ABSTRACT

We present a data processing algorithm for angular reconstruction and event selection applied to 2-D photoelectron track images from X-ray polarimeters. The method reconstructs the initial emission angle of a photoelectron from the initial portion of the track, which is obtained by continuously cutting a track until the image moments or number of pixels fall below tunable thresholds. In addition, event selection which rejects round tracks quantified with eccentricity and circularity is performed so that polarimetry sensitivity considering a trade-off between the modulation factor and signal acceptance is maximized. The modulation factors with applying track selection are 26.6 ± 0.4 , 46.1 ± 0.4 , 62.3 ± 0.4 , and $61.8 \pm 0.3\%$ at 2.7, 4.5, 6.4, and 8.0 keV, respectively, using the same data previously analyzed by Iwakiri et al. (2016), where the corresponding numbers are 26.9 ± 0.4 , 43.4 ± 0.4 , 54.4 ± 0.3 , and $59.1 \pm 0.3\%$. The method improves polarimeter sensitivity by 5%–10% at the high energy end of the band previously presented (Iwakiri et al. 2016).

1. Introduction

Recent progress in micropattern gas detectors enables us to sensitively track charged particles with energies down to 1 keV. The angular distribution of photoelectrons is sensitive to the electric field vector (or polarization direction) of incident photons. Since the photoelectric effect is the dominant interaction of X-rays, the micropattern gas polarimeter is expected to open up a new window in cosmic X-ray polarimetry.

The angular distribution, $d\sigma/d\Omega$, of the K-shell photoelectron emission in the non-relativistic region is theoretically given by:

$$\frac{d\sigma}{d\Omega} \propto \frac{\sin^2\theta}{(1 - \beta \cos\theta)^4} \cos^2\phi, \quad (1)$$

where β is the ratio of the photoelectron velocity to the speed of light, ϕ is the azimuth angle of the X-ray electric vector, and θ is the polar

angle with respect to the incident X-ray direction (e.g. Ref. [1]). Since the angular distribution is represented by the product of independent functions of θ and ϕ , a 2-D photoelectron track projected onto a plane perpendicular to the incident X-ray direction is sufficient to measure the X-ray polarization direction. The projected distribution is given by $\cos^2\phi$, meaning that the modulation factor, defined as the ratio of sinusoidal amplitude to unmodulated offset, is intrinsically 100% for all θ in the photoelectric effect.¹

Two major types of micropattern gas polarimeters have been developed to image the photoelectron track with sufficient resolution to

¹ This is a simpler case than for a Compton scattering polarimeter where the intrinsic modulation factor approaches zero for forward and backward scattering; this situation requires 3-D tracking of the scattered X-rays to achieve the maximum polarization sensitivity (e.g. Refs. [2,3]).

determine the emission angle: a position-sensitive detector with a 2-D readout system called the gas pixel detector (GPD) [4,5] and a position-insensitive but more efficient polarimeter with 1-D strip electrodes using the time projection chamber (TPC) technique [6,7]. In the GPD, the photoelectron track drifts parallel to the original direction of the photon, while in the TPC the drift is perpendicular. This difference enables imaging of astronomical sources in the GPD and higher efficiency in the TPC. Despite this fundamental difference, both the GPD and TPC produce 2-D tracks. In both polarimeters, an algorithm to reconstruct the initial angle of photoelectrons derived from a 2-D track image is essential to maximize polarimetry sensitivity (e.g. Ref. [6] for the TPC and Refs. [8,9] for the GPD). The new algorithm described here extends and improves our previous method in Ref. [6]. In addition, it adopts measured data-driven approach, while the method in Ref. [8] needs helps with a Monte Carlo simulation to know the real interaction position and bring a reconstructed position close to it.

This paper describes the angular reconstruction and track selection for 2-D images with image moments and its verification using experimental data from the TPC polarimeter we have developed [7]. The method is applicable to the other photoelectric polarimeters, such as the GPD polarimeter with hexagonal pixels. Section 2 briefly reviews the polarimeter and the experimental setup. We describe the angular reconstruction in Section 3 and the track selection in Section 4, and lastly, conclude the study in Section 5. Throughout this paper, all errors are given at the 1σ confidence level unless otherwise stated.

