithmetic in the algorithm will be real.

(b) Transform the eigenproblem $Az = \lambda Bz$ to

$$(A - (\mu + \nu)B)z = \frac{\lambda - (\mu + \nu)}{\lambda - (\mu - \nu)}(A - (\mu - \nu)B)z$$

and let $A_0 = A - (\mu + \nu)B$ and $B_0 = A - (\mu - \nu)B$ in Algorithm 2. Then Algorithm 2 will split the spectrum of $A - \lambda B$ along the line through μ and perpendicular to the segment from $\mu + \nu$ to $\mu - \nu$. If A and B are real, and we choose μ and ν to be real, then will we split along the vertical line through μ , and all arithmetic in the algorithm will be real. This is the splitting computed by the matrix sign function. This eliminates the need for matrix exponentiation in Malyshev's algorithm [43].

Other more general regions can be obtained by taking A_0 and B_0 as more complicated polynomial functions of A and B .

3 Inverse free iteration vs. the matrix sign function

In this section we compare the cost of a single iteration of the new algorithm with the matrix sign function based algorithm. Numerical experiments will be presented in section 10.

We begin by reviewing the matrix sign function. The sign function $\text{sign}(A)$ of a matrix A with no eigenvalues on the imaginary axis can be defined via the Jordan canonical form of A : Let

$$A = X \begin{pmatrix} J_+ & 0 \\ 0 & J_- \end{pmatrix} X^{-1}$$

be the Jordan canonical form of A , where the eigenvalues of J_+ are in the open right half plane, and the eigenvalues of J_- are in the open left half plane. Then $\text{sign}(A)$, as introduced by Roberts [47], is

$$\text{sign}(A) \equiv X \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix} X^{-1}.$$

It is easy to show that the two matrices

$$P_+ = \frac{1}{2}(I + \text{sign}(A)) \quad \text{and} \quad P_- = \frac{1}{2}(I - \text{sign}(A)) \quad (3.7)$$

are the spectral projectors onto the invariant subspaces corresponding to the eigenvalues of A in the open right and open left half planes, respectively. Now let the *rank revealing QR decomposition* of the matrix P_+ be $P_+ = QR\Pi$, so that R is upper triangular, Q is unitary, and Π is a permutation matrix chosen so that the leading columns of Q span the range space of P_+ . Then Q yields the desired spectral decomposition [6]:

$$Q^H A Q = \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix}$$

where the eigenvalues of A_{11} are the eigenvalues of A in open right half plane, and the eigenvalues of A_{22} are the eigenvalues of A in the open left half plane. By computing the sign function of Möbius transformations of A , the spectrum can be divided along arbitrary lines and circles.

The simplest scheme for computing the matrix sign function is the Newton iteration applied to $(\text{sign}(A))^2 = I$:

$$A_{j+1} = \frac{1}{2}(A_j + A_j^{-1}), \quad j = 0, 1, 2, \dots \quad \text{with } A_0 = A. \quad (3.8)$$

The iteration is globally and ultimately quadratically convergent with $\lim_{j \rightarrow \infty} A_j = \text{sign}(A)$ [47, 36]. The iteration could fail to converge if A has pure imaginary eigenvalues (or, in finite precision, if A is “close” to having pure imaginary eigenvalues.) There are many ways to improve the accuracy and convergence rates of this basic iteration [16, 33, 38].

The matrix sign function may also be used in the generalized eigenproblem $A - \lambda B$ by implicitly applying (3.8) to AB^{-1} [29]. We do not want to invert B if it is ill-conditioned, which is why we want to apply the previous algorithm implicitly. This leads to the following iteration:

$$A_{j+1} = \frac{1}{2}(A_j + BA_j^{-1}B), \quad j = 0, 1, 2, \dots \quad \text{with } A_0 = A. \quad (3.9)$$

A_j converges quadratically to a matrix C if B is nonsingular and $A - \lambda B$ has no pure imaginary eigenvalues. In this case CB^{-1} is the matrix sign function of AB^{-1} , and so following (3.7) we want to use the QR decomposition to calculate the range space of $P_{\pm} = \frac{1}{2}(I \pm CB^{-1})$, which has the same range space as $2P_{\pm}B = B \pm C$. Thus we can compute the invariant subspace of AB^{-1} (left deflating subspace of $A - \lambda B$) without inverting B , by computing the rank revealing QR decomposition of $B \pm C$. The right deflating subspace of $A - \lambda B$ can be obtained by applying this algorithm to $A^H - \lambda B^H$, since transposing swaps right and left spaces.

Now we consider the convergence of (3.9) when B is singular, and $A - \lambda B$ has no pure imaginary eigenvalues. By considering the Weierstrass Canonical Form of $A - \lambda B$ [28], it suffices to consider $A_0 = I$ and B a nilpotent Jordan block. Then it is easy to show by induction that

$$A_j = 2^{-j}I + \frac{2^j - 2^{-j}}{3}B^2 + O(B^4)$$

so that A_j diverges to infinity if B is 3-by-3 or larger, and converges to 0 otherwise. In the latter case, the range space of $B \pm A_j$ converges to the space spanned by $e_1 = [1, 0, \dots, 0]^T$, which is indeed a left deflating subspace. The situation is more complicated in the former case.

By avoiding all explicit matrix inversions, and requiring only QR decomposition and matrix-matrix multiplication instead, our new algorithms may eliminate the possible instability associated with inverting ill-conditioned matrices. However, it does not avoid all accuracy or convergence difficulties associated with eigenvalues very close to the unit circle. In addition, the generalized eigenproblem has another possible source of difficulty: when $A - \lambda B$ is close to a singular pencil [28, 23]. We shall discuss this further in sections 5 and 7.

The advantage of the new approach is obtained at the cost of more storage and more arithmetic. For example, when the matrix A is real, Algorithm 1 needs $4n^2$ more storage space than standard Newton iteration (some other iterations for the sign function which converge faster than Newton require even more storage). This will certainly limit the problem size we will be able to solve. Table 1 tabulates the arithmetic cost of one loop of the inverse free iteration versus the Newton iteration (3.8) and (3.9) for the real ordinary and real generalized spectral divide and conquer problems, respectively. From Table 1, we see that for the standard spectral divide and conquer problem, the one loop of the inverse free iteration does about 6.7 times more arithmetic than the one loop of the Newton iteration. For the generalized divide and conquer problem, it is about 2.2 times more arithmetic. We expect that these extra expenses of the new approach will be compensated by better numerical stability in some cases, especially for the generalized eigenproblem; see section 10.

Table 1: The Arithmetic Cost of One Loop Iteration

The Real Ordinary SDC Problem			
Inverse free iteration		Newton iteration	
SGEQRF	$\frac{10}{3}n^3 + O(n^2)$	SGETRF	$\frac{2}{3}n^3 + O(n^2)$
SORMQR	$6n^3 + O(n^2)$	SGETRI	$\frac{4}{3}n^3 + O(n^2)$
SGEMM(2)	$4n^3 + O(n^2)$		
Total	$13.3n^3 + O(n^2)$	Total	$2n^3 + O(n^2)$

The Real Generalized SDC Problem			
Inverse free iteration		Newton iteration	
SGEQRF	$\frac{10}{3}n^3 + O(n^2)$	SGETRF	$\frac{2}{3}n^3 + O(n^2)$
SORMQR	$6n^3 + O(n^2)$	SGETRI	$\frac{4}{3}n^3 + O(n^2)$
SGEMM(2)	$4n^3 + O(n^2)$	SGEMM(2)	$4n^3 + O(n^2)$
Total	$13.3n^3 + O(n^2)$	Total	$6n^3 + O(n^2)$

4 Why the algorithms work

The simplest way we know to see why the algorithms work is as follows. We believe this is much simpler than the explanation in [42], for example.

For simplicity we will assume that all matrices we want to invert are invertible. Our later error analysis will not depend on this. It suffices to consider the first half of Algorithm 2. We will exhibit a basis for the pencil $A - \lambda B$ in which the transformations of the algorithm will be transparent. From step 2) of Algorithm 2, we see that

$$\begin{pmatrix} Q_{11}^H & Q_{21}^H \\ Q_{12}^H & Q_{22}^H \end{pmatrix} \cdot \begin{pmatrix} B_j \\ -A_j \end{pmatrix} = \begin{pmatrix} Q_{11}^H B_j - Q_{21}^H A_j \\ Q_{12}^H B_j - Q_{22}^H A_j \end{pmatrix} = \begin{pmatrix} R \\ 0 \end{pmatrix}$$

so $Q_{12}^H B_j = Q_{22}^H A_j$ or $B_j A_j^{-1} = Q_{12}^{-H} Q_{22}^H$. Therefore

$$A_{j+1}^{-1} B_{j+1} = A_j^{-1} Q_{12}^{-H} Q_{22}^H B_j = (A_j^{-1} B_j)^2$$

so the algorithm is simply repeatedly squaring the eigenvalues, driving the ones inside the unit disk to 0 and those outside to ∞ . Repeated squaring yields quadratic convergence. This is analogous to the sign function iteration where computing $(A + A^{-1})/2$ is equivalent to taking the Cayley transform $(A - I)(A + I)^{-1}$ of A , squaring, and taking the inverse Cayley transform. Therefore, in step 3) of Algorithm 2 we have

$$(A_p + B_p)^{-1} A_p = (I + A_p^{-1} B_p)^{-1} = (I + (A^{-1} B)^{2^p})^{-1}. \quad (4.10)$$

To see that this approaches a projector onto the right deflating subspace corresponding to eigenvalues outside the unit circle as required by the algorithm, we will use the the Weierstrass Canonical Form of the pencil $A - \lambda B$ [28]. Write

$$A - \lambda B = P_L' \begin{pmatrix} J_0 - \lambda I & \\ & J_\infty - \lambda N \end{pmatrix} P_R^{-1}$$

where P'_L and P_R are nonsingular, J_0 contains the Jordan blocks of eigenvalues inside the unit circle, J_∞ contains the Jordan blocks of eigenvalues outside the unit circle, and N is block diagonal with identity blocks corresponding to blocks of finite eigenvalues in J_∞ , and nilpotent blocks corresponding to infinite eigenvalues (identity blocks in J_∞) [28]. In this notation, the projector first mentioned in section 2.3 is

$$P_{R,|z|>1} = P_R \begin{pmatrix} 0 & \\ & I \end{pmatrix} P_R^{-1}$$

and the deflating subspace in question is spanned by the trailing columns of P_R .

