Abstract

We analyzed the total, hydrophobic, and hydrophilic accessible surfaces (ASAs) of residues from a nonredundant bank of 587 3D structure proteins. In an extended fold, residues are classified into three families with respect to their hydrophobicity balance. As expected, residues lose part of their solvent-accessible surface with folding but the three groups remain. The decrease of accessibility is more pronounced for hydrophobic than hydrophilic residues. Amazingly, Lysine is the residue with the largest hydrophobic accessible surface in folded structures. Our analysis points out a clear difference between the mean (other studies) and median (this study) ASA values of hydrophobic residues, which should be taken into consideration for future investigations on a protein-accessible surface, in order to improve predictions requiring ASA values. The different secondary structures correspond to different accessibility of residues. Random coils, turns, and β -structures (outside β -sheets) are the most accessible folds, with an average of 30% accessibility. The helical residues are about 20% accessible, and the difference between the hydrophobic and the hydrophilic residues illustrates the amphipathy of many helices. Residues from β -sheets are the most inaccessible to solvent (10% accessible). Hence, β -sheets are the most appropriate structures to shield the hydrophobic parts of residues from water. We also show that there is an equal balance between the hydrophobic and the hydrophilic accessible surfaces of the 3D protein surfaces irrespective of the protein size. This results in a patchwork surface of hydrophobic and hydrophilic areas, which could be important for protein interactions and/or activity.

Keywords: Solvent accessibility; Pex files; hydrophobicity; secondary structure; amphipathy

Understanding the folding of proteins remains one of the major scientific challenges. One way to explore this complex problem is to get information from the protein structures themselves. We recently developed an analytical tool, named Pex files, in which numerical data on various structural parameters of proteins are described, such as secondary structures, side chain interactions, H-bonds, and more (Thomas et al. 2001, 2002a,b). Here we introduce a new Pex file that, in addition to the major structural parameters of proteins, lists a series of parameters describing the solvent accessibility.

The folding process of soluble proteins decreases the surface in contact with the solvent. This is related to the sec-

ondary structures of proteins. Accurate knowledge of residue accessibility would thus aid the prediction of secondary structures. Different methods of prediction are based on the use of protein structure databases and on multiple sequence alignments. They have various efficiencies, notably depending on the number of relative accessibility states (i.e., exposed, buried, and in-between; Rost and Sander 1994; Rost 1996; Li and Pan 2001; Naderi-Manesh et al. 2001; Yuan et al. 2002).

Further, because active sites of proteins are often located at the surface of the protein, greater insight into residue accessibility would be important in understanding and predicting structure/function relationships.

In the present study, we analyzed 587 proteins from the Protein Data Bank (PDB) using the Pex files. We extracted the total, hydrophobic, and hydrophilic accessible surfaces of residues. The method used to calculate the accessible surface is that of Shrake and Rupley (1973). The 587-pro-

tein bank is a nonredundant bank of structures (Liu and Chou 1999).

Results

Calculation of residue accessible surfaces in extended conformation

To check that the calculation of accessible surfaces in ASA-Pex files is correct, we used a window of three residues along the structure; the surface of the central residue is calculated. This mimics the surface of residues measured in tripeptide by others, such as Gly-X-Gly or Ala-X-Ala (Creighton 1993; Samanta et al. 2002) and corresponds to the residue surface in the unfolded state. A very good correlation is observed between Pex data and previously published values (Table 1). When the residue surface is split into hydrophilic and hydrophobic surfaces (Table 1; Fig. 1), the residues with the highest hydrophobic versus hydrophilic ASA ratio are Phe and Met. Their hydrophobic surface is more than four times higher than the hydrophilic one. Residues with the smallest ratio (3–4 times more hydrophilic than hydrophobic) are Asp and Asn. Plotting the hydrophobic/hydrophilic ratio as a function of the total ASA value clusters the residues into three groups (Fig.1): One group is the hydrophobic amino acids ($G < A < V, C, P < I, L < F, M$) for which the hydrophobic/hydrophilic ratio is increasing with the surface; the second con-

tains the hydrophilic residues ($D, N < E, Q < R$) whose ratio is rather independent of the residue surface; and a third group containing S, T, H, K, Y and W, whose ratio varies almost exponentially with the residue surface. This underlines that the aromatic residues with polar atoms (W, Y, H) do not behave like Phenylalanine and are not pure hydrophobic residues. It is worth noting that Lysine, although generally considered as a hydrophilic residue, has a ratio near 1 (Fig.1) and belongs to the third group, unlike Arg. This is due to its long hydrophobic chain holding the polar head.