2. Experimental setup and track images

The TPC polarimeter we have developed for measuring linear polarization of cosmic X-rays is capable of taking a 3.6-mm square image divided into 30-by-30 pixels to track a photoelectron induced by an incident X-ray. Pure dimethyl ether (DME) is sealed as target gas at a pressure of 190 Torr in the polarimeter chamber. The polarimeter was tested with linearly polarized X-rays at the X-19A beamline at the National Synchrotron Light Source facility in Brookhaven National Laboratory. The details of the measurement setup and data processing are available in Ref. [10]. Data sets at 10 monochromatic energies (2.7–8.0 keV) were used in this work, each having approximately 50,000 events. In addition, the polarimeter was irradiated with the X-ray beam at three different positions, which correspond to the electron drift length from the interaction point to the nearest readout electrode of 0.6, 0.8, and 1.0 cm, where the position of the 0.8 cm drift length is designed to be at the optical axis of the X-ray mirror. The three data sets at each energy are combined into a single data set and analyzed in the same manner because the drift length would be unknown in a measurement of cosmic X-rays. The beam polarization direction was aligned diagonally with the square image. The beam polarization was separately measured with a scattering polarimeter and was determined to be 94% [11].

Typical track images taken with 2.7, 4.5, 6.4, and 8.0 keV X-rays are shown in Fig. 1. Pixels in which the measured signal is less than three times the noise are set to zero. The electron continuous-slowning-down approximation ranges at 2.2, 4.0, 5.9, and 7.5 keV, which are the photoelectron energies calculated by subtracting the K-shell binding energy of oxygen in DME from the incident X-ray energies, are estimated to be 0.31, 0.90, 1.8, and 2.7 mm, (or 2.6, 7.4, 15, and 22 pixel), respectively. They were calculated according to the analytic formula given in Ref. [12], although it was validated for electrons in condensed materials. For the lowest energies, and shortest tracks, the images are dominated by electron diffusion. The standard deviation is estimated to be 0.15 mm or 1.3 pixel for 0.8 cm drift distance with Magboltz [13]. Above 4.5 keV, tracks are clearly elongated. The high charge density region corresponds to the Bragg peak at the end of the track. This is because the electron ionization loss per unit length depends on the inverse of its energy according to an approximation of the Bethe formula in the low-energy limit: $-dE/dx \propto E^{-1}$, and therefore the charge distribution tends to be biased along its trajectory. In addition, in the higher energy range, some of the tracks are curved due to large-angle scattering of the photoelectron with a gas molecule.

3. Angular reconstruction

An accurate and robust method to reconstruct the initial ejection angle of a photoelectron from the various track images (see Fig. 1) is vital to achieve high polarization sensitivity. In digital image processing, image orientation, Φ , having the centroid as its pivot is given by:

$$\Phi = \frac{1}{2} \arctan \left(\frac{2\mu_{11}}{\mu_{20} - \mu_{02}} \right) \quad (2)$$

in general (e.g. Ref. [14]). In the above equation, μ_{ij} is a centralized (i, j) -moment of a 2-D image in which the pixel at (x, y) has a charge amount of Q_{xy} :

$$\mu_{ij} = \sum_x \sum_y (x - \bar{x})^i (y - \bar{y})^j Q_{xy}, \quad (3)$$

where (\bar{x}, \bar{y}) is the charge centroid position. The Φ direction is the same as the major principal axis of the charge distribution. Although Φ calculated with the atan2 function ranges from $-\pi/2$ to $\pi/2$, it is expandable to all angles $[-\pi, \pi]$ by using the sign of the third moment or skewness, which is sensitive to bias of the charge distribution, along the major principal axis with respect to the centroid. Fig. 2(a) illustrates an example of the above track reconstruction hereafter called “the single-stage reconstruction”. It is clear that the single-stage method fails to accurately reconstruct the initial photoelectron angle for curved tracks which often appear in the higher energy range.