Since J_∞ is nonsingular, we may write

$$A - \lambda B = P'_L \begin{pmatrix} I & \\ & J_\infty \end{pmatrix} \begin{pmatrix} J_0 - \lambda I & \\ & I - \lambda J_\infty^{-1} N \end{pmatrix} P_R^{-1} \equiv P_L \begin{pmatrix} J_0 - \lambda I & \\ & I - \lambda J'_0 \end{pmatrix} P_R^{-1}, \quad (4.11)$$

where $J'_0 = J_\infty^{-1} N$ has all its eigenvalues either nonzero and inside the unit circle (corresponding to finite eigenvalues of J_∞) or at zero (corresponding to nilpotent blocks of N). Thus

$$A^{-1}B = \left(P_L \begin{pmatrix} J_0 & \\ & I \end{pmatrix} P_R^{-1} \right)^{-1} \cdot \left(P_L \begin{pmatrix} I & \\ & J'_0 \end{pmatrix} P_R^{-1} \right) = P_R \begin{pmatrix} J_0^{-1} & \\ & J'_0 \end{pmatrix} P_R^{-1}$$

and

$$(A_p + B_p)^{-1}A_p = (I + (A^{-1}B)^{2p})^{-1} = P_R \begin{pmatrix} (I + J_0^{-2p})^{-1} & \\ & (I + J'^{2p}_0)^{-1} \end{pmatrix} P_R^{-1}. \quad (4.12)$$

Since $J_0^{-2p} \rightarrow \infty$ and $J'^{2p}_0 \rightarrow 0$ as $p \rightarrow \infty$, the last displayed expression converges to $P_{R,|z|>1}$ as desired. The approximate projector $(A_p + B_p)^{-1}B_p$ onto the other right deflating subspace is just

$$I - (A_p + B_p)^{-1}A_p = (I + (A^{-1}B)^{2p})^{-1}(A^{-1}B)^{2p} = P_R \begin{pmatrix} (I + J_0^{2p})^{-1} & \\ & (I + J'^{-2p}_0)^{-1} \end{pmatrix} P_R^{-1} \quad (4.13)$$

which converges to

$$P_{R,|z|<1} = I - P_{R,|z|>1} = P_R \begin{pmatrix} I & \\ & 0 \end{pmatrix} P_R^{-1}. \quad (4.14)$$

The projectors

$$P_{L,|z|>1} = P_L \begin{pmatrix} 0 & \\ & I \end{pmatrix} P_L^{-1} \text{ and } P_{L,|z|<1} = I - P_{L,|z|>1} = P_L \begin{pmatrix} I & \\ & 0 \end{pmatrix} P_L^{-1}$$

onto left deflating subspaces are computed in Algorithm 2 by applying the same procedure to $A^H - \lambda B^H$, since taking the conjugate transpose swaps right and left spaces.

We discuss the convergence rate of this iteration in the next section, after we have introduced the condition number.

An alternative approach to computing the left deflating spaces, which saves the cost of running the algorithm again but requires a possibly ill-conditioned linear system to be solved, is as follows. Note that

$$P_{L,|z|>1} \cdot (A, B) = (P_L \begin{pmatrix} 0 & \\ & I \end{pmatrix} P_L^{-1}, P_L \begin{pmatrix} 0 & \\ & J'_0 \end{pmatrix} P_L^{-1}) = (A, B) \begin{pmatrix} P_{R,|z|>1} & \\ & P_{R,|z|>1} \end{pmatrix}.$$

We can solve this for $P_{L,|z|>1}$ by using the decomposition

$$\begin{pmatrix} A^H \\ B^H \end{pmatrix} = Q \cdot \begin{pmatrix} R \\ 0 \end{pmatrix}$$

so

$$P_{L,|z|>1}[R^H, 0] = (AP_{R,|z|>1}, BP_{R,|z|>1})Q$$

and thus

$$P_{L,|z|>1} = (AP_{R,|z|>1}, BP_{R,|z|>1})Q \begin{pmatrix} I \\ 0 \end{pmatrix} R^{-H}.$$

The condition number of R is the same as the condition number of the $n \times 2n$ matrix (A, B) . If (A, B) is nearly singular, this means the pencil $A - \lambda B$ is nearly singular, which means its eigenvalues are all very ill-conditioned, among other things [23]. We discuss this further below.

5 Perturbation theory

Algorithms 1 and 2 will work (in exact arithmetic) unless there is an eigenvalue on the unit circle. This includes the case of singular pencils, in the sense that if $A - \lambda B$ is a singular pencil then $A - zB$ will be singular for any z , including the unit circle. Thus the set of matrices with an eigenvalue on the unit circle, or pencils such that $A - zB$ is singular for some z on the unit circle, are the sets of “ill-posed problems” for Algorithms 1 and 2.

Our goal is to show that the reciprocal of the distance to this set of ill-posed problems is a natural condition number for this problem. This will rely on a clever expression for the orthogonal projectors by Malyshev [42]. In contrast to Malyshev’s work, however, our analysis will be much simpler and lead to a potentially much smaller condition number.

We begin with a simple formula for the distance to the nearest ill-posed problem. We define this distance as follows:

$$d_{(A,B)} \equiv \inf\{\|E\| + \|F\| : (A + E) - z(B + F) \text{ is singular for some } z \text{ where } |z| = 1\} . \quad (5.15)$$

This infimum is clearly attained for some E and F by compactness. Note also that $d_{(A,B)} = d_{(B,A)} = d_{(A^H, B^H)} = d_{(B^H, A^H)}$.

Lemma 1 $d_{(A,B)} = \min_{\theta} \sigma_{\min}(A - e^{i\theta} B)$.

Proof. Let $\sigma = \min_{\theta} \sigma_{\min}(A - e^{i\theta} B)$. Then there is a θ and an E such that $\|E\| = \sigma$ and $A + E - e^{i\theta} B$ is singular, implying $d_{(A,B)} \leq \|E\| = \sigma$. To prove the opposite inequality, the definition of $d_{(A,B)}$ implies that there are a θ and matrices E and F with $\|E\| + \|F\| = d_{(A,B)}$ such that $A + E - e^{i\theta}(B + F) = (A - e^{i\theta} B) + (E - e^{i\theta} F)$ is singular. Thus

$$d_{(A,B)} = \|E\| + \|F\| \geq \|E - e^{i\theta} F\| \geq \sigma_{\min}(A - e^{i\theta} B) \geq \sigma$$

as desired. ■

As a remark, note that essentially the same proof shows that for *any* domain \mathcal{D}

$$\min\{\|E, F\|_F : \det((A + E) - z(B + F)) = 0 \text{ for some } z \in \mathcal{D}\} = \min_{\substack{s, c \\ z=s/c \in \mathcal{D} \\ |s|^2+|c|^2=1}} \sigma_{\min}(cA - sB),$$

which is the natural way to extend the notion of pseudospectrum to matrix pencils [54].