Surfaces are expressed in angströms². Reference surfaces are those determined experimentally on Gly-X-Gly peptides by Creighton (1993). The ratio of pho surface vs. phi surface corresponds to the ratio of column 4 vs. column 5.

Calculation of residue accessible surface in folded proteins

Accessible surfaces of residues in folded proteins were determined as described in Materials and Methods. As expected, all residues decrease their accessibility to the solvent, to about 45% for Lys and Glu and down to a few percent (about 5%) for the most hydrophobic residues (Ile, Leu, Val, and Cys), with respect to the residue accessibility of the unfolded state (Table 2). On average, the accessible surface of residues of folded proteins is reduced to 20%.

There is a clear difference in the behavior of the hydrophobic and hydrophilic residues, the latter being largely more accessible, as shown in Figure 2. Folding similarly reduces the hydrophobic and hydrophilic surfaces for each residue, except for Proline (and to a lesser extent Glycine), which buries much more hydrophilic than hydrophobic surface (Table 2, Fig. 2). Figure 3 summarizes these observations, showing the hydrophilic versus the hydrophobic accessible surface of the residues of folded proteins. The same three groups of residues observed in Figure 1 can be distinguished. They correspond to the hydrophobic residues (C,I,L,V,A,M,F,G with low hydrophobic and hydrophilic ASAs) and to the hydrophilic residues (N,D,Q,E,R with high hydrophilic and low hydrophobic ASAs); and the third group (S,T,Y,W,H) has intermediate hydrophobic and hydrophilic ASA values. Note the peculiar behavior of Pro and Lys in that both have high hydrophobic ASA but differ in their hydrophilic ASA value.

Values of the accessible surface of hydrophilic residues are in good agreement with those previously reported (Samanta et al. 2002). However, the ASA for the hydrophobic amino acids and especially for Ileu, Leu, Val, Cys, and Met are 2 to 3 times lower than the previously reported values (Table 2). This is due to the fact that we used median instead of mean ASA values. We believe that median ASA values are more appropriate than means when we look at the frequency distribution of residue ASAs in 3D structures (Fig. 4). Where the ASA distribution of hydrophilic residues such as Lys or Gln appears partly gaussian, indicating that mean and median values should not be too different (Fig. 4A,B, respectively), frequency distributions of the hydrophobic residues ASA are clearly not symmetrical. Many of those amino acids are completely inaccessible to the solvent, as shown for Ile (Fig. 4C) or Phe (Fig. 4D). Mean values of these distributions correspond to the previously reported ASA values of amino acids as shown in Table 2, suggesting that our data are not different from the literature. However, mean values are obviously inadequate to describe the distribution of ASAs, the median being more appropriate. This suggests that ASAs of hydrophobic residues were overestimated in a number of studies.

Accessible surfaces in the different secondary structures

Five classes of secondary structures were considered: α -helix (Ha), parallel (Bp) and antiparallel (Ba) β -strands,

Surfaces are expressed in angströms².

Figure 2. Values of median pho (black bars) and phi (gray bars) ASA for each residue in the extended state (A) and in folded proteins (B). Residues are sorted by decreasing total ASA values.

β -structures (B), and random coil/turn (C-T) conformations. These structural elements are defined in Materials and Methods. They correspond to 32,806 residues analyzed for Ha; 2851 residues for Bp; 27,603 residues for Ba; 36,230 residues for B; and 45,220 residues for C-T.

For each structural class, the total, hydrophobic, and hydrophilic median ASAs were calculated (Tables 3–7) and compared to the residue ASA in the extended conformation (ASA calculated with a window of 3). The most accessible residues belong to the random coil/turn (C-T) class, whereas the Ba and Bp structures result in the most solvent-inaccessible residues.