Since the track direction is randomized by Coulomb scattering with gas molecules, the charge distribution near the beginning of the track carries the most information about the initial direction and thus the photon electric field. In order to improve the estimated track direction for curved tracks, the image region with the track end should be disregarded. In the previous works [6,11], we divided the track image by the minor principal axis, which is perpendicular to the major axis with respect to the centroid, ignore the half with the track end determined with the sign of the third moment along the major axis, and calculate the angle with the remaining half (which includes the interaction point) from Eq. (2). In the cutting of pixels with their position, a charge amount in each pixel is assumed to be located at its center. This revised method, hereafter called “the two-stage reconstruction” and illustrated in Fig. 2(b), is applied to elongated tracks (eccentricity $e > 0.8$), while the single-stage method is applied to tracks with $e \leq 0.8$. (Eccentricity is defined in Section 4.) Further improvement is possible for some tracks; the improved angle in Fig. 2(b) is closer to the initial direction, but does not yet account for all of the visible curvature in the first half of the track.

In order to adaptively remove the curved part of a track image and keep the beginning without overcutting, we use image moments up to the second order for not only a grayscale image with Q_{xy} but also its binary image created by image thresholding with the same value (three times the noise) as that described in Section 2. We hereafter distinguish the two moments by defining μ_{ij} and μ'_{ij} for grayscale and binary images, respectively. For example, the zeroth moment for a binary track image is μ'_{00} which represents the number of hit pixels. We can calculate the maximum and minimum of second moments, M_2^{\max} and M_2^{\min} , which corresponds to the standard deviations along the major and minor axes, respectively, as follows:

$$M_2^{\max} = \frac{1}{2} \left[\mu_{20} + \mu_{02} + \sqrt{(\mu_{20} - \mu_{02})^2 + 4\mu_{11}^2} \right], \quad (4)$$

$$M_2^{\min} = \frac{1}{2} \left[\mu_{20} + \mu_{02} - \sqrt{(\mu_{20} - \mu_{02})^2 + 4\mu_{11}^2} \right]. \quad (5)$$

The track image is repeatedly cut off in half pixel steps along the major axis of the entire image until the remaining number of pixels or the maximum second moment falls below set thresholds. The modulation factor derived from all the data is the highest when the threshold condition is set to be

$$(\mu'_{00} \leq 23) \text{ or } (M_2^{\max} \leq 3.0), \quad (6)$$

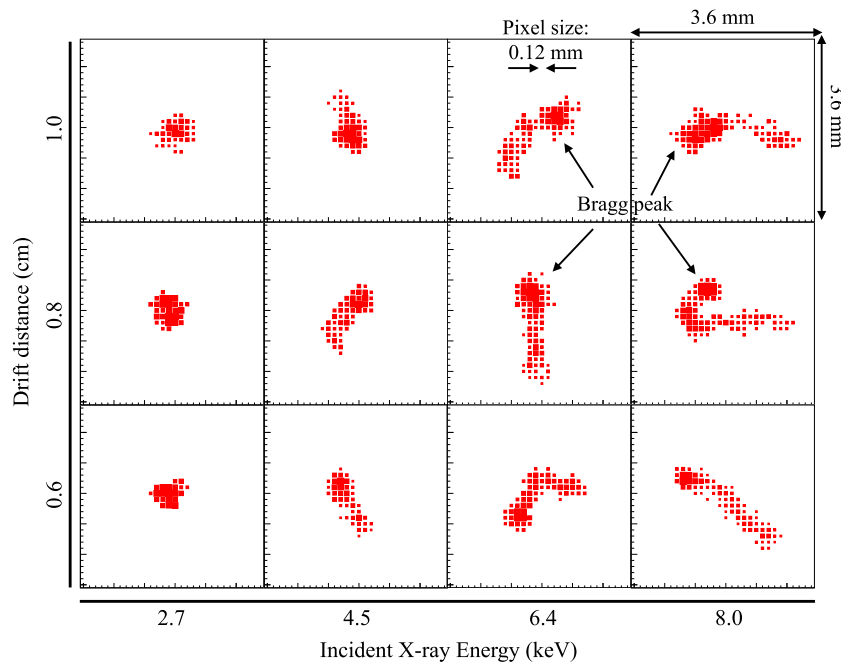

Fig. 1. Zoo of photoelectron track images acquired with the TPC polarimeter. The images are separately taken and are arranged in a plane of the X-ray irradiation position represented in the electron drift distance vs. the incident X-ray energy. The readout electronics limit the pixel size to 30 samples in the drift velocity direction; the track images are centered in the time dimension by the triggering algorithm and limited to 30 samples in the spatial coordinate before being analyzed. The box size in each pixel is proportional to the measured charge.

