(Received 14 May 1990; accepted 15 January 1990)

Summary — A precommercial thinning was conducted on young balsam fir (*Abies balsamea* (L) Mill) and white birch (*Betula papyrifera* Marsh) trees. Changes in light environment and growth response of the trees were followed during the next 2 growing seasons. The relative growth rate (RGR) of thinned balsam firs increased during both the first and the second growing season. This increase in growth was attributed to a greater net assimilation rate (NAR) which was associated with a higher level of light availability. Thinning tended to positively affect the RGR of white birch during the first summer following treatment but not during the second growing season. Similar fluctuations were noted for NAR even though light levels remained high for thinned white birch trees during both the first and the second growing season. Balsam fir produced more sapwood per unit of additional leaf area than controls during the first summer following treatment but no differences were observed during the second. The sapwood area growth to leaf area growth ratios of thinned and control white birches were similar during both the first and the second summer following thinning. Thus the sapwood area—leaf area relationship appears to be more stable following abrupt changes in environmental conditions for the indeterminate growth species, white birch, than for the determinate growth species, balsam fir.

growth analysis / thinning / net assimilation rate / light use efficiency / sapwood area—leaf area ratio

Résumé — Analyse de la croissance et de l'interception de la lumière du sapin baumier et du bouleau à papier à la suite d'une éclaircie précommerciale. Une éclaircie précommerciale a été réalisée autour de jeunes tiges de sapin baumier (*Abies balsamea* (L) Mill) et de bouleau à papier (*Betula papyrifera* Marsh) et leur croissance de même que les changements de conditions lumineuses ont été étudiés pendant les deux saisons de croissance suivant le traitement. Le taux de croissance (RGR) des sapins baumiers éclaircis a augmenté pendant les 2 saisons de croissance suivant le traitement. Cette hausse de croissance a résulté d'une augmentation du taux d'assimilation net (NAR) qui a été associée à une plus grande disponibilité de la lumière. L'éclaircie a eu tendance à affecter positivement le RGR des bouleaux à papier pendant la première année suivant le traitement mais l'effet contraire a été observé pendant la deuxième année. Cette même tendance a aussi été observée pour le NAR quoique le niveau de lumière soit resté plus élevé pour les bouleaux

* Correspondence and reprints

à papier éclaircis pendant la deuxième année suivant le traitement. Les sapins baumiers éclaircis ont produit plus d'aubier par unité de croissance en superficie foliaire que les témoins pendant le premier été suivant le traitement, mais aucune différence n'a été observée pendant le second été. La relation entre la croissance en superficie d'aubier et la croissance en superficie foliaire des bouleaux à papier dégagés a été semblable à celle des témoins pendant les 2 saisons de croissance suivant le traitement. Il semble donc que, à la suite d'un changement des conditions environnementales, la relation entre la superficie d'aubier et la superficie foliaire des arbres soit plus stable dans le cas de l'espèce à croissance indéterminée, le bouleau à papier, que pour l'espèce à croissance déterminée, le sapin baumier.

analyse de croissance / éclaircie / taux d'assimilation net / efficacité d'utilisation de la lumière / relation superficie d'aubier–superficie foliaire

INTRODUCTION

Intra- and inter-specific competition in dense stands can limit the availability of environmental resources such as light, water, and mineral nutrients. Reducing competition through thinning is a common silvicultural practice which increases the supply of these environmental resources to selected crop trees. The increased light intensity is often associated with a higher transpiration rate on a unit leaf area basis (Black *et al.*, 1980; Whitehead *et al.*, 1984). Following thinning, this increased water loss per unit leaf area is normally compensated for by lower transpiration and rainfall interception rates per unit of ground area, often resulting in higher soil water content (Whitehead *et al.*, 1984; Aussenac and Granier, 1988). Nevertheless, if little or no osmotic adjustment occurs, leaves of thinned trees can reach zero turgor, a symptom associated with thinning shock (Pothier and Margolis, 1990). Thinning can also increase the availability of mineral nutrients by reducing root competition if sprouting does not occur. Moreover, additional nutrients can be released by faster litter decomposition caused by the increase in temperature (Piene, 1978).

