### ANALYTICAL AND EXPERIMENTAL STUDIES OF SHOCK INTERFERENCE HEATING IN HYPERSONIC FLOWS

By J. Wayne Keyes and Frank D. Hains\* Langley Research Center

#### SUMMARY

This paper presents an analytical and experimental study of shock interference heating in hypersonic flows. The study included measurements of heat-transfer and pressure amplification from interference effects, and the development of flow models and methods of predicting the peak values suitable for engineering purposes. Theoretical parametric studies were also conducted to determine the effect of flow and geometric variables on interference heating. The experimental investigation was conducted in four facilities which encompassed a Mach number range from 6 to 20, specific heat ratios of 1.27, 1.40, and 1.67 and free-stream Reynolds number from  $3 \times 10^6$  to  $25.6 \times 10^6$  per meter. Six interference flow patterns defined in previous investigations were generated by the interaction between a plane shock and the bow shock created by a 0.025-meterand a 0.051-meter-diameter hemisphere, a cylindrical fin, and a  $30^0$  wedge.

In most cases, calculations based on the flow models and methods developed in the present investigation gave reasonable estimates of the measured peak pressure and heat transfer when real-gas effects were negligible. Flow-visualization data are currently necessary to utilize the methods since measured shock lengths and angles are required. Pressure and heat-transfer peaks as high as 7.5 and 17 times stagnation values were recorded on the 0.051-meter-diameter hemisphere at Mach 6. Values up to 11.5 and 15 times undisturbed wedge pressure and laminar heating, respectively, were also measured at Mach 6. Results of the parametric study indicated that shock interference heating is strongly affected by Mach number, specific heat ratio, impinging shock strength, and model geometry. Because of real-gas effects, interference heating on the actual flight vehicle may be higher than that measured on a wind-tunnel model.

#### INTRODUCTION

Shock interference heating is a problem in the design of the thermal protection system and structural components of high-speed vehicles such as the space shuttle and the

<sup>\*</sup>Formerly with Bell Aerospace Co., Div. of Textron, Inc., Buffalo, New York, and presently with Science Applications, Inc., Arlington, Virginia.

hypersonic cruise aircraft. (See refs. 1 to 5.) Extremely high pressure and heating can occur in small areas on the vehicle's surface because of interfering flow fields which also may be unsteady. These interfering flow fields or shock interference patterns are sensitive to Mach number, free-stream flow conditions, and angle-of-attack changes as the vehicle moves along its flight path.

Some previous investigations of shock interference flows are reported in references 6 to 31 (see table I) and references 32 to 34. Few of these references present a conclusive understanding of the overall shock interference problem. Edney (ref. 6) made a detailed study of the entire spectrum of interference flow patterns. Edney defined six types of shock interference patterns and showed that as a result of the shape and type of pattern, the local pressure and heating peaks were caused by either shock—boundarylayer interaction, free shear layer attachment, or supersonic jet impingement. Other mechanisms resulting from shock interaction which cause less severe heating and pressure effects are (1) the jet grazing the surface and (2) an expansion fan interacting with the surface boundary layer.

The present paper presents the results of a comprehensive analytical and experimental study of shock interference heating. The purposes of this study were

(1) To determine the effects of Mach number, specific heat ratio, impinging shock strength, and geometry on the pressure and heat-transfer amplification for each type of interference pattern

(2) To develop semiempirical methods using the flow models of reference 6 to calculate both the inviscid and viscous interactions as well as the peak pressure and heat transfer for each type (computer programs generated from these methods are presented in ref. 35).

The experimental study was conducted over a wide range of free-stream Mach numbers (Mach 6 to 20), specific heat ratios (1.27, 1.40, and 1.67), unit Reynolds numbers  $(3 \times 10^6 \text{ to } 25.6 \times 10^6 \text{ per meter})$ , and impinging shock strength (shock generator angles up to  $30^{\circ}$ ). Center-line pressure and heat-transfer distributions and flow-visualization data were obtained on several basic shapes.