Random coil/turn structures

This class has the most accessible residues, with an average of 30% of accessible surface (Table 3). There is a segregation between the hydrophobic (I,L,V,M,W,F,Y) and the hydrophilic (K,R,N,D,Q,E,T,S) residues. The former are 10%–20% percent accessible and the latter are about 50% accessible. Gly, His, and Ala have intermediate values, and Pro is highly accessible. Hydrophobic and hydrophilic accessible surfaces are similarly decreased, except for Gly and Pro.

It should be noted that the hydrophilic accessible surface of the most hydrophobic residues (i.e., Ile, Val, Leu, Met, Phe) should correspond to the accessibility of their backbone (Table 3).

β -Strands (B-structures)

The residues are almost as accessible in B-structures as in random coil/turn structures, and the segregation between the hydrophobic and the hydrophilic residues is also observed (Table 4). A noticeable difference lies in how the hydrophobic and hydrophilic accessible surfaces of residues decrease (cf. columns 9, 10 of Tables 3 and 4). Although the hydrophobic and hydrophilic ASAs of hydrophilic residues are similarly reduced, hydrophobic residues show a twofold more pronounced decrease in the hydrophobic surface compared to the hydrophilic surface. This suggests that B-structure is more prone to shield the hydrophobic moiety of hydrophobic amino acids compared to the random coil/turn structure.

For Proline, which is 30% accessible, the opposite is observed; that is, the hydrophilic surface is less accessible than the hydrophobic one (as in the random coil/turn structure).

Further, as for random coil/turn, the hydrophilic accessible surface of the most hydrophobic residues in B-structures should correspond to the accessibility of the backbone.

Parallel and antiparallel sheets

These folds correspond to the less accessible residues: On average, only 10% of the residue surface is accessible (Tables 5,6). This is particularly true for the hydrophobic residues such as Leu, Ile, Val, Met, Cys, and Phe (1%–5% accessibility). In these folds, again, the most accessible residues are Lys and Glu (23%–33% accessibility) and hydro-

phobic and hydrophilic residues are segregated, Ser and Thr having intermediate values. For almost all residues, the Ba/Bp structures appear to shield their hydrophobic domains from the solvent better than any other structure, as reported by Choithia (1976).

ASAs are expressed in angstroms² and are compared to those obtained with a window 3.

This suggests that a sequence will have a smaller hydrophobic accessible surface as a β -sheet than in any other conformation. This could be related to the formation of fibrils observed with highly hydrophobic peptides. Indeed, fibrils are made of antiparallel β -strands, as reported regard-

residues) is no more accessible in Ba/Bp structures, in contrast to what happens for random coil/turn and B-conformations.

α-Helices

Residues of helical folds have an intermediate solvent accessibility of ~20% (Table 7). The difference between the accessibility of hydrophobic and hydrophilic residues is highly marked. For *α*-helices, K, E, R, N, D, Q, S, and T are 45% (Lys) to 19% (Ser) accessible with an average of 35% accessibility, whereas hydrophobic residues are only 1%–5% accessible (except for Trp and Tyr, which are 10% accessible). This is linked to the observation that most *α*-helices of protein 3D structures are amphipathic (Chou et al. 1997). Amphipathic helices have most of the hydrophobic residues oriented toward the protein core, whereas the hydrophilic residues are water-accessible.

It should be noted that the helical structure similarly reduces the hydrophobic and the hydrophilic surfaces of all residues, in contrast to what happens in *β*-folds.

In the helical structure, as for *β*-sheets, the backbone is not accessible (hydrophilic surfaces of hydrophobic residues are almost null).

The same calculations of surfaces were made by selecting the secondary structures attributed to the CO-side of the residue. The number of residues analyzed for each structural class remains similar, as were the surfaces (data not shown).

Analysis of ASAs in data sets containing only β - or α -proteins

In light of our observation that the β -fold better shields hydrophobic parts of amino acids from water whereas helical structure better segregates hydrophobic and hydrophilic residues (the latter remaining accessible to the solvent), we wondered whether this would also hold true for two data sets one containing proteins with α -structures (no β -residues) and the other with β -proteins (no helical folds). These sets were extracted from the 587-protein bank by selecting 26 β -proteins and 55 α -proteins, as described in Materials and Methods.