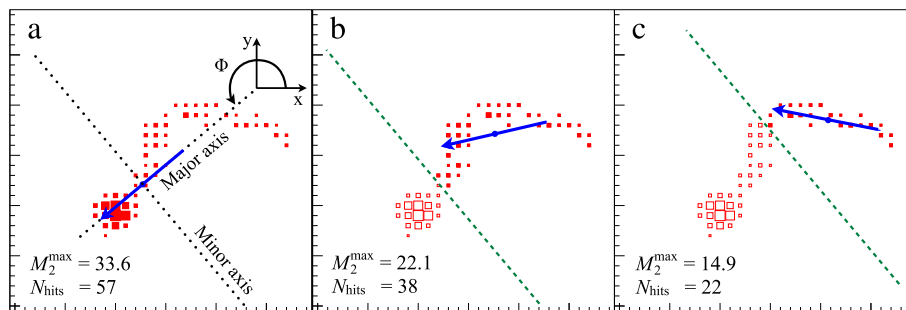

Fig. 2. Comparison of reconstructed angles using different methods. The track image is from an X-ray at 8.0 keV. The arrows in the panels (a), (b), and (c) represent angles reconstructed using the single-stage, two-stage, and adaptive cut methods, respectively. The filled and hollow squares represent used and unused pixels to calculate the image moments and reconstruct the angle Φ of each arrow by using Eq. (2). In panels (b) and (c), the dashed lines, which have the same angle as the minor axis determined with the single-stage method in the panel (a), split pixels into the above two types.

which is found by scanning the two thresholds at intervals of 1 and 0.1, respectively. The condition controls the remaining track size and avoids overcutting low-energy and round tracks for which the single-stage reconstruction without the pixel cut is the best. Fig. 2(c) shows an example of this reconstruction method named “the adaptive cut method”. Although conditions with M_2^{\min} and the third moments are individually added to the above equation, they do not improve the angular reconstruction. When the two threshold values in the condition (6) change by 10%, the modulation factor varies within 1%. In addition, we individually maximized the modulation factors derived from each data set taken with a monochromatic energy at a drift height in the same manner, and found that the difference of the modulation factor from that determined with the condition (6) is within 2%. It shows that the method is robust against the energy and the drift height.

The angular distributions (or so-called modulation curves) determined with the three reconstruction methods described above are plotted in Fig. 3. The sinusoidal amplitude, which is proportional to the polarimetry sensitivity, is clearly improved with the revised methods. The modulation factor, μ , is calculated by fitting the modulation curve to a sinusoidal model: $C\{\mu \cos[2(\phi - \phi_0)] + 1\}$, where C is a constant factor or unmodulated offset and ϕ_0 is the polarization angle. In addition, the

modulation factors at all the energies are corrected with the X-ray beam polarization of 94%. The obtained modulation factors for 8.0 keV X-rays are 32.7 ± 0.4 , 46.8 ± 0.3 , and $56.4 \pm 0.3\%$ determined with the single-stage, two-stage, and adaptive cut methods, respectively. The modulation factors as a function of the incident X-ray energy are shown in Fig. 4. The improved method leads to high modulation factors in the higher energy range above 5 keV. It also provides the monotonical increase of the modulation factor with the incident X-ray energy, while the single- and two-stage methods give drops to the higher energy. In the lower energy range, no drastic improvement is found because the modulation factor in that band is suppressed by track image blurring due to electron diffusion (see Fig. 1). The modulation factors determined with the adaptive cut method are 22.8 ± 0.4 , 43.0 ± 0.4 , 55.8 ± 0.3 , and $56.4 \pm 0.3\%$ at 2.7, 4.5, 6.4, and 8.0 keV, respectively.

Alternatively, a novel reconstruction method based on the shortest path problem in graph theory was recently developed and applied to the GPD polarimeter [9]. The new method called “the graph-based reconstruction” in this paper is also applied to our data set. This calculation needs two parameters: the filter radius to make a reconstructed path and the distance for exponential decay to generate a distance-weighted charge map from a reconstructed interaction point. The above radius

Fig. 3. Modulation curves derived from the different reconstruction methods for 8.0 keV X-rays. The histograms with circles, squares, and triangles are produced with the single-stage, two-stage, and adaptive cut methods, respectively. The dashed lines are the best-fit sinusoidal models to the data.