Now we turn to the perturbation theory of the approximate projector computed in step 3) of Algorithm 2, $(A_p + B_p)^{-1}B_p$, which is also given by the formula in (4.13). Following Malyshev [42], we will express this approximate projector as one block component of the solution of a particular linear system (our linear system differs slightly from his). Let $m = 2^p$. All the subblocks in the following mn -by- mn linear system are n -by- n . All subblocks not shown in the coefficient matrix are zero.

$$M_m(A, B) \cdot \begin{pmatrix} Z_{m-1} \\ \vdots \\ Z_0 \end{pmatrix} \equiv \begin{pmatrix} -A & & -B \\ B & \ddots & \\ & \ddots & \ddots \\ & & B & -A \end{pmatrix} \cdot \begin{pmatrix} Z_{m-1} \\ \vdots \\ Z_0 \end{pmatrix} = \begin{pmatrix} -B \\ 0 \\ \vdots \\ 0 \end{pmatrix} \equiv \tilde{B}_m \quad (5.16)$$

If B or A were nonsingular, we could confirm that the solution of (5.16) would be

$$\begin{pmatrix} Z_{m-1} \\ Z_{m-2} \\ \vdots \\ Z_0 \end{pmatrix} = \begin{pmatrix} (B^{-1}A)^{m-1}(I + (B^{-1}A)^m)^{-1} \\ (B^{-1}A)^{m-2}(I + (B^{-1}A)^m)^{-1} \\ \vdots \\ (I + (B^{-1}A)^m)^{-1} \end{pmatrix} \text{ or } \begin{pmatrix} (A^{-1}B)(I + (A^{-1}B)^m)^{-1} \\ (A^{-1}B)^2(I + (A^{-1}B)^m)^{-1} \\ \vdots \\ (A^{-1}B)^m(I + (A^{-1}B)^m)^{-1} \end{pmatrix}.$$

Thus we see that $Z_0 = (A^{-1}B)^m(I + (A^{-1}B)^m)^{-1}$ as in (4.13). By using the Weierstrass Canonical Form of $A - \lambda B$, we can change basis and solve this system explicitly without assuming A or B is nonsingular. It will still turn out that $Z_0 = (A_p + B_p)^{-1}B_p$. By using standard perturbation theory for linear systems, we will get the perturbation theory for $(A_p + B_p)^{-1}B_p$ (or $(A_p + B_p)^{-1}A_p = I - (A_p + B_p)^{-1}B_p$) that we want.

The motivation for (5.16) in [42] is from a recurrence for the coefficients of the Fourier expansion of $(B - e^{i\theta}A)^{-1}$, but that will not concern us here.

We now change variables from Z_i to $Z'_i = P_R^{-1}Z_iP_R$, which we should expect to block diagonalize A, B and Z_i and so decouple (5.16). Making this substitution, premultiplying the block equations in (5.16) by P_L^{-1} , and using (4.11), we get

$$\begin{pmatrix} -\bar{A} & & -\bar{B} \\ \bar{B} & \ddots & \\ & \ddots & \ddots \\ & & \bar{B} & -\bar{A} \end{pmatrix} \cdot \begin{pmatrix} Z'_{m-1} \\ Z'_{m-2} \\ \vdots \\ Z'_0 \end{pmatrix} = \begin{pmatrix} -\bar{B} \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (5.17)$$

where

$$\bar{B} = \begin{pmatrix} I & \\ & J'_0 \end{pmatrix} \text{ and } \bar{A} = \begin{pmatrix} J_0 & \\ & I \end{pmatrix}.$$

Now we can write $Z'_j = \begin{pmatrix} Z_{j,+} & \\ & Z_{j,-} \end{pmatrix}$ and decompose (5.17) into two systems,

$$\begin{pmatrix} -J_0 & & & -I \\ I & -J_0 & & \\ & \ddots & \ddots & \\ & & I & -J_0 \end{pmatrix} \cdot \begin{pmatrix} Z_{m-1,+} \\ Z_{m-2,+} \\ \vdots \\ Z_{0,+} \end{pmatrix} = \begin{pmatrix} -I \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (5.18)$$

and

$$\begin{pmatrix} -I & & & -J'_0 \\ J'_0 & -I & & \\ & \ddots & \ddots & \\ & & J'_0 & -I \end{pmatrix} \cdot \begin{pmatrix} Z_{m-1,-} \\ Z_{m-2,-} \\ \vdots \\ Z_{0,-} \end{pmatrix} = \begin{pmatrix} -J'_0 \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \quad (5.19)$$

These equations are rather simple, and it is easy to verify that the following are the solutions:

$$\begin{pmatrix} Z_{m-1,+} \\ Z_{m-2,+} \\ \vdots \\ Z_{1,+} \\ Z_{0,+} \end{pmatrix} = \begin{pmatrix} J_0^{m-1}(I + J_0^m)^{-1} \\ J_0^{m-2}(I + J_0^m)^{-1} \\ \vdots \\ J_0(I + J_0^m)^{-1} \\ (I + J_0^m)^{-1} \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} Z_{m-1,-} \\ Z_{m-2,-} \\ \vdots \\ Z_{1,-} \\ Z_{0,-} \end{pmatrix} = \begin{pmatrix} J'_0(I + J'^m_0)^{-1} \\ J'^2_0(I + J'^m_0)^{-1} \\ \vdots \\ J'^{m-1}_0(I + J'^m_0)^{-1} \\ J'^m_0(I + J'^m_0)^{-1} \end{pmatrix}. \quad (5.20)$$

Thus, we can reconstruct

$$\begin{aligned} Z_0 &= P_R Z'_0 P_R^{-1} = P_R \begin{pmatrix} (I + J_0^m)^{-1} & \\ & J'^m_0(I + J'^m_0)^{-1} \end{pmatrix} P_R^{-1} \\ &= P_R \begin{pmatrix} (I + J_0^m)^{-1} & \\ & (I + J'^m_0)^{-1} \end{pmatrix} P_R^{-1} \\ &= (A_p + B_p)^{-1} B_p \end{aligned} \quad (5.21)$$

as given in (4.13).

Now we can ask how much Z_0 can change when we change A and B in (5.16). We will answer this question using a slight variation on the usual normwise perturbation theory, and take full account of the structure of coefficient matrix. In fact, we will see that we get the same condition number whether or not we take the structure into account or not. Let I_m be an m -by- m identity matrix, and J_m be an m -by- m matrix with 1 on the subdiagonal, and -1 in position $(1, m)$. Then one can easily confirm that the coefficient matrix in (5.16) can be written using the Kronecker product \otimes as

$$M_m(A, B) = -I_m \otimes A + J_m \otimes B.$$

Since J_m is orthogonal, and hence normal, its eigendecomposition can be written $J_m = U \Lambda U^H$, where U is a unitary matrix and $\Lambda = \text{diag}(e^{i\theta_1}, \dots, e^{i\theta_m})$ is the diagonal matrix of eigenvalues, all of which must lie on the unit circle. In fact, one can easily confirm that the characteristic polynomial of J_m is $\det(\lambda I - J_m) = \lambda^m + 1$, so the eigenvalues are m -th roots of -1 . Then transforming

$M_m(A, B)$ using the unitary similarity $U \otimes I_n$, we get

$$\begin{aligned} (U \otimes I_n)^H M_m(A, B)(U \otimes I_n) &= -U^H I_m U \otimes A + U J_m U^H \otimes B \\ &= -I_m \otimes A + \Lambda \otimes B \\ &= \text{diag}(-A + e^{i\theta_1} B, \dots, -A + e^{i\theta_m} B) . \end{aligned}$$

Therefore, the smallest singular value of $M_m(A, B)$ is $\min_{1 \leq j \leq m} \sigma_{\min}(-A + e^{i\theta_j} B)$. As m grows, and the process converges, this smallest singular value decreases to $\min_{\theta} \sigma_{\min}(-A + e^{i\theta} B) = d_{(A, B)}$. This shows that $d_{(A, B)}^{-1}$ is a condition number for $(A_p + B_p)^{-1} B_p$, and in fact a lower bound bound for all finite m . We may also bound

$$\left\| \begin{pmatrix} Z_{m-1} \\ \vdots \\ Z_0 \end{pmatrix} \right\|_2 \leq \frac{\|B\|}{d_{(A, B)}} . \quad (5.22)$$

6 Convergence analysis

Using equation (4.12), we will bound the error

$$\|(A_p + B_p)^{-1} A_p - P_{R, |z| > 1}\| = \|(I + (A^{-1} B)^{2p})^{-1} - P_{R, |z| > 1}\|$$

after p steps of the algorithm. Our bound will be in terms of $\|P_{R, |z| > 1}\|$ and $d_{(A, B)}$. It can be much tighter than the corresponding bound in Theorem 1.4 of [42], for reasons discussed in section 8.

Theorem 1 *Let $d_{(A, B)}$ be defined as in (5.15). Then if*

$$p \geq \log_2 \frac{\|(A, B)\| - d_{(A, B)}}{d_{(A, B)}}$$

we may bound

$$\frac{\|(A_p + B_p)^{-1} A_p - P_{R, |z| > 1}\|}{\|P_{R, |z| > 1}\|} \leq \frac{2^{p+3} (1 - \frac{d_{(A, B)}}{\|(A, B)\|})^{2p}}{\max(0, 1 - 2^{p+2} (1 - \frac{d_{(A, B)}}{\|(A, B)\|})^{2p})} . \quad (6.23)$$

Thus, we see that convergence is quadratic, and depends on the smallest relative perturbation $\frac{d_{(A, B)}}{\|(A, B)\|}$ that makes $A - \lambda B$ have an eigenvalue on the unit circle; the smaller this perturbation, the slower the convergence.

We begin the proof with an estimate on the growth of matrix powers. Many related bounds are in the literature [54, 34]; ours differs slightly because it involves powers of the matrix $Y^{-1} X$.