Because of the large quantity of information gathered, the results are presented in two parts. The first part includes a discussion of the flow models and methods of prediction, a comparison of experimental and calculated results, and the results of a parametric study made by use of the prediction methods. The second part covers the experimental phase of the study. Included also is an appendix on interference heating for a typical space shuttle configuration. Some results from the present study are available in references 36 to 39.

#### ANALYSIS AND COMPARISONS WITH DATA

#### TYPES OF SHOCK INTERFERENCE PATTERNS

In evaluating the effects of shock interference heating, it is necessary to determine the type of interference pattern that will exist when two shocks of different strengths intersect. The pattern that will occur depends on body geometry, the strength of the impinging shock, and its position relative to the body. (See ref. 6.) The six possible shock interference flow patterns defined by Edney are shown in figure 1. For the sake of simplicity an example of how the interference patterns can change on a hemisphere from one type to another with impinging shock location is presented in figure 2.

The interference patterns can be further grouped according to the mechanism that caused the pressure and heat-transfer change at the surface. Types I, II, and V are associated with a shock—boundary-layer interaction and type III is characterized by an attaching free shear layer. Type IV is characterized by an impinging or grazing supersonic jet and type VI by an expansion-fan—boundary-layer interaction.

#### FLOW MODELS AND METHODS OF PREDICTION

The six flow models are similar to those discussed in reference 6; therefore, only the model highlights and modifications are discussed in the following section. In general, the methods of predicting the peak pressure and heating are semiempirical and are primarily for engineering design calculations. The methods are based upon local twodimensional flow models with the exception of types III and V where a tangent-cone approximation is used for three-dimensional bodies. Computer programs generated from these methods are described in reference 35.

#### Type I Interference

A type I interference pattern occurs when two weak shocks of opposite families intersect as shown in figure 3. These weak shocks can be attached shocks generated by wedges and cones or parts of detached shocks located well downstream of the sonic point. (See fig. 2.) The actual rise in pressure and heating at the surface is caused by the interaction of the transmitted impinging shock and the wall boundary layer. The flow field associated with type I is supersonic throughout.

The flow conditions in regions 2 and 3 are calculated from the Rankine-Hugoniot shock relation of reference 40 once the flow conditions in region 1 and the strengths of the bow and impinging shocks are specified. Unless the strengths of the two shocks are equal, a shear layer will be produced at point A and between regions 4 and 5 where the static pressures must be equal and the flow directions parallel. An iterative procedure is utilized to obtain the strength of the transmitted shocks and the orientation of the shear layer relative to the free-stream direction which satisfy these conditions. From the strength of the transmitted impinging shock and the local surface inclination at impingement, flow conditions in region 6 are calculated by using the Rankine-Hugoniot shock relations. When the regular oblique shock reflection at the surface is no longer possible, a Mach reflection (refs. 41 and 42) will occur as shown in the insert of figure 3 with the pressure rise from region 2 to region 6 at the wall approximated by the normal shock relations.

8

When the pressure rise is known, the heat transfer can be obtained from shock boundary-layer interaction studies. Calculations based on methods developed in several of these studies, for example, references 43 to 45, were compared with experimental data in reference 46. It was found that these methods gave good heating estimates for weak shocks at low supersonic Mach numbers. For a strong shock—boundary-layer interaction and a higher Mach number, the agreement was not as good. A promising method based on the Lax-Wendroff difference technique for the solution of the timedependent Navier-Stokes equations has been presented by MacCormack (ref. 47). However, any of these detailed methods require considerable computer time and are not suitable for rapid engineering calculations. In the present study, the following correlations and constants developed by Markarian (ref. 48) were used for predicting the peak heating. The correlations are of the form

$$\frac{Q_{pk}}{Q_u} = \left(\frac{p_{pk}}{p_u}\right)^N \tag{1}$$

where N = 1.29 for laminar interactions and 0.85 for turbulent interactions and  $p_{pk}/p_u$  is the inviscid pressure ratio  $p_6/p_2$  across the interaction. Calculation of the peak heating requires a knowledge of the reference or undisturbed heating  $Q_u$  upstream of the interaction. In the present study, reference values  $Q_{wedge}$  are obtained from expressions in reference 49 for laminar and turbulent boundary layers on plane surfaces by using the measured location of the impingement point. Also, the reference pressure  $p_{wedge}$  is the undisturbed value ahead of the interaction on the wedge.