Light availability is usually the most important factor affecting tree growth following removal of competing vegetation

(Brand, 1986). This higher light intensity can modify leaf morphology by increasing the thickness of leaf mesophyll and the amount of chlorophyll per unit leaf area which can lead to increased photosynthetic rates (Nygren and Kellomäki, 1983; Oren *et al.*, 1986). Higher photosynthetic rates per unit leaf area were thought to be responsible for the increased stemwood growth observed soon after thinning of Douglas fir (Brix, 1983). The contribution of net assimilation rate to the growth response began to decline 2 yr after treatment, and was gradually replaced during subsequent years by the effect of increased foliage biomass (Brix, 1983).

The growth response of a tree following thinning is determined primarily by its photosynthetic capacity (Brix, 1983). Consequently, this study aims to examine the response of thinned trees in terms of foliage quantity, foliage efficiency and the relationship between sapwood area and leaf area. Since photosynthetic photon flux density (PPFD) was expected to be the major environmental component affecting tree growth, it was measured around sample trees and then integrated into the growth analysis. Two common competitors in the forests of eastern Canada, balsam fir (*Abies balsamea* (L) Mill), and white birch (*Betula papyrifera* Marsh) were selected for this study.

MATERIALS AND METHODS

Study area

The study took place at Forêt Montmorency (47.3°N 71.2°W) located ≈ 80 km north of Québec City, Québec, Canada. Mean annual precipitation is ≈ 1 430 mm, ≈ 66% (950 mm) in the form of rain. The mean annual temperature is 0.3 °C with monthly averages ranging from -15.8 to 14.8 °C for January and July, respectively. The growing season typically extends from the beginning of June to the end of August.

A mixed balsam fir–white birch stand was selected for study. The stand, established from natural regeneration following a 1975 clearcut, was located on an east-facing exposure with a 12% slope. The soil was a well-drained humic orthic podzol derived from till. The stand contained ≈ 30 000 stems/ha in 1987, ≈ 70% of which were white birch. At the beginning of the experiment, the average diameter at breast height and total height of balsam fir were 1.4 cm and 2.2 m, respectively, while the values for white birch were 1.6 cm and 3.3 m, respectively.

During the autumn of 1987, 5 blocks were randomly established in the stand. Within each block, 6 balsam fir and 6 white birch trees were randomly selected. For 3 trees of each species, all trees within a distance of 1.5 m from a selected tree were cut down. The other 3 trees of each species were left as controls.

Biomass measurements

At the end of August in 1988 and 1989, 1 tree of each species-treatment combination was cut per block. The 20 trees (2 species × 2 treatments × 5 blocks) were divided by height into 3 crown sections, placed in separate plastic bags, and stored in a refrigerator.

For each crown section, all current year shoots and leaves were removed and their fresh weights were determined. Subsamples of ≈ 30 balsam fir needles and 5 white birch leaves were then collected, and leaf areas were measured with a leaf area meter (Model Li-3000, Li-Cor Ltd, Lincoln, NE, USA). These subsamples, and all remaining leaves, were dried at 70 °C for

at least 48 h. Shoot subsamples were also dried for the determination of fresh weight–dry weight conversion factors. The same procedure was used for balsam fir shoots and needles of the previous growing season. Leaves, shoots and stems from the rest of the crown section were weighed separately and another set of subsamples was taken for determination of fresh weight–dry weight conversion factors. Furthermore, the basal area growth for 1988 and 1989 was calculated for each of the 3 crown sections and its percentage in relation to the total basal area was calculated. This factor was applied to the total biomass of the stem and branches of each crown section in order to estimate stem and branch growth for each of the 2 years.

Light measurements

On 5 cloudless days during each growing season, the percentage of photosynthetic photon flux density (*PPFD*) reaching each sample tree was estimated using a Li-Cor quantum sensor (Li-190SB, Li-Cor Ltd, Lincoln, NE, USA). The quantum sensor, which was connected to an integrating millivoltmeter, was uniformly scanned up and down and from side to side of the sun-facing side of each sample tree for ≈ 20 s. Just prior to each of these measurements, another integrated measure of *PPFD* was taken in an opening under full sun. By dividing these 2 values, we were able to assess the percentage of *PPFD* reaching our study trees. Photosynthetic photon flux density measurements were taken at randomly selected times between 9:00 and 15:00 for each tree. Thus, these *PPFD* measurements represent average values from the main part of the day and do not include any measurements taken when the sun was near the horizon.