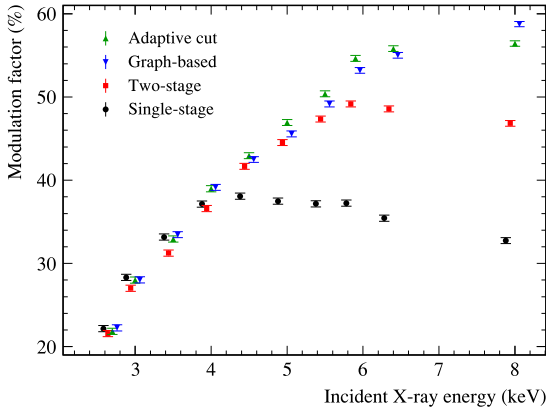

Fig. 4. Comparison of modulation factors calculated with various methods of angular reconstruction. The circles, squares, triangles, and inverted triangles show modulation factors calculated with the single-stage, two-stage, adaptive cut, and graph-based reconstruction methods, respectively. The horizontal positions of all the data points except for the triangles are slightly shifted for clarification.

and distance are 0.22 and 0.05 mm in Ref. [9], respectively. In our case, the two parameters are set to be 0.60 and 0.12 mm to maximize the modulation factor without a systematic modulation in the energy range of 2.7–10 keV. Both of them are larger than those for the GPD polarimeter because the diffusion size in the TPC polarimeter at low gas pressure is approximately double. In addition, our data set includes lower-energy and shorter tracks which require the larger radius so that the almost entire track is used to estimate the X-ray interaction point, while the GPD data set in Ref. [9] consists of 5–15 keV X-rays. The graph-based modulation factors plotted in Fig. 4 show that they are comparable to those determined with the adaptive cut method.

4. Track selection

Event selection with track roundness is capable of further improving polarization sensitivity. When a photoelectron is ejected in the direction nearly aligned with an incident X-ray, a 2-D photoelectron track image projected onto a plane perpendicular to the X-ray direction becomes a point or a filled circle blurred by electron diffusion. Such a track image loses the initial direction of the photoelectron or polarization information of the incident X-ray, and therefore should not be used for polarimetry analysis.

In order to quantify image roundness, two measures of eccentricity and circularity are in common use. Eccentricity, e , is defined here as:

$$e = \sqrt{1 - \frac{M_2^{\min}}{M_2^{\max}}}. \quad (7)$$

Eccentricity has been used for track selection of X-ray gas polarimeters in the past, although it is defined in the different way (e.g. Refs. [10,15,16]). Alternatively, we introduce circularity, c , for track selection. Circularity is often defined as the ratio of the image area to square of the image perimeter. However, this value changes with image noise caused by electron diffusion and electronic noise. Instead, we use a noise-insensitive circularity measure [17] defined as:

$$c = \frac{\mu_{00}^{\prime 2}}{2\pi(\mu_{20}^{\prime} + \mu_{02}^{\prime})}. \quad (8)$$

This circularity measure is invariant with translations, rotations, and scaling and ranges from 0 to 1 in the same way as eccentricity. However, a circular (straight line) image has circularity of 1 (0) and eccentricity 0 (1), showing the values mean the opposite.

Fig. 5 shows an example of photoelectron track images with eccentricity and circularity measures for 8.0 keV X-rays. The atoll-shaped track in Fig. 5(b) has similar eccentricity to the round-shaped track in Fig. 5(a), but different circularity, showing that circularity is a better indicator of image roundness for such a curved track induced by high-energy X-rays. On the other hand, in the lower energy range where the electron diffusion size is larger than the track length, the round-shaped tracks in Fig. 6 have similar circularity due to its noise-insensitive quality but different eccentricity. Therefore, eccentricity is more effective to select low-energy round-shaped tracks than circularity.

In order to optimize track selection with eccentricity and circularity, we define the figure of merit, $F \equiv \varepsilon \sqrt{\mu}$, where ε is signal acceptance decreased by track selection and μ is the modulation factor of the polarimeter. The figure of merit is derived from the minimum detectable polarization (e.g. Refs. [18,19]) on the assumption that the background signal is negligible. In the ideal case, where μ becomes 100% by subtracting the unmodulated component from the modulation curve, F can improve by $\mu^{-1/2}$. Since the improvement factor monotonically decreases with μ in the range from 0 to 1, track selection can be more efficient in the lower energy range where μ is relatively low (see Fig. 4).