#### Type II Interference

A type II interference pattern occurs when two shocks of opposite families intersect as shown in figure 4. Both shocks are weak as in type I, but are of such strength that in order to turn the flow, a Mach reflection must exist in the center of the flow field with an embedded subsonic region located between the intersection points (A and B) and the accompanying shear layers. (See also ref. 42, p. 557.) On a blunt body, type II interference occurs when the impinging shock intersects the bow shock nearer to the sonic point than type I, as shown in figure 2. A detailed analysis of the complete flow field is difficult because the extent of the subsonic region (region 5) is unknown and depends on the size and shape of the body (ref. 6). The conditions in the supersonic regions (4 and 6) can be calculated, since the influence of the impinging shock on these regions is small compared with the influence of the bow shock (ref. 6). The inviscid pressure ratio  $p_6/p_2$  across the reflected shock at the shock—boundary-layer interaction can be calculated from these conditions. If the free-stream conditions in region 1 and either the body angle or shock angle are known, the triple shock at point A is solved by using an iterative procedure similar to type I with the exception that strong shock relations are used between regions 1 and 5. A Mach reflection with a nearly normal leg at the wall apparently forms when the regular shock reflection between regions 4 and 6 is no longer possible. (See sketch in fig. 4.) The heat-transfer rise is determined by using equation (1) and  $p_6/p_2$ . The reference or undisturbed pressure and heating upstream of  $X_i$  are also calculated in exactly the same manner as for type I.

#### Type III Interference

A type III shock interference pattern occurs when a weak impinging shock intersects a strong detached bow shock as shown in figure 5. The shear layer emanating from the shock intersection (point A) attaches to the surface with subsonic flow above the layer turning upward and subsonic flow below the layer passing through an oblique shock in order to turn parallel with the surface. Whether the shear layer attaches to the surface depends on the Mach number in region 4  $M_4$ , and the angle between the shear layer and the surface  $\bar{\theta}_5$ . If  $M_4$  is sufficiently high and  $\bar{\theta}_5$  does not exceed the maximum turning angle for  $M_4$ , then the layer will be attached. If, however, the maximum angle is exceeded, the shear layer will detach and a type IV pattern will be formed. If it is assumed that the shear layer attaches at point C and the oblique shock does exist, then another triple shock will occur at point B. (See fig. 5.) On a blunt body the shock intersection occurs near or above the lower sonic point as shown in figure 2.

The conditions in regions 2 and 4 are obtained by solving the triple shock at point A by using an iterative procedure. Required are the impinging shock strengths and the free-stream flow conditions. The iteration also requires the use of the strong shock relations between regions 1 and 2. Results from this exact analysis are used in an approximate analytic technique to determine the peak pressure and heat transfer at shear layer attachment. The strength of shock BC is determined by assuming the angle between the shear layer and the local body slope  $\bar{\theta}_5$  is known. The peak wall pressure in region 5 is calculated by using the flow conditions in region 4 and the Rankine-Hugoniot shock relations for attachment on a two-dimensional body. For attachment on a three-dimensional body, tangent-cone approximations (ref. 35) are used by assuming that shock BC is conical. In the present study the tangent-cone method is used since the model configuration consisted of a plane shock impinging with the bow shock of a hemisphere.