The total incident *PPFD* for each growing season (June 1–August 31) was estimated from a Bellani pyranometer located in an opening near the experimental site. The daily readings of the Bellani pyranometer were corrected for changes in temperature and then transformed into net short-wave radiation (150–4 000 nm) using the equation of Bernier and Plamondon (1983). Total *PPFD* was calculated assuming that 50% of the net short-wave radiation lay within the waveband 400–700 nm (Hunt *et al.* 1984).

The product of incident *PPFD* for each growing season and the percentage of *PPFD* available to the trees was taken as an estimate of light availability (I_0) for each sample tree. Moreover, the amount of *PPFD* intercepted by trees (J) was estimated by the product of I_0 times the projected leaf area of each tree (Hunt *et al.*, 1984).

Growth analysis

Growth analysis was performed using the relative growth rate (*RGR*) and its classical subdivision into specific leaf area (*SLA*), leaf weight ratio (*LWR*), and net assimilation rate (*NAR*):

$$[1] \quad RGR = \frac{1}{W} \frac{\partial W}{\partial t} = \frac{LA}{LW} \times \frac{LW}{W} \times \frac{1}{LA} \frac{\partial W}{\partial t} \\ = SLA \times LWR \times NAR$$

where W is the total dry mass of stemwood and branches (g), LA is the projected leaf area of the tree (m^2), LW is the leaf weight of the tree (g), and $\partial W/\partial t$ is the instantaneous rate of change in plant dry mass. The calculations of *RGR*, *SLA*, *LWR*, and *NAR* were made according to Margolis and Brand (1990).

These calculations used estimates of LA of the previous growing season because direct measurements would have required defoliating the trees at the beginning of the experiment. For balsam fir, projected leaf area of the previous year was assessed by subtracting the current year leaf area production from the total leaf area adjusted to account for the 12.5% turnover of balsam fir foliage per year (Bakusis and Hansen, 1965). The same procedure was applied for the determination of the previous year leaf weight. For white birch, the previous year leaf area was estimated from the sapwood area to leaf area ratios determined for the current year leaf area and subtracting the current year sapwood growth. Previous growing season leaf weight for white birch was computed as the product of the previous year leaf area and the specific leaf weight (g/m^2) of the control white birches only.

Net assimilation rate (*NAR*) was further subdivided into light availability and light use efficiency (Margolis and Brand, 1990):

$$[2] \quad NAR = \frac{1}{LA} \frac{\partial W}{\partial t} = \frac{J}{LA} \times \frac{1}{J} \frac{\partial W}{\partial t} = I_0 \times LUE$$

where J is the amount of *PPFD* energy intercepted by a plant per unit time ($MJ \text{ yr}^{-1}$). Thus, I_0 corresponds to the light availability, ie the amount of incident light per unit area per unit time ($MJ \text{ m}^{-2} \text{ yr}^{-1}$), and LUE is the light use efficiency ie the amount of wood (g dry weight) produced per unit of intercepted light ($g \text{ MJ}^{-1}$). Since *RGR*, *NAR* and *LUE* are average values over periods of 1 yr, the product of $SLA \times LWR \times NAR$ (Eq 1) and $I_0 \times LUE$ (Eq 2) only approximate *RGR* and *NAR*, respectively. These products will equal *RGR* and *NAR* only if the values are calculated instantaneously (Radford, 1967). Since the values shown in tables I and II are yearly averages, multiplying these average values together does not necessarily give the same result that one would expect from the equations. In fact, fairly large discrepancies did occur.

Statistical analysis

Data were subjected to analyses of variance for a split-plot design where species was the main plot, and the thinning treatment was the split plot. Least significant differences at the 95% level were computed using the Waller-Duncan multiple comparison test. Logarithmic data transformation was applied when the variances of groups were found to be proportional to their means.