Lemma 2 *Let $X - \lambda Y$ have all its eigenvalues inside the unit circle. Then*

$$\|(Y^{-1} X)^m\| \leq \begin{cases} e_m \cdot m \cdot \left(1 - \frac{d_{(X, Y)}}{\|Y\|}\right)^m & \text{if } m > \frac{\|Y\| - d_{(X, Y)}}{d_{(X, Y)}} \\ \frac{\|Y\|}{d_{(X, Y)}} & \text{if } m \leq \frac{\|Y\| - d_{(X, Y)}}{d_{(X, Y)}} \end{cases} .$$

where $\exp(1) \leq e_m \equiv (1 + m^{-1})^{m+1} \leq 4$, and $\lim_{m \rightarrow \infty} e_m = \exp(1)$. We may also bound $e_m \cdot m \leq e(m+1)$.

Proof of Lemma 2. Let r satisfy $\rho(Y^{-1}X) < r \leq 1$, where $\rho(Y^{-1}X)$ is the spectral radius of $Y^{-1}X$. Then

$$\begin{aligned}
\|(Y^{-1}X)^m\| &= \left\| \frac{1}{2\pi i} \int_0^{2\pi} (re^{i\theta})^m (re^{i\theta}I - Y^{-1}X)^{-1} dr e^{i\theta} \right\| \\
&= \left\| \frac{1}{2\pi i} \int_0^{2\pi} (re^{i\theta})^m (re^{i\theta}Y - X)^{-1} dr e^{i\theta} Y \right\| \\
&\leq \frac{r^{m+1} \|Y\|}{\min_{\theta} \sigma_{\min}(re^{i\theta}Y - X)} \\
&= \frac{r^{m+1} \|Y\|}{\min_{\theta} \sigma_{\min}(e^{i\theta}Y - X + Y e^{i\theta}(r-1))} \\
&\leq \frac{r^{m+1} \|Y\|}{\min_{\theta} \sigma_{\min}(e^{i\theta}Y - X) - \|Y\|(1-r)} \\
&= \frac{r^{m+1}}{d_{(X,Y)}/\|Y\| - 1 + r} \\
&\equiv f(r)
\end{aligned}$$

We may easily show that if $m \geq [\|Y\| - d_{(X,Y)}]/d_{(X,Y)}$, then $f(r)$ has a minimum at $\rho(Y^{-1}X) < r = \frac{m+1}{m}(1 - d_{(X,Y)}/\|Y\|) \leq 1$, and the value of this minimum is

$$m \cdot (1 + m^{-1})^{m+1} \cdot (1 - d_{(X,Y)}/\|Y\|)^m \equiv m \cdot e_m \cdot (1 - d_{(X,Y)}/\|Y\|)^m.$$

If $m \leq [\|Y\| - d_{(X,Y)}]/d_{(X,Y)}$, then the upper bound is attained at $r = 1$. ■

Completely analogously, one may prove the following lemma, which is a special case of a bound in [54].

Lemma 3 *Let X have all its eigenvalues inside the unit circle. Let $d_X \equiv \min_{\theta} \sigma_{\min}(e^{i\theta}I - X)$; d_X is the smallest perturbation of X that will make it have an eigenvalue on the unit circle. Then*

$$\|X^m\| \leq \begin{cases} e_m \cdot m \cdot (1 - d_X)^m & \text{if } m > \frac{1-d_X}{d_X} \\ \frac{1}{d_X} & \text{if } m \leq \frac{1-d_X}{d_X} \end{cases}.$$

where e_m is as defined in Lemma 2.

Proof of Theorem 1. By a unitary change of basis, we may without loss of generality assume that

$$A - \lambda B = \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix} - \lambda \begin{pmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{pmatrix}$$

where the eigenvalues of $A_{11} - \lambda B_{11}$ are inside the unit circle, and the eigenvalues of $A_{22} - \lambda B_{22}$ are outside the unit circle. Let L and R be the unique matrices such that [23, 50]

$$\begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix} - \lambda \begin{pmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{pmatrix} = \begin{pmatrix} I & L \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} A_{11} - \lambda B_{11} & 0 \\ 0 & A_{22} - \lambda B_{22} \end{pmatrix} \cdot \begin{pmatrix} I & R \\ 0 & I \end{pmatrix}^{-1}.$$

Then, assuming for the moment that A is invertible, we get

$$A^{-1}B = \begin{pmatrix} I & R \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} A_{11}^{-1}B_{11} & 0 \\ 0 & A_{22}^{-1}B_{22} \end{pmatrix} \cdot \begin{pmatrix} I & R \\ 0 & I \end{pmatrix}^{-1}$$

and

$$P_{R,|z|>1} = \begin{pmatrix} I & R \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} I & R \\ 0 & I \end{pmatrix}^{-1} = \begin{pmatrix} 0 & R \\ 0 & I \end{pmatrix}.$$

Then we see that $E_p \equiv (I + (A^{-1}B)^{2p})^{-1} - P_{R,|z|>1}$ may be written

$$\begin{aligned} E_p &= \begin{pmatrix} I & R \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} (I + (A_{11}^{-1}B_{11})^{2p})^{-1} & 0 \\ 0 & (I + (A_{22}^{-1}B_{22})^{2p})^{-1} - I \end{pmatrix} \cdot \begin{pmatrix} I & R \\ 0 & I \end{pmatrix}^{-1} \\ &= \begin{pmatrix} I & R \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} (I + (B_{11}^{-1}A_{11})^{2p})^{-1}(B_{11}^{-1}A_{11})^{2p} & 0 \\ 0 & -(I + (A_{22}^{-1}B_{22})^{2p})^{-1}(A_{22}^{-1}B_{22})^{2p} \end{pmatrix} \\ &\quad \cdot \begin{pmatrix} I & R \\ 0 & I \end{pmatrix}^{-1} \\ &= \begin{pmatrix} (I + (B_{11}^{-1}A_{11})^{2p})^{-1}(B_{11}^{-1}A_{11})^{2p} & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} I & -R \\ 0 & 0 \end{pmatrix} \\ &\quad - \begin{pmatrix} 0 & R \\ 0 & I \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 \\ 0 & (I + (A_{22}^{-1}B_{22})^{2p})^{-1}(A_{22}^{-1}B_{22})^{2p} \end{pmatrix}. \end{aligned}$$

The derivation of this formula used the fact that A , and so A_{11} , were nonsingular, but the final formula does not require this. Since the rational function in the formula is correct off the set of measure zero where A is singular, and continuous on this set of measure zero, where the true function is also continuous, it must necessarily be correct everywhere. Thus

$$\begin{aligned} \|E_p\| &\leq \|P_{R,|z|>1}\| \cdot (\|(I + (B_{11}^{-1}A_{11})^{2p})^{-1}(B_{11}^{-1}A_{11})^{2p}\| + \|(I + (A_{22}^{-1}B_{22})^{2p})^{-1}(A_{22}^{-1}B_{22})^{2p}\|) \\ &\leq \|P_{R,|z|>1}\| \cdot \left(\frac{\|(B_{11}^{-1}A_{11})^{2p}\|}{1 - \|(B_{11}^{-1}A_{11})^{2p}\|} + \frac{\|(A_{22}^{-1}B_{22})^{2p}\|}{1 - \|(A_{22}^{-1}B_{22})^{2p}\|} \right) \end{aligned}$$

provided the denominators are positive. From Lemma 2, we may bound

$$\|(B_{11}^{-1}A_{11})^{2p}\| \leq 4 \cdot 2^p \cdot \left(1 - \frac{d(A_{11}, B_{11})}{\|B_{11}\|}\right)^{2p} \quad \text{and} \quad \|(A_{22}^{-1}B_{22})^{2p}\| \leq 4 \cdot 2^p \cdot \left(1 - \frac{d(A_{22}, B_{22})}{\|A_{22}\|}\right)^{2p}$$

for p sufficiently large. Since

$$\frac{d(A_{11}, B_{11})}{\|B_{11}\|} \geq \frac{d(A, B)}{\|(A, B)\|} \quad \text{and} \quad \frac{d(A_{22}, B_{22})}{\|A_{22}\|} \geq \frac{d(A, B)}{\|(A, B)\|}$$

this yields the desired bound. \blacksquare

A weakness in Lemmas 2 and 3 comes from using the single number $d_{(A,B)}$ (or d_A) to characterize a matrix. For example,

$$A_1 = \begin{pmatrix} .5 & 1000 & 0 \\ 0 & .5 & 1000 \\ 0 & 0 & .5 \end{pmatrix} \quad \text{and} \quad A_2 = \begin{pmatrix} \alpha & 0 & 0 \\ 0 & \alpha & 0 \\ 0 & 0 & \alpha \end{pmatrix},$$

where $\alpha \approx 1 - 1.25 \cdot 10^{-7}$ have the same value of d_A , namely about $1.25 \cdot 10^{-7}$. $\|A_2^n\|$ clearly never increases, let alone to $1/d_A \approx 8 \cdot 10^6$ as predicted by Lemma 3; in contrast $\|A_1^n\|$ gets as large as $1.5 \cdot 10^6$. For large n , $\|A_2^n\|$ decreases precisely as $(1 - d_A)^n \approx .999999875^n$, as predicted by Lemma 3; in contrast $\|A_1^n\|$ decreases much faster, as $.5^n$. To see that both parts of the bound can be attained simultaneously, consider $\text{diag}(A_1, A_2)$. Despite the potential overestimation, we will use $d_{(A,B)}$ in all our analyses in the paper, both because it gives tighter bounds than those previously published, and in the inevitable tradeoff between accuracy and simplicity of bounds of this sort, we have chosen simplicity.