We search for the selection criteria which maximizes F . In the previous paper [10], track selection was performed only with eccentricity. In this study, selection is optimized and performed by using a rectangular region cut for tracks on a 2-D plane of eccentricity vs. circularity at each incident X-ray energy. We empirically find that F is maximized by the following condition: [$e > 0.48$ and $c < c_{\text{th}}(E)$], where $c_{\text{th}}(E)$ is the circularity threshold given by the error function, erf, of an energy,

$$c_{\text{th}}(E) = -0.149 \operatorname{erf}[(E - 5.53)/1.38] + 0.851. \quad (9)$$

The energy, E , is obtained by scaling the measured pulse height of each event. Because $c_{\text{th}}(E)$ approaches 1 in the lower energy range, eccentricity cut is dominantly performed there.

Fig. 7 shows sensitivity improvement by using the above track selection. The modulation factors with applying track selection are 26.6 ± 0.4 , 46.1 ± 0.4 , 62.3 ± 0.4 , and $61.8 \pm 0.3\%$ at 2.7, 4.5, 6.4, and 8.0 keV, respectively. Although the modulation factors are shifted up $\sim 5\%$ at all the energies, polarimetry sensitivity, F , is not so effectively improved because signal acceptance decreases by $\sim 20\%$. Compared to the previous work [10], in which we performed the adaptive method with a different loop condition and selected round tracks only with eccentricity, polarization sensitivity increases by 5%–10% in the higher energy range where the newly introduced selection with circularity is dominant. On the other hand, sensitivity is unchanged in the lower energy range where tracks are blurred by electron diffusion. Just for reference, the 8.0 keV modulation factor calculated from the rejected events is $17.1 \pm 1.0\%$, showing that the event selection is reasonable.

Fig. 5. Eccentricity and circularity measures for photoelectron track images produced by 8.0 keV X-rays.

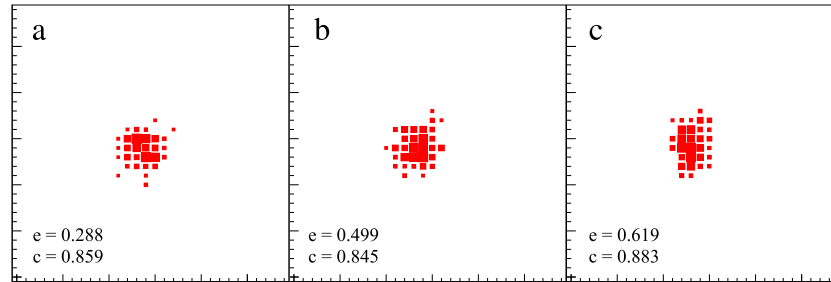

Fig. 6. Same as Fig. 5, but the incident X-ray energy is 2.7 keV.

Fig. 7. Comparison of polarization sensitivity. The top, middle, and bottom panels show the modulation factor, signal acceptance, and figure of merit, respectively. The multiply and circle symbols represent values with and without the round track selection, respectively. The plus symbols are values in the previous work [10]. The bottom panel shows the relative improvement of polarization sensitivity with the adaptive cut method; the circle and plus symbols are figures of merit normalized by the multiply symbols at each energy.

5. Conclusion

We have developed angular reconstruction based on the image moments of a photoelectron track image taken with the TPC X-ray polarimeter. The algorithm processes track images in the same way with energy-independent parameters. The obtained modulation factor is $21.8 \pm 0.4\%$ at 2.7 keV, monotonically increases with the energy, turns over around 6.4 keV, and shows a roughly constant value of 56% at the higher energy range. These modulation factors are comparable to those determined with the algorithm utilizing graph theory. Furthermore, the round track rejection method using eccentricity and the newly introduced circularity increases the modulation factors by $\sim 5\%$ at all the energies at the cost of signal loss by $\sim 20\%$. The resulting polarization sensitivity is unchanged in the lower energy range, but is improved by 5%–10% above 4 keV, compared to the previous work [10].