RESULTS

Precommercial thinning increased *RGR* of balsam fir by 43% the first growing season following treatment and 65% the second growing season (table I). Thinning did not significantly affect *LWR* of balsam fir but rather resulted in a decreased *SLA*. Net assimilation rate (*NAR*) was increased 78% and 92% by the treatment during the first and the second growing seasons following thinning, respectively (table I). Thus, for a given amount of leaf area, thinned balsam fir produced more wood

Table I. Relative growth rate (*RGR*) and its partitioning into specific leaf area (*SLA*), leaf weight ratio (*LWR*), net assimilation rate (*NAR*), light availability (I_0), and light use efficiency (*LUE*) for control and thinned balsam fir 1 and 2 growing seasons following treatment.

than controls. The increase in *NAR* was associated with higher light availability I_0 (table I), whereas light use efficiency (*LUE*) was inversely related to I_0 (fig 1).

The overall effect of the thinning on the growth rate of white birch was less clear (table II). Whereas the *NAR* increased significantly the first season, the compensating decrease in *SLA* resulted in no significant differences between *RGR*s. During

the second growing season, however, the *LWR* of the thinned birches increased significantly but *NAR* was no longer statistically significant and thinned trees even showed a tendency toward a lower *NAR* than the controls. The increase in the *LWR* was compensated for by a decrease in the *SLA* and thus the *RGR* of thinned and control birches showed no significant differences (table II).

Table II. Relative growth rate (*RGR*) and its partitioning into specific leaf area (*SLA*), leaf area ratio (*LWR*), net assimilation rate (*NAR*), light availability (I_0), and light use efficiency (*LUE*) for control and thinned white birch 1 and 2 growing seasons following treatment.

Fig 1. Relation between light use efficiency and light availability of thinned and control balsam fir trees.

Thinning did not affect the relative height growth rate of either species (table III). The diameter growth rate of balsam fir was stimulated by thinning for both years of growth, but no statistical differences were detected for white birch (table III).

The sapwood area–leaf area ratio of neither balsam fir nor white birch differed between treatments (table III). However, the slope of the sapwood area growth–leaf area growth relation of thinned balsam firs was different from that of controls ($P < 0.10$) during the first year following treatment (fig 2). During this first summer, thinned balsam firs tended to produce more sapwood area per amount of leaf area growth than did control trees. During the second year following thinning, however, both treated and control balsam fir trees had similar slopes for the sapwood area growth to leaf area growth relationship (fig 2). On the other hand, thinning did not significantly affect the sapwood area growth to leaf area growth relationship of white birch during either the first or the second growing season (fig 3) even though there was a significant increase in *LWR* for thinned trees 2 yr after treatment (table II).

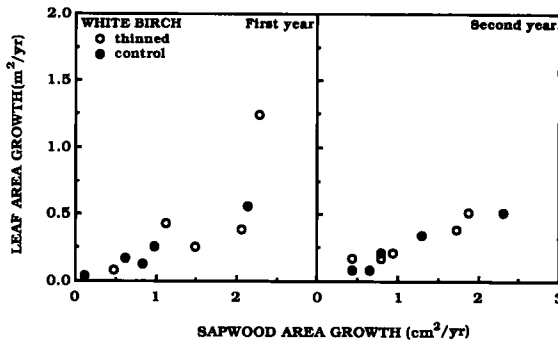

Fig 3. Relation between leaf area growth and sapwood area growth of thinned and control white birch trees one and two growing seasons following thinning.

DISCUSSION

The relative growth rate of thinned balsam fir was increased during both the first and the second growing seasons following treatment (table I). On the other hand, the ratio of photosynthetic to nonphotosynthetic tissues (*LWR*) was not affected by treatment (table I). Neither were there any significant differences in total leaf area between treatments during either of the 2

growing seasons. Consequently, the improvement in growth of balsam fir following thinning can be attributed to leaves which have a higher efficiency for producing wood, *ie* trees with a higher *NAR*.

Net assimilation rate can be partitioned into light availability and light use efficiency (Eq 2). The thinning increased I_o of balsam fir 420% and 123% during the first and the second growing seasons following treatment, respectively (table I). These increas-

es in I_0 probably increased photosynthetic rates by increasing the period of time that leaves were light-saturated as well as increasing *PPFD* levels when leaves were not light-saturated.