One can use the bound in Lemma 3 to bound the norm of A^n computed in floating point [34]; this work will appear elsewhere.

7 Error analysis

Following Malyshev [42], the analysis depends on the observation that step 2) of Algorithm 2 is just computing the QR decomposition of $M_n(A, B)$, in a manner analogous to block cyclic reduction [15]. Malyshev works hard to derive a rigorous *a priori* bound on the total roundoff error, yielding an expression which is complicated and possibly much too large. It can be too large because it depends on his condition number ω (see section 8) instead of our smaller $d_{(A,B)}^{-1}$, because we use the GQR decomposition instead of explicitly inverting $(A_p + B_p)$ in step 3), and because worst case roundoff analysis is often pessimistic. In algorithmic practice, we will use an *a posteriori* bound $\max(\|E_{21}\|, \|F_{21}\|)$, which will be a precise measure of the backward error in one spectral decomposition, rather than the *a priori* bounds presented here.

We begin by illustrating why step 2 of Algorithm 2 is equivalent to solving (5.16) using QR decomposition. We take $p = 3$, which means $m = 2^3 = 8$. Let

$$\begin{pmatrix} Q_{11}^{(j)} & Q_{12}^{(j)} \\ Q_{21}^{(j)} & Q_{22}^{(j)} \end{pmatrix}$$

be the orthogonal matrix computed in the j th iteration of step 2), and let

$$\tilde{Q}^{(j)} = \begin{pmatrix} Q_{21}^{(j)} & Q_{22}^{(j)} \\ Q_{11}^{(j)} & Q_{12}^{(j)} \end{pmatrix}.$$

Then we see that step 2) of algorithm 2 is equivalent to the identity

$$\tilde{Q}^{(j)H} \begin{pmatrix} -A_j & 0 & B_j \\ B_j & A_j & 0 \end{pmatrix} = \begin{pmatrix} R_j & \star & \star \\ 0 & A_{j+1} & B_{j+1} \end{pmatrix} \quad (7.24)$$

where the \star s are entries which do not interest us. Multiplying block rows 1 and 2, 3 and 4, 5 and 6, and 7 and 8 in (5.16) by $\tilde{Q}^{(0)H}$ and using (7.24) yields

$$\begin{pmatrix} R_1 & \star & & & \star \\ 0 & -A_1 & & & -B_1 \\ & \star & R_1 & \star & \\ & B_1 & 0 & -A_1 & \\ & & \star & R_1 & \star \\ & & B_1 & 0 & -A_1 \\ & & & \star & R_1 & \star \\ & & & B_1 & 0 & -A_1 \end{pmatrix} \cdot \begin{pmatrix} Z_7 \\ Z_6 \\ Z_5 \\ Z_4 \\ Z_3 \\ Z_2 \\ Z_1 \\ Z_0 \end{pmatrix} = \begin{pmatrix} \star \\ -B_1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}.$$

Reordering the odd-numbered blocks before the even ones results in

$$\left(\begin{array}{ccc|cccc} R_1 & & & \star & & \star \\ & R_1 & & \star & \star & \\ & & R_1 & & \star & \\ & & & R_1 & \star & \star \\ \hline & & & -A_1 & & -B_1 \\ & & & B_1 & -A_1 & \\ & & & & B_1 & -A_1 \\ & & & & & B_1 & -A_1 \end{array} \right) \cdot \begin{pmatrix} Z_7 \\ Z_5 \\ Z_3 \\ Z_1 \\ \hline Z_6 \\ Z_4 \\ Z_2 \\ Z_0 \end{pmatrix} = \begin{pmatrix} \star \\ 0 \\ 0 \\ 0 \\ \hline -B_1 \\ 0 \\ 0 \\ 0 \end{pmatrix}. \quad (7.25)$$

Repeating this with $\tilde{Q}^{(1)H}$ on the lower right corner of (7.25), and similarly reordering blocks, we get

$$\left(\begin{array}{ccc|cccc} R_1 & & & \star & & \star \\ & R_1 & & \star & \star & \\ & & R_1 & & \star & \\ & & & R_1 & \star & \star \\ \hline & & & R_2 & \star & \star \\ & & & & R_2 & \star & \star \\ & & & & & -A_2 & -B_2 \\ & & & & & B_2 & -A_2 \end{array} \right) \cdot \begin{pmatrix} Z_7 \\ Z_5 \\ Z_3 \\ Z_1 \\ \hline Z_6 \\ Z_2 \\ \hline Z_4 \\ Z_0 \end{pmatrix} = \begin{pmatrix} \star \\ 0 \\ 0 \\ 0 \\ \hline \star \\ 0 \\ \hline -B_2 \\ 0 \end{pmatrix}. \quad (7.26)$$

One more step with $\tilde{Q}^{(2)H}$ on the lower right corner of (7.26) yields

$$\left(\begin{array}{ccc|cccc} R_1 & & & \star & & \star \\ & R_1 & & \star & \star & \\ & & R_1 & & \star & \\ & & & R_1 & \star & \star \\ \hline & & & R_2 & \star & \star \\ & & & & R_2 & \star & \star \\ & & & & & R_3 & \star \\ & & & & & & -A_3 - B_3 \end{array} \right) \cdot \begin{pmatrix} Z_7 \\ Z_5 \\ Z_3 \\ Z_1 \\ \hline Z_6 \\ Z_2 \\ \hline Z_4 \\ Z_0 \end{pmatrix} = \begin{pmatrix} \star \\ 0 \\ 0 \\ 0 \\ \hline \star \\ 0 \\ \hline \star \\ -B_3 \end{pmatrix}. \quad (7.27)$$

Thus, we see again that $Z_0 = (A_3 + B_3)^{-1}B_3$ as desired. It is clear from this development that the process is backward stable in the following sense: the computed $A_3 + B_3$ (or more generally

$A_m + B_m$) in the transformed coefficient matrix, and B_3 (or B_m) in the transformed right hand side, are the exact results corresponding to a slightly perturbed $M_{2m}(A, B) + \delta M_{2m}$ and initial right hand side $\tilde{B}_{2m} + \delta \tilde{B}_{2m}$, where $\|\delta M_{2m}\| = O(\varepsilon)\|(A, B)\|$ and $\|\delta \tilde{B}_{2m}\| = O(\varepsilon)\|B\|$.

Next we must analyze the computation of Q_R in step 3) of Algorithm 2. As described in section 2.3, if we use the GQR decomposition to compute Q_R without inverses, then Q_R is nearly the exact orthogonal factor of $(A_m + B_m + E)^{-1}(B_m + F)$ where $\|E\| = O(\varepsilon)\|A_m + B_m\| = O(\varepsilon)\|(A, B)\|$, and $\|F\| = O(\varepsilon)\|B_m\| = O(\varepsilon)\|B\|$. We can take these E and F and “push them back” into δM and $\delta \tilde{B}_m$, respectively, since the mapping from $M_{2m}(A, B) + \delta M_{2m}$ to $A_m + B_m$ is an orthogonal projection, as is the map from \tilde{B}_{2m} to B_m . So altogether, combining the analysis of steps 1) and 2), we can say that Q_R is nearly the exact answer for $M_{2m}(A, B) + \delta M'_{2m}$ and $\tilde{B}_{2m} + \delta \tilde{B}'_{2m}$ where $\|\delta M'_{2m}\| = O(\varepsilon)\|(A, B)\|$ and $\|\delta \tilde{B}'_{2m}\| = O(\varepsilon)\|B\|$. Since the condition number of the linear system (5.16) is (no larger than) $d_{(A,B)}^{-1}$, and the norm of the solution is bounded by (5.22) the absolute error in the computed Z_0 of which Q_R is nearly the true factor is bounded by² $O(\varepsilon) \cdot \|B\| \cdot \|(A, B)\| d_{(A,B)}^{-2} \leq O(\varepsilon) \cdot \|(A, B)\|^2 d_{(A,B)}^{-2}$.