Table 8 shows that the accessible surfaces of residues in helical conformation of α -proteins (corresponding to 6,530 residues) are the same as those determined for the 587 proteins, confirming the amphipathic character of the helical fold.

In Table 9, Ba and Bp structures were grouped, because only 144 residues were from parallel β -sheets. The two structures altogether correspond to 1,273 residues. Hydrophobic residues are poorly accessible, but the ASAs of hydrophilic residues (R,N,D,E,H,K,S,T) are higher (20%–50% increase) than those in the Ba and Bp residues analyzed in the 587-protein bank. This is most likely because the β -proteins must finally be soluble: Indeed, they contain more hydrophilic residues (42% as compared to 27% for the 587-protein bank). Nonetheless, residues in β -structures remain the less accessible (about 12% on average compared to

20% for the helical structure) and again, β -sheet is the best fold to shield the hydrophobic part of amino acids from water.

Analysis of the total surface of the 587 proteins

We next examined the relationships between the total accessible surface of a folded protein and its sequence length. Figure 5 shows that the water-accessible surface of proteins is a simple function of the number of residues. This is in agreement with the study of 12 proteins by Chothia (1976).

More surprising is the ratio of hydrophilic to hydrophobic accessible surfaces, which lies near 1 for all of the proteins we analyzed. Figure 6 shows that hydrophobic and hydrophilic accessible surfaces are proportional to the total protein surface (regression coefficient near 0.99) and that the proportionality is similar for hydrophobic and hydrophilic surfaces. This supports that the surface of a soluble protein is not only hydrophilic, as often meant. These data suggest that folding tends to equilibrate the hydrophobic and hydrophilic solvent-accessible areas. This is illustrated by calculating the molecular hydrophobicity potentials (MHPs; Brasseur 1991) that draw the envelope of the hydrophobic and hydrophilic environments of a molecule (Fig. 7) and demonstrates that soluble molecules have significant hydrophobic patches.

Discussion

We analyzed the water-accessible surfaces of all residues from 587 nonredundant structures of proteins determined by NMR and X-ray diffraction with 1.2 to 2.9 Å resolution. As expected, we show that residues lose part of their accessible surface due to folding and that the decrease is more pronounced for hydrophobic residues, as previously described (Chothia 1976). However, we also report that the accessible surfaces of hydrophobic amino acids in proteins are for the most part smaller than previously reported (Samanta et al. 2002). Many hydrophobic residues are completely buried, and the distributions of residue ASAs are far from being gaussian. Hence, the average accessibility of a residue in a protein is better described by a median than by a mean value. Because our analysis depicts a clear difference between the mean and median ASA values of hydrophobic residues, this should be taken into consideration for future investigations of protein accessible surfaces and would probably help to improve predictions using ASA values.

Three groups of amino acids can be distinguished based on the relationships between their hydrophobic and hydrophilic accessible surfaces, either in the extended state or in the folded proteins. One group is made of the hydrophobic residues (I,L,V,F,M,A,G), another contains the hydrophilic residues (D,N,E,Q,R), and the third shows intermediate behavior (H,Y,W,S,T). Proline and Lysine are apart. Among the hydrophilic residues, Lysine is peculiar: It is often looked at as a hydrophilic residue but in the unfolded state,

it has almost equal hydrophobic and hydrophilic accessible surfaces. Moreover, in the folded state, it has the highest hydrophobic ASA of all residues. Proline also has special features, as it has the highest hydrophobic accessible surface among the hydrophobic residues. This is related to its preferential location in accessible turns of proteins.

The classification of amino acids into three amino acid “families” following their hydrophobic/hydrophilic accessible surface should be important in terms of the prediction of conservative mutations.

The different types of secondary structure correspond to different accessible surfaces. Random coils, turns, and β -strands that are either not H-bound or are H-bound to a structure that is not a strand are the most accessible folds, with an average of 30% of residue accessibility. In these structures, the backbone of the most hydrophobic residues (I,V,L,M,F) is quite accessible, with 10%–15% accessibility.

The β -sheets (parallel and antiparallel strands) are the most solvent-inaccessible structures (with about 10% of

Figure 5. Log of the total ASA as a function of the log of the number of residues for the 587 proteins analyzed. The coefficient of the linear regression is 0.97.

residue accessibility), whereas the helical conformation has an intermediate value, with about 20% of the residue surface accessible.