Another way in which *NAR* can be increased is by increasing the efficiency of transforming a given unit of light into wood. This would be seen as an increased *LUE* at a given value of I_0 . Although the maximum photosynthetic rate per unit leaf area can be increased with increasing light levels, it is normally reached below 50% of full sunlight for temperate tree species of small size (Leverenz and Jarvis, 1979; Nygren and Kellomäki, 1983). Since the thinning increased *PPFD* beyond 80% of full sunlight, a significant part of this energy was probably not used by the leaves for photosynthesis because factors other than light availability became limiting. This would explain the curvilinear nature of the relation between *LUE* and I_0 (fig 1) as well as the lower *LUE* values calculated for thinned trees in comparison to controls (table I).

Thinning tended to positively affect *RGR* of white birch during the first summer following treatment whereas the reverse effect was observed during the second (table II). Similar fluctuations were noted in *NAR* (table II). The decreased *RGR* and *NAR* of the thinned white birch during the second growing season was accompanied by similar trends in diameter and height growth rates (table III). Such growth responses after thinning are often referred to as thinning shock (Harrington and Reuke-ma, 1983). However, the thinned white birches were still able to respond to treatment by decreasing *SLA* during both summers (table II) and this suggests that their leaves were still more photosynthetically active than controls (Nygren and Kellomäki, 1983; Oren *et al*, 1986). An increase in the allocation of photosynthates

to leaf production (table II), to root production, to respiration or to storage are possible reasons for the low above-ground stemwood growth of the thinned white birches during the second summer after treatment.

During the first summer following treatment, thinned balsam firs produced more sapwood per unit of additional leaf area than controls (fig 2). This situation probably occurred because the determinate growth habit of balsam fir placed restrictions on the number of foliage elements and thus on the potential leaf area growth whereas cambial growth was not restricted (Lanner, 1985). Consequently, thinned and control balsam firs produced similar increases in leaf area during the first growing season whereas the thinning increased sapwood area growth relative to controls. This led to differences in the sapwood area growth to leaf area growth relationship (fig 2). As proposed by Jarvis (1975), a higher sapwood area growth to leaf area growth ratio following thinning could potentially reduce the resistance to water flow from roots to leaves and thus help trees acclimate to a higher rate of transpiration.

Thinned and control balsam fir no longer showed different sapwood area growth to leaf area growth ratios during the second growing season following treatment (fig 2). This can be explained by the increased leaf area growth of thinned trees due to favorable light conditions during bud formation in the first growing season following the treatment. Since both sapwood area growth and leaf area growth were stimulated by the treatment during this second summer, the relation between them for thinned trees equilibrated with that of the controls (fig 2).

The sapwood area growth to leaf area growth ratio of thinned and control white birches were similar during both the first and the second growing seasons following

thinning (fig 3). Thus the sapwood area-leaf area relationship appeared to be more stable following abrupt changes in environmental conditions for white birch than for balsam fir. This faster adjustment of white birch following new environmental conditions is most likely due to its indeterminate growth habit.

The morphological differences between balsam fir and white birch have been shown to influence their physiological response to precommercial thinning. Pothier and Margolis (1990) demonstrated that the deciduous habit of white birch *versus* the evergreen habit of balsam fir can affect leaf water relations following thinning. They also demonstrated that differences in the wood anatomy of the 2 species (*ie* vessels *versus* tracheids) permitted the main stem of white birch to maintain a sapwood permeability \approx 2 times greater than that of balsam fir (Pothier and Margolis, 1990). Assuming similar differences in the resistance to water flow through minor branches, white birch would be able to maintain a transpiration rate nearly 2 times greater than balsam fir for the same leaf water potential. The results reported in this current paper show that balsam fir responded to thinning with greater *NAR* during both the first and the second growing seasons following treatment while white birch responded with a greater *NAR* the first year and a greater *LWR* the second year. Finally, we suggest that the indeterminate growth habit of white birch permitted it to reestablish an equilibrium between sapwood area growth and leaf area growth more rapidly than did the determinate growth species balsam fir.