To bound the error in the space spanned by the leading columns of Q_R , which is our approximate deflating subspace, we need to know how much a right singular subspace of a matrix Z_0 , i.e. the space spanned by the right singular vectors corresponding to a subset \mathcal{S} of the singular values, is perturbed when Z_0 is perturbed by a matrix of norm η . If Z_0 were the exact projector in (4.14), \mathcal{S} would consist of all the nonzero singular values. In practice, of course, this is a question of rank determination. No matter what \mathcal{S} is, the space spanned by the corresponding singular vectors is perturbed by at most $O(\eta)/\text{gap}_{\mathcal{S}}$ [46, 53, 50], where $\text{gap}_{\mathcal{S}}$ is the shortest distance from any singular value in \mathcal{S} to any singular value not in \mathcal{S} :

$$\text{gap}_{\mathcal{S}} \equiv \min_{\substack{\sigma \in \mathcal{S} \\ \bar{\sigma} \notin \mathcal{S}}} |\sigma - \bar{\sigma}|.$$

So we need to estimate $\text{gap}_{\mathcal{S}}$ in order to compute an error bound. We will do this for Z_0 equal to its limit $P_{R,|z|<1}$ in (4.14). There is always a unitary change of basis in which a projector is of the form $\begin{pmatrix} I & \Sigma \\ 0 & 0 \end{pmatrix}$, where $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_{l_R})$ is diagonal with $\sigma_1 \geq \dots \geq \sigma_{l_R} \geq 0$. From this it is easy to compute the singular values of the projector: $\{\sqrt{1 + \sigma_1^2}, \dots, \sqrt{1 + \sigma_{l_R}^2}, 1, \dots, 1, 0, \dots, 0\}$, where the number of ones in the set of singular values is equal to $\max(2l_R - n, 0)$. Since $\mathcal{S} = \{\sqrt{1 + \sigma_1^2}, \dots, \sqrt{1 + \sigma_{l_R}^2}, 1, \dots, 1\}$, we get

$$\text{gap}_{\mathcal{S}} = \begin{cases} \sqrt{1 + \sigma_{l_R}^2} & \text{if } 2l_R \leq n \\ 1 & \text{if } 2l_R > n \end{cases}.$$

Thus, we get that in the limit as $m \rightarrow \infty$, the error δQ_R in Q_R is bounded by

$$\|\delta Q_R\| = \frac{O(\varepsilon) \cdot \|(A, B)\|^2}{d_{(A,B)}^2 \cdot \text{gap}_{\mathcal{S}}}. \quad (7.28)$$

²This bound is true even if we compute the inverse of $A_m + B_m$ explicitly.

A similar bound holds for $\|\delta Q_L\|$ in Algorithm 2. Thus

$$\begin{aligned}\|E_{21}\| &\leq \|(Q_L + \delta Q_L)^H A(Q_R + \delta Q_R) - Q_L^H A Q_R\| = \|\delta Q_L^H A Q_R + Q_L^H A \delta Q_R\| + O(\varepsilon^2) \\ &\leq (\|\delta Q_L\| + \|\delta Q_R\|)\|A\| + O(\varepsilon^2)\end{aligned}$$

with a similar bound for $\|F_{21}\|$.

So altogether, in the limit as $m \rightarrow \infty$, we expect the following bound on backward stability³:

$$\max\left(\frac{\|E_{21}\|}{\|A\|}, \frac{\|F_{21}\|}{\|B\|}\right) \leq \frac{O(\varepsilon) \cdot \|(A, B)\|^2}{d_{(A,B)}^2 \cdot \min(\text{gap}_{S_R}, \text{gap}_{S_L})} \leq \frac{O(\varepsilon) \cdot \|(A, B)\|^2}{d_{(A,B)}^2}, \quad (7.29)$$

where gap_{S_R} refers to the gap in the singular values of $P_{R,|z|<1}$, and gap_{S_L} refers to the gap in the singular values of $P_{L,|z|<1}$.

For simplicity, consider Algorithm 1, where $P_{R,|z|<1} = P_{L,|z|<1}$. An interesting feature of the error bound is that it may be smaller if $2l_R \leq n$ than otherwise. This is borne out by numerical experiments, where it can be more accurate to make the choice in step 3) of Algorithm 1 which leads to A_{11} being smaller than A_{22} . Also, when $2l_R \leq n$, the error bound is a decreasing function of σ_{l_R} . On the other hand, If σ_{l_R} is large, this means σ_1 and so $\|P_{R,|z|<1}\| = \sqrt{1 + \sigma_1^2}$ are large, and this in turn means the eigenvalues inside the unit circle are ill-conditioned [23]. This should mean the eigenvalues are *harder* to divide, not easier. Of course as they become more ill-conditioned, $d_{(A,B)}$ decreases at the same time, which counterbalances the increase in σ_{l_R} .

In practice, we will use the *a posteriori* bounds $\|E_{21}\|$ and $\|F_{21}\|$ anyway, since if we block upper-triangularize $Q_L^H(A - \lambda B)Q_R$ by setting the $(2, 1)$ blocks to zero, $\|E_{21}\|$ and $\|F_{21}\|$ are precisely the backward errors we commit. In the next section, we will compare our error bound with those in [42].

8 Remark on Malyshev's condition number

We have just shown that $d_{(A,B)}^{-1}$ is a natural condition number for this problem. In this subsection, we will show that Malyshev's condition number can be much larger [42]. Malyshev's condition number is

$$\begin{aligned}\omega &\equiv \left\| \frac{1}{2\pi} \int_0^{2\pi} (B - e^{i\phi} A)^{-1} (AA^H + BB^H) (B - e^{i\phi} A)^{-H} d\phi \right\| \\ &= \left\| \frac{1}{2\pi} \int_0^{2\pi} (B' - e^{i\phi} A')^{-1} (B' - e^{i\phi} A')^{-H} d\phi \right\|\end{aligned} \quad (8.30)$$

where $A' = (AA^H + BB^H)^{-1/2} A$ and $B' = (AA^H + BB^H)^{-1/2} B$; this means $A' A'^H + B' B'^H = I$. Malyshev begins his version of the algorithm by replacing A by A' and B by B' , which we could too if we wanted to.

Malyshev's absolute error bound on the computed Z_0 is essentially $O(\varepsilon)\omega^2$, whereas ours is $O(\varepsilon)d_{(A,B)}^{-2}$, assuming $\|(A, B)\| \approx 1$. We will show that $d_{(A,B)}^{-1}$ can be as small as the square root of ω .

³In fact this bound holds for sufficiently large m as well.

Since

$$\sigma_{\min}(AA^H + BB^H) \leq \frac{d_{(A,B)}}{d_{(A',B')}} \leq \sigma_{\max}(AA^H + BB^H)$$

it is sufficient to compare ω and $d_{(A,B)}^{-1}$ when $AA^H + BB^H$ is well-conditioned. Malyshev shows that, in our notation, $d_{(A',B')}^{-1} < 5\pi\omega$, showing that $d_{(A',B')}^{-1}$ is never much larger than ω . Malyshev shows that $d_{(A,B)}^{-1}$ and ω can be close when $B = I$ and A is real symmetric. By taking norms inside the integral in (8.30), one gets the other bound $\sqrt{\omega} \leq d_{(A,B)}^{-1}$, showing that $d_{(A,B)}^{-1}$ can be as small as the square root of ω . To see that $d_{(A,B)}^{-1}$ can indeed be this small, consider the following example. Let $A = I$ and $B = D - N$, where D is diagonal with entries equally spaced along any arc of the circle centered at the origin with radius $0 < d < 1$ and angular extent $\pi/8$, and N has ones on the superdiagonal and zeros elsewhere. When d is close to 1 and the dimension of A is at least about 20, one can computationally confirm that $d_{(A,B)}^{-1}$ is close to $\sqrt{\omega}$. This example works because when $e^{i\theta}$ is in the same sector as the eigenvalues of B , $(B - e^{i\theta}A)^{-1}$ is as large as it can get, and its largest entry is in position $(1, n)$:

$$\frac{1}{\prod_{k=1}^n (B_{kk} - e^{i\theta})}$$

Thus the integral for ω is bounded above by a modest multiple of the integral of the square of the magnitude of the quantity just displayed (times $\sigma_{\max}(AA^H + BB^H)$), which is near its maximum value $d_{(A,B)}^{-2}$ for a range of θ close to $[0, \pi/8]$, so the integral is within a constant of $d_{(A,B)}^{-2}$.

9 Stopping criterion

In this section we justify the stopping criterion used in Algorithms 1 and 2 by showing that R_j converges quadratically.

From step 2) of Algorithm 2, we see that

$$B_{j+1} = Q_{22}^H B_j = Q_{22}^H Q_{11} R_j \quad \text{and} \quad A_{j+1} = Q_{12}^H A_j = -Q_{12}^H Q_{21} R_j.$$

For two symmetric non-negative definite matrices P_1 and P_2 , we use the relation $P_1 \leq P_2$ to mean that $P_2 - P_1$ is non-negative definite. The above relations imply

$$\begin{aligned} R_{j+1}^H R_{j+1} &= B_{j+1}^H B_{j+1} + A_{j+1}^H A_{j+1} \\ &= R_j^H (Q_{11}^H Q_{22} Q_{22}^H Q_{11} + Q_{21}^H Q_{12} Q_{12}^H Q_{21}) R_j \\ &\leq R_j^H (Q_{11}^H Q_{11} + Q_{21}^H Q_{21}) R_j \\ &= R_j^H R_j. \end{aligned}$$

Since $R_j^H R_j \geq 0$ for all j , the above relation implies that the sequence $\{R_j^H R_j\}$ converges. On the other hand, since R_j can be viewed as a diagonal block in the upper triangular matrix of the cyclic QR decomposition of the coefficient matrix in (5.16), we have $\sigma_{\min}(R_j) \geq d_{(A,B)}$. Hence the sequence $\{R_j^H R_j\}$ converges to a symmetric positive definite matrix. Let this limit matrix be $R^H R$, where R is upper triangular with positive diagonal elements. It follows that the sequence $\{R_j\}$ converges to R .