Both helical and β -sheet conformations shield the backbone of the most hydrophobic residues from water, in contrast to what happens for the “unordered” structures.

In all folds, there is a noticeable difference between the hydrophobic and hydrophilic residues, the latter being always more solvent-accessible. The greatest difference is observed in α -helices related to their amphipathic character. When the protein folds, the hydrophobic side of the helix is buried in the protein core, and the hydrophilic side remains solvent-accessible. The β -sheets are the most appropriate structures to shield the hydrophobicity of residues. This is likely important in the formation of fibrils in pathological and nonpathological phenomena.

Note that Lysine and Glutamic acid are the most accessible residues, whereas Leucine, Isoleucine, and Valine are the most inaccessible, irrespective of secondary structures.

As described earlier by Chothia (1976) regarding 12 proteins, there is a simple relationship between the total accessible surface of folded proteins and their size. We also show that there is a balance between the hydrophobic and the hydrophilic surfaces of the 3D protein surface. This balance is maintained irrespective of the protein size, resulting in a patchwork surface of hydrophobic and hydrophilic areas. Size and accessibility of the patches should be important for protein-protein interaction sites and/or for activity, as suggested by others (Eisenhaber and Argos 1996; Jones and Thornton 1997).

Materials and methods

Proteins

The PDB files of the 587 proteins were transformed into ASA Pex files, giving a total of 156,215 residues that were analyzed. These

Figure 7. (Left panels) Molecular hydrophobicity potentials (MHPs) around three proteins analyzed (one α -protein, apolipoprotein III, PDB code 1AEP; one β -protein, human fibronectin, FBR; one α/β -protein, diene lactone hydrolase, 1DIN). MHPs, based on atomic transfer energies, allow the visualization of pho (orange) and phi (green) domains around a protein and are calculated as described in (Brasseur 1991). (Right panels) Ribbon representations of the protein in the same orientation as in the left panels. (A) 1AEP, (B) 1FBR, (C) 1DIN.

structures were issued from the nonredundant bank described by Liu and Chou (1999) containing 593 entries. Five proteins were discarded, their format being incompatible with their transformation into Pex files. The PDB codes are listed below; the experimental resolution is between 1.2 and 2.9 Å. ASA Pex files are accessible on the CBMN Web site (<http://www.fsagx.ac.be/bp/>) or can be obtained from author R. Brasseur.

For the β -only proteins data set, 26 files were extracted with the criterion that the proteins do not contain α -helical structure; for the α -only proteins, 54 files were extracted with the criterion that they do neither contain Ba- or Bp-structured residues.

The α -bank corresponds to the following files:

1aep, 1arv, 1ash, 1axn, 1bbh, 1bcf, 1ccr, 1cem, 1cns, 1cnt, 1col, 1cpq, 1eca, 1etp, 1h1b, 1huw, 1ign, 1ilk, 1jvr, 1kxu, 1lis, 1lki, 1lrv, 1maz, 1mey, 1mls, 1msf, 1nfn, 1oct, 1pbw, 1poc, 1rci, 1rfb, 1rhg, 1spg, 1sra, 1uby, 1vin, 1vls, 1xsm, 2abd, 2abk, 2ccy, 2cyp, 2end, 2fal, 2hbg, 2hmz, 2lfb, 2tct, 2tmv, 3sdh, 6fab, 9wga.

The β -bank corresponds to the following files:

1cea, 1cur, 1fbr, 1fnf, 1hce, 1i1b, 1knb, 1lcl, 1msa, 1msp, 1nfa, 1npo, 1pco, 1pdg, 1ptx, 1svp, 1tqx, 1tpg, 1tul, 1ulp, 1vmo, 1wba, 1yha, 2mpr, 2pii, 4fgf.

ASA-Pex files

Each Pex file originates from the PDB file of a protein. Each line of the Pex corresponds to a residue in the order of the sequence, and each column is a parameter calculated in the 3D structure as described by Thomas (Thomas et al. 2001). In the ASA-Pex file, calculation of accessible surface areas (ASAs) of the whole residue (lateral chain and backbone) was achieved using the method of Shrake and Rupley (1973). In brief, the spherical surface of each atom is covered by a net of 642 points (the initial method used 92 points), and the points that lie within other expanded atoms are determined. The SERF algorithm where this method is implemented was used (Flower 1997).