Peak heating caused by an attaching free shear layer is analogous to a reattaching separated boundary layer. (See ref. 6.) In the present study, correlations proposed by Bushnell and Weinstein (ref. 50) for reattachment heating on two-dimensional ramps are

used. The peak heating at attachment is

$$Q_{pk} = A\rho_{w,5}u_5c_p(T_{aw} - T_w) \left(\frac{\mu_w \sin \bar{\theta}_5}{\rho_{w,5}u_5\delta_{SL}}\right)^N$$
(2)

where the shear layer thickness at attachment  $\delta_{SL}$  is given by

$$\delta_{\rm SL} = 5 \left( \frac{\ell_{\rm SL} \mu_4}{\rho_4 u_4} \right)^{0.5}$$
 (Laminar) (3)

$$\delta_{\rm SL} = 0.123\ell_{\rm SL} \tag{Turbulent} \tag{4}$$

The shear layer length  $\ell_{\rm SL}$  (AC in fig. 5) is calculated by use of the measured shock displacement length  $L_{\rm SH}$  and the geometry of the shock shear layer triangle ABC. Shear layer transition data presented in reference 39 are useful in determining the state of the shear layer at attachment since it has been shown in references 6 and 38 that the heating for turbulent attachment is higher than that for laminar attachment for the same pressure rise. The constants A and N in equation (2) as obtained from data in reference 50 for a laminar shear layer are 0.19 and 0.5 and for a turbulent shear layer, 0.021 and 0.2.

A comparison which was made in reference 38 of peak heating for free shear layer attachment (data from present study) and reattaching separated boundary-layer curves (from ref. 50) is reproduced in figure 6 with some modifications. The flagged data based on the calculated laminar shear layer thickness are corrected for the difference in constants (five in eq. (3) and four in ref. 38). Corrections to the helium data (solid symbols) using revised calculated shear layer lengths are also included. Since the shear layer in the Mach 6 data at the lower Reynolds numbers (based on  $\delta_{SL}$ ) may be transitional, both the laminar and turbulent values are shown. It can be seen in figure 6 that more realistic values of A are 0.40 for laminar and 0.06 for turbulent free shear layer attachments. For a transitional shear layer attachment, both the laminar and turbulent values of  $\delta_{ST}$ are used with the turbulent constant to calculate the peak heating. Possible reasons for this difference in the values of A are that the correlations in reference 50 for reattaching separated boundary layers are for two-dimensional ramps and the attaching free shear layers in reference 38 are three-dimensional in nature. Also, the shear layer angles relative to the surface are higher for the attaching shear layer than the reattaching boundary layers.

In the present study the reference heating  $Q_{stag}$  used for type III interference is the laminar stagnation-point value on a hemisphere (ref. 51) obtained from

$$Q_{\text{stag}} = 0.76 (N_{\text{Pr}})^{-0.6} c_p (\rho_w \mu_w)^{0.1} (\rho_{\text{stag}} \mu_{\text{stag}})^{0.4} (T_{\text{stag}} - T_w) \left[ \left( \frac{du_w}{ds} \right)_{\text{stag}} \right]^{0.5}$$
(5)

where the velocity gradient (from ref. 52) is

$$\left(\frac{\mathrm{du}_{\mathrm{W}}}{\mathrm{ds}}\right)_{\mathrm{stag}} = \frac{\mathrm{u}_{\infty}}{\mathrm{R}_{\mathrm{b}}} \left\{ \frac{\gamma - 1}{\gamma} \left[ 1 + \frac{2}{(\gamma - 1)\mathrm{M}_{\infty}^{2}} \right] \left( 1 - \frac{1}{\gamma \mathrm{M}_{\infty}^{2}} \right) \right\}^{0.5}$$
(6)

and the subscript stag refers to values at the edge of the boundary layer. The reference pressure  $p_{stag}$  is the stagnation pressure on a hemisphere.