To see the quadratic convergence of $\{R_j\}$, we note that

$$\begin{aligned} R_{j+1}^H R_{j+1} &= R_j^H (Q_{11}^H Q_{22} Q_{22}^H Q_{11} + Q_{21}^H Q_{12} Q_{12}^H Q_{21}) R_j \\ &= R_j^H R_j - R_j^H (S_j S_j^H + S_j^H S_j) R_j \end{aligned}$$

where $S_j = Q_{11}^H Q_{21}$. It then follows that S_j converges to the zero matrix. Furthermore, let $R_{j+1} = (I + E_j)R_j$, then E_j is upper triangular and the above relation implies that

$$(I + E_j)^H (I + E_j) = I - (S_j S_j^H + S_j^H S_j).$$

In other words, $(I + E_j)^H (I + E_j)$ is the Cholesky factorization of $I - (S_j S_j^H + S_j^H S_j)$. Hence $\|E_j\| = O(\|S_j\|^2)$ and

$$\|R_{j+1} - R_j\| \leq \|E_j\| \|R_j\| = O(\|S_j\|^2 \|R_j\|).$$

Note that $Q_{11} = B_j R_j^{-1}$ and $Q_{21} = -A_j R_j^{-1}$ and so

$$S_j = -R_j^{-H} B_j^H A_j R_j^{-1}.$$

In the following we establish the quadratic convergence of S_j . To this end we first establish a recursive relation for the sequence $\{B_j^H A_j\}$. Recall that by step 2) of Algorithm 2,

$$B_{j+1} = Q_{22}^H B_j \quad \text{and} \quad A_{j+1} = Q_{12}^H A_j.$$

Hence

$$B_{j+1}^H A_{j+1} = B_j^H Q_{22} Q_{12}^H A_j. \quad (9.31)$$

Since

$$Q_{12}^H B_j - Q_{22}^H A_j = 0,$$

we have

$$Q_{12}^H = Q_{22}^H A_j B_j^{-1}.$$

On the other hand we also have

$$Q_{12}^H Q_{12} + Q_{22}^H Q_{22} = I.$$

Combining these two relations, we obtain that

$$\begin{aligned} Q_{12} &= H_j^H (I + H_j H_j^H)^{-\frac{1}{2}} W \\ Q_{22} &= (I + H_j H_j^H)^{-\frac{1}{2}} W, \end{aligned}$$

where $H_j = A_j B_j^{-1}$ and W is an arbitrary $n \times n$ orthogonal matrix. Hence

$$\begin{aligned} Q_{22} Q_{12}^H &= (I + H_j H_j^H)^{-1} H_j \\ &= H_j (I + H_j^H H_j)^{-1} \\ &= A_j B_j^{-1} \left(I + (A_j B_j^{-1})^H A_j B_j^{-1} \right)^{-1} \\ &= A_j (B_j^H B_j + A_j^H A_j)^{-1} B_j^H. \end{aligned}$$

Substituting this relation into (9.31) we obtain

$$B_{j+1}^H A_{j+1} = B_j^H A_j \left(B_j^H B_j + A_j^H A_j \right)^{-1} B_j^H A_j. \quad (9.32)$$

Recall that $R_{j+1} = (I + E_j)R_j$ and $S_j = -R_j^{-H} B_j^H A_j R_j^{-1}$, equation (9.32) can be rewritten as

$$S_{j+1} = -(I + E_j)^{-H} S_j^2 (I + E_j)^{-1}, \quad (9.33)$$

with $E_j = O(\|S_j\|^2)$. This establishes the quadratic convergence of $\{S_j\}$ and hence $\{R_j\}$. We point out that this implies that the sequence $\{B_j^H A_j\}$ also quadratically converges to the zero matrix.

10 Numerical experiments

In this section, we present results of our numerical experiments with Algorithms 1 and 2 and compare them with the matrix sign function based algorithm. In all experiments we split the spectrum along the imaginary axis. This means we apply Algorithm 1 to $A_0 = I - A$ and $B_0 = I + A$ and Algorithm 2 to $A_0 = B - A$ and $B_0 = B + A$. We focus primarily on the ordinary SDC problem (Algorithm 1). All algorithms were implemented in MATLAB version 4.0a on a SUN workstation 1+ using IEEE standard double precision arithmetic with machine precision $\varepsilon \approx 2.2 \times 10^{-16}$.

The Newton iteration (3.8) for computing the matrix sign function of a matrix A is terminated if

$$\|A_{j+1} - A_j\|_1 \leq 10n\varepsilon\|A_j\|_1.$$

The inner loop iteration in Algorithms 1 and 2 for computing the desired projector is terminated if

$$\|R_j - R_{j-1}\|_1 \leq 10n\varepsilon\|R_{j-1}\|_1.$$

We set the maximal number of iterations *maxit*=60 for both the Newton iteration and the inverse free iteration.

Algorithms 1 and 2 and the matrix sign function based algorithm work well for the numerous random matrices we tested. In a typical example for the standard SDC problem, we let A be a 100 by 100 random matrix with entries independent and normally distributed with mean 0 and variance 1; A has condition number about 10^4 . Algorithm 1 took 13 inverse free iterations to converge and returned with $\|E_{21}\|_1/\|A_{21}\|_1 \approx 5.44 \times 10^{-15}$. The matrix sign function took 12 Newton iterations to converge and returned with $\|E_{21}\|_1/\|A_{21}\|_1 \approx 2.12 \times 10^{-14}$. Both algorithms determined 48 eigenvalues in the open left half plane, all of which agreed with the eigenvalues computed by the QR algorithm to 12 decimal digits.

In a typical example for the generalized SDC problem, we let A and B be 50 by 50 random matrices with entries distributed as above. Algorithm 2 took 10 inverse free iterations to compute the right deflating subspace, and 10 inverse free iterations for the left deflating subspace, and returned with $\|E_{21}\|_1/\|A_{21}\|_1 \approx 3.31 \times 10^{-15}$ and $\|F_{21}\|_1/\|B_{21}\|_1 \approx 2.64 \times 10^{-15}$. Using the QZ algorithm, we found that the closest distance of the eigenvalues of the pencil $A - \lambda B$ to the imaginary axis was about 10^{-3} .

We now present three examples, where test matrices are constructed so that they are ill-conditioned for inversion, have eigenvalues close to the imaginary axis, and/or have large norm of the spectral projector corresponding to the eigenvalues we want to split. Thus, they should be difficult cases for our algorithms.

Table 2: Numerical Results for Example 1

$\Delta(A) \approx \eta^2$	rcond(A)	Newton iteration		Inverse free iteration	
		<i>iter</i>	$\frac{\ E_{21}\ _1}{\ A\ _1}$	<i>iter</i>	$\frac{\ E_{21}\ _1}{\ A\ _1}$
1	$6.83e-2$	7	$2.19e-16$	7	$3.14e-16$
10^{-2}	$3.18e-2$	14	$1.26e-15$	14	$1.75e-15$
10^{-6}	$3.12e-2$	27	$2.21e-11$	27	$1.94e-11$
10^{-10}	$4.28e-2$	41	$3.65e-07$	40	$1.56e-07$

In the following tables, we use $\text{rcond}(A)$ to denote the estimate of the reciprocal condition number of matrix A computed by MATLAB function `rcond`. $\Delta(A) = \min_{\lambda_j \in \lambda(A)} |\Re \lambda_j|$ is the distance of the nearest eigenvalue to the imaginary axis. $\text{sep} = \text{sep}(A_{11}, A_{22}) = \sigma_{\min}(I \otimes A_{11} - A_{22}^T \otimes I)$ is the separation of matrices A_{11} and A_{22} [50], and $\|P\| = \sqrt{1 + \|R\|^2}$ is the norm of the spectral projector $P = \begin{pmatrix} I & R \\ 0 & 0 \end{pmatrix}$ corresponding the eigenvalues of A_{11} ; R satisfies $A_{11}R - RA_{22} = -A_{12}$.

A number 10^α in parenthesis next to an iteration number *iter* in the following tables indicates that the convergence of the Newton iteration or the inverse free iteration was stationary at about 10^α from the *iter*th iteration forward, and failed to satisfy the stopping criterion even after 60 iterations.

All random matrices used below are with entries independent and normally distributed with mean 0 and variance 1.

Example 1. This example is taken from [4, 1]. Let

$$B = \begin{pmatrix} -\eta & 1 & 0 & 0 \\ -1 & -\eta & 0 & 0 \\ 0 & 0 & \eta & 1 \\ 0 & 0 & -1 & \eta \end{pmatrix}, \quad G = R = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \begin{pmatrix} 1 & 1 & 1 & 1 \end{pmatrix}.$$

and

$$A = Q^T \begin{pmatrix} B & R \\ G & -B^T \end{pmatrix} Q.$$

where Q is an orthogonal matrix generated from the QR decomposition of a random matrix. As $\eta \rightarrow 0$, two pairs of complex conjugate eigenvalues of A approach the imaginary axis, one pair at about $-\eta^2 \pm i$ and the other pair at about $-\eta^2 \pm i$.