Determination of the hydrophobic and hydrophilic accessible surfaces of residues

The method of Shrake and Rupley (1973) was also used to calculate the hydrophobic and hydrophilic ASAs. With this method, the

hydrophobic and hydrophilic ASAs correspond to the sum of the surface of hydrophobic or hydrophilic atoms of the residue, respectively. Atoms are considered hydrophobic or hydrophilic depending on their transfer energy, as described (Brasseur 1991).

Median values of total, hydrophobic, and hydrophilic accessible surfaces were calculated using Excel software (Microsoft).

Determination of the secondary structure of the residues

In the PDB files, no protein has a complete description of secondary structures. We therefore established our definition of secondary structures based on the (ϕ/ψ) values and on the occurrence of main chain H-bonds (O...H distance less than 3.5 Å), as described in Thomas et al (2001). Two different structures were attributed to the same residue according to the fact that that residue can be involved in two H-bonds, one on its NH side, the other on its CO side. Both secondary structures are listed in the Pex. In the present study, the NH secondary structure was considered.

Definition of the different secondary structures

Helices

Helical residues have a main chain H-bond and ϕ/ψ within a circle of 45° around the couple $\phi = -57^\circ$ and $\psi = -47^\circ$. The main chain H-bond has an O...H distance less than 3 Å. The helix is α (Ha) when the n and the $n \pm 4$ residues are H-bound.

β -Structures

Residues are in β when the ϕ/ψ are within a circle of 90° around the $\phi = -129^\circ$ and $\psi = 123^\circ$. When two strands are H-bound, they are either antiparallel (Ba) or parallel (Bp) sheets. The sheets are parallel when the vectors between the C α of the residues n and $n + 1$ of each strand draw an angle of -90° to $+90^\circ$. They are antiparallel when the same vector angles are between 90° and 180° or -90° and -180° apart. B is for β -strands that are either not H-bound or are H-bound to a structure that is not a strand.

Random coils/turns

The ϕ/ψ values of the different turns are from Srinivasan and Rose (1995). The presence of an H-bond is not mandatory.

The ϕ/ψ of random coils span a large range of values, including the left helices that were not individualized in this study. Random coils also account for right helices and β -residues when the H-acceptor (the O = C residue, $n + i$) and the NH-donor (n) are too far away in the sequence for a helix ($i > 6$) or too close for a β -sheet ($i < 3$).

Molecular hydrophobicity potential (MHP) calculations

MHP is a three-dimensional plot of the hydrophobicity potential of a molecule created to visualize its amphipathy. The hydrophobicity of a molecule is calculated using its partition coefficient between water and octanol.

We postulate that the hydrophobicity induced by an atom i and measured at a point M of space decreases exponentially with the distance between this point M and the surface of an atom i according to the equation (Brasseur 1991):

$$\text{MHP}_M = \sum_{i=1}^N E_{\text{tri}} \exp(r_i - d_i)$$

where N is all atoms of the molecule, E_{tri} is the transfer energy of atom i , r_i is the radius of the atom i , and d_i is the distance between atom i and the point M. E_{tri} is the energy required to transfer an atom i from a hydrophobic to a hydrophilic medium. Atomic E_{tri} values were calculated from the molecular transfer energies compiled by Tanford (1973), assuming that molecular E_{tr} are the sum of their atomic E_{tr} . Atomic E_{tr} values were derived for seven different atom types (Brasseur 1991).

The hydrophobic and hydrophilic isopotential surfaces were calculated by a cross-sectional computational method. A 1-Å mesh-grid plane was set to sweep across the molecule by steps of 1 Å. At each step, the sum of the hydrophobicity and hydrophilicity values at all grid nodes was calculated. The hydrophobic and hydrophilic MHP surfaces were then drawn by joining the isopotential values.

All calculations were performed on Pentium III processors, using Z-TAMMO and Z-PEX software. Molecular graphs were drawn using WinMGM (Ab Initio).