Table 2 lists the results computed by Algorithm 1 and the matrix sign function based algorithm. From Table 2, we see that if a matrix is not ill-conditioned to invert, the Newton iteration performs as well as the inverse free iteration. When there are eigenvalues close to the boundary of our selected region (the imaginary axis), the inverse free iteration suffers the same slow convergence and the large backward error as the Newton iteration. These eigenvalues are simply too close to separate. Note that the Newton iteration takes about 6 to 7 times less work than the inverse free iteration.

For this example, we also compared the observed numerical convergence rate of Algorithm 1 with the theoretical prediction of the convergence rate given in Theorem 1. To compute the theoretical

Figure 1: Convergence History of Example 1, $\eta = 0.1$

prediction, we need to estimate $d_{(A,B)}$. Algorithms for computing d_A and related problems are given in [18, 13, 12, 17]. Since our examples are quite small, and we needed little accuracy, we used “intelligent brute force” to estimate $d_{(A,B)}$.

Figure 1 plots the observed convergence rate of Algorithm 1 and the theoretical convergence rate, which is the upper bound in (6.23), for the matrix A with $\eta = 0.1$. We estimated $d_{(A_0, B_0)} \approx 9.72 \times 10^{-3}$, and $\|(A_0, B_0)\| \approx 6.16$. Although the theoretical convergence rate is an overestimate, it does reproduce the basic convergence behavior of the algorithm, in particular the ultimate quadratic convergence. Regarding the analysis of the backward accuracy as given in (7.29), for this example, we have

$$\frac{\|E_{21}\|}{\|A\|} \approx 7.87 \times 10^{-15} < \frac{\varepsilon \|(A_0, B_0)\|^2}{d_{(A_0, B_0)}^2} \approx 8.89 \times 10^{-11}.$$

As we have observed in many experiments, the bound in (7.29) is often pessimistic, and so the algorithm works much better than we can prove. We have some ideas on this but it is not complete. More study is needed.

Example 2: In this example, A is a parameterized matrix of the form

$$A = Q^T \tilde{A} Q,$$

where Q is an orthogonal matrix generated from the QR decomposition of a random matrix,

$$\tilde{A} = \begin{matrix} & \begin{matrix} k & k \end{matrix} \\ \begin{matrix} k \\ k \end{matrix} & \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix} \end{matrix}$$

Figure 2: Eigenvalue distribution of 40 by 40 matrix A with $k = 20$, $\alpha = 0.45$

Table 3: Numerical Results for Example 2

				Newton iteration		Inverse free iteration	
$\Delta(A)$	$\text{rcond}(A)$	sep	$\ P\ $	iter	$\frac{\ E_{21}\ _1}{\ A\ _1}$	iter	$\frac{\ E_{21}\ _1}{\ A\ _1}$
10^{-1}	$8.19e-04$	$2.00e-1$	$6.42e+0$	9	$8.15e-16$	9	$2.49e-16$
10^{-3}	$1.61e-07$	$2.00e-3$	$2.07e+2$	$15(10^{-13})$	$4.23e-12$	15	$1.19e-15$
10^{-5}	$4.12e-12$	$2.00e-5$	$8.06e+4$	$21(10^{-09})$	$3.27e-07$	22	$8.46e-15$
10^{-7}	$1.38e-15$	$2.00e-7$	$2.29e+6$	$28(10^{-05})$	$2.09e-04$	$28(10^{-13})$	$2.44e-13$

$$A_{11} = \begin{pmatrix} 1-\alpha & & & \alpha \\ & 1-\alpha & & \\ & & \ddots & \\ & & & 1-\alpha \\ \alpha & & & & \alpha \end{pmatrix}, \quad A_{22} = -A_{11}^T, \quad 0 \leq \alpha \leq 0.5,$$

and A_{12} is a random matrix. Note that the eigenvalues of A_{11} lie on a circle with center $1 - \alpha$ and radius α and those of A_{22} lie on a circle with center $-1 + \alpha$ and radius α . The closest distance of the eigenvalues of A to the imaginary axis is $\Delta(A) = 1 - 2\alpha$. As $\alpha \rightarrow 0.5$, two eigenvalues of A simultaneously approach the imaginary axis from the right and left. Figure 2 is the eigenvalue distribution when $k = 20$ and $\alpha = .45$.

Table 3 reports the computed results for different values of α with $k = 10$. From this data, we see that when the eigenvalues of A are adequately separated from the imaginary axis ($\Delta(A) \geq \sqrt{\epsilon}$), the results computed by the inverse free iteration are superior to the ones from Newton iteration, especially when the matrix is ill-conditioned with respect to inversion. This is what we expect from the theoretical analysis of the algorithms. The following example further confirms this observation.

Table 4: Numerical results for Example 3

d	rcond(A)	sep	$\ P\ $	Newton iteration		Inverse free iteration	
				$iter$	$\frac{\ E_{21}\ _1}{\ A\ _1}$	$iter$	$\frac{\ E_{21}\ _1}{\ A\ _1}$
1.0	$4.09e-06$	$1.36e-03$	$7.39e+1$	$9(10^{-13})$	$4.56e-14$	10	$7.08e-16$
0.5	$1.29e-06$	$2.37e-04$	$4.32e+2$	$11(10^{-12})$	$1.99e-12$	10	$1.66e-15$
0.3	$3.43e-10$	$4.71e-06$	$2.76e+5$	$14(10^{-07})$	$4.55e-09$	15	$1.64e-15$
0.2	$6.82e-11$	$3.94e-07$	$5.48e+4$	$16(10^{-07})$	$2.76e-08$	12	$1.43e-13$
0.1	$8.12e-14$	$1.54e-10$	$7.48e+8$	-	(fail)	$15(10^{-13})$	$3.66e-11$

Example 3. The test matrices in this example are specially constructed random matrices of the form

$$A = Q^T \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix} Q, \quad (10.34)$$

where Q is an orthogonal matrix generated from the QR decomposition of a random matrix. Submatrices A_{11} and A_{22} are first set to be 5×5 random upper triangular matrices, and then their diagonal elements replaced by $d|a_{ii}|$ and $-d|a_{ii}|$, respectively, where $a_{ii}(1 \leq i \leq n)$ are other random numbers and d is a positive parameter. A_{12} is another 5×5 random matrix. As d gets small, all the eigenvalues get close to the origin and become ill-conditioned. This is the hardest kind of spectrum to divide.

The numerical results are reported in Table 4. All eigenvalues are fairly distant from the imaginary axis ($\Delta(A) \approx O(10^{-3})$), but the conditioning of the generated matrices with respect to inversion can be quite large. The separation of A_{11} and A_{22} can also become small, and $\|P\|$ large, indicating that the eigenvalues are hard to separate. Table 4 gives results for d in the set $\{1, 0.5, 0.3, 0.2, 0.1\}$. Again, Newton iteration is inferior to inverse free iteration for the ill-conditioned problems. In particular, in the case of $d = 0.1$, we observed that from the fourth Newton iteration onward $\text{rcond}(A_4)$ was about $O(10^{-18})$, and that Newton failed to converge. However, the inverse free iteration is still fairly accurate, although the convergence rate and the backward accuracy do deteriorate.

11 Open problems

Here we propose some open problems about spectral divide and conquer algorithms.

1. In Algorithm 2, we test that whether l_L is equal to l_R , where l_L is the number of eigenvalues in the specified region determined from computing the left deflating space, and l_R is the number of eigenvalues in the specified region determined from computing the right deflating space. Normally, we expect them to be the same, however, what does it mean when $l_L \neq l_R$? Perhaps this is an indicator that the pencil is nearly singular.
2. Iterative refinement, based either on nonsymmetric Jacobi iteration [22, 26, 27, 51, 44, 49, 48, 55] or refining invariant subspace ([20] and the references therein) could be used to make E_{21} (and F_{21}) smaller if they are unacceptably large.

12 Conclusions and future work

In this paper, we have further developed the algorithms proposed by Godunov, Bulgakov and Malyshev for doing spectral divide and conquer. With reasonable storage and arithmetic cost, the new algorithms apply equally well to the standard and generalized eigenproblem, and avoid all matrix inversions in the inner loop, requiring QR decompositions and matrix multiplication instead. They form an alternative to the matrix sign function for the parallel solution of the nonsymmetric eigenproblem.

Although the new approach eliminates the possible instability associated with inverting ill-conditioned matrices, it does not eliminate the problem of slow or misconvergence when eigenvalues lie too close to the boundary of the selected region. Numerical experiments indicate that the distance of the eigenvalues to the boundary affects the speed of convergence of the new approach as it does to the matrix sign function based algorithm, but the new approach can yield an accurate solution even when the sign function fails. The backward error bounds given in section 7 are often pessimistic. The new algorithms perform much better than our error analysis can justify. We believe that in dealing with the standard spectral divide and conquer problem, the matrix sign function based algorithm is still generally superior.

Future work includes building a “rank-revealing” generalized QR decomposition, devising an inexpensive condition estimator, incorporating iterative refinement, and understanding how to deal with (nearly) singular pencils. The applications of the inverse free iteration for solving algebraic Riccati equations deserves closer study too.

The performance evaluation of the new algorithms on massively parallel machines, such as the Intel Delta and Thinking Machines CM-5, are underway and will be reported in a subsequent paper.