#### Type IV Interference

When a weak impinging shock intersects the nearly normal part of the bow shock, a type IV interference occurs. This interference results in a complex flow pattern with a supersonic jet embedded in the subsonic flow region between the bow shock and the surface. (See figs. 2 and 7.) Up to region 6 the flow model is the same as type III; therefore, type IV interference can be considered a special case of type III interference with a detached shear layer  $(\bar{\theta}_5 > \theta_4, \text{ fig. 5})$ . From figure 7, it can be seen that the jet consists of triangular regions, the actual number of regions being dependent upon the standoff distance of the entire configuration. Upon impingement on the wall, a jet bow shock is produced that creates a small stagnation region with high pressure and heating. As stated in reference 6, the peak heating is dependent upon the peak pressure, the jet width, the jet angle of incidence with the surface, and the state of the jet (laminar or turbulent), where all these quantities are interrelated.

Flow conditions and the geometry of this complex jet pattern shown in figure 7 are calculated by assuming zero shear layer thickness and neglecting jet mixing with the slower moving flow in regions 2 and 5. Conditions in regions 2, 3, and 4 and the shear layer deflection angle are obtained in the same way as those for type III. Orientation of the continuation of the bow shock between regions 3 and 5 and the shock between regions 4 and 6 are determined from the triple-point solution at point B. It is assumed that a shear layer emanates from point B to form the lower jet boundary between regions 5 and 6 ( $p_5 = p_6$ ). The location of point C is determined from the geometry of the triangle enclosing region 4 by using the shock displacement distance  $L_{SH}$  (which is obtained empirically). The pressure differential between regions 2 and 5 ( $p_5 > p_2$ ) causes the jet to turn upward.

Since the flow in the jet passes through a series of expansions and weak compression waves, the conditions in regions 6 and 8 ( $p_6 = p_5 = p_8$ , etc.) and all subsequent

12

even-numbered regions in the jet are the same. Likewise the conditions in all oddnumbered regions are the same. The total pressure in the jet is assumed to be constant. The incremental increases in the flow deflection angle between regions such as  $\theta_7$ to  $\theta_6$  are constant. Based on this reasoning, an expansion fan centered at E and intersecting the lower jet boundary at F complete the jet geometry through region 8. Good agreement between measured and calculated flow patterns was realized in reference 6 by using these assumptions.

It has been shown in reference 6 that two possible shock configurations can occur at the intersection of the bow and impinging shocks depending on their relative strengths. Figure 8(a) shows sketches of the jet configuration for a downward sloping shear layer with the jet bow shock located in region 8 whereas figure 8(b) shows the configuration for an upward sloping shear layer. Only the downward sloping shear layer was seen in the present study. In some configurations the jet was turned sufficiently to graze or move parallel to the wall without impinging as observed in schlieren photographs. In this case (denoted type IVa) even though impingement does not occur, regions of high heating are produced because of the interaction of the jet flow with the boundary layer.

A typical example of how the calculated total pressure varies in a type IV pattern as a function of free-stream pitot pressure is presented in figure 9. The jet total pressure, the total pressure in region 4, and the wall stagnation pressures of the jet in regions 7 and 8 remain relatively high compared with the free-stream pitot pressure. The wall stagnation pressure is obtained from normal-shock relations by using conditions in region 7 or 8. Also an approximate 10-percent difference in wall stagnation pressure occurred with a small shift in jet bow shock location from region 7 to region 8.

In order to calculate the peak heating at jet impingement, the jet stagnation velocity gradient along the wall must be determined. Several methods have been suggested for calculating the velocity gradient and the peak heating. (See refs. 6 and 36.) A method discussed in reference 6 for impingement on a sphere suggests that the peak heating is analogous to that on a blunt body (diameter equal to the jet width) submerged in a supersonic flow field (jet flow). An expression based on this analogy is

$$\frac{Q_{pk}}{Q_{stag}} = 1.03 \left( \frac{R_b}{\overline{w}} \frac{p_{pk}}{p_{stag}} \right)^{0.5}$$
(7)

where  $p_{pk}$  and  $Q_{pk}$  are stagnation values on a cylinder of diameter  $\overline{w}$  (jet width) and where  $p_{stag}$  and  $Q_{stag}$  are the stagnation values on a sphere of radius  $R_b$ . This expression was obtained by using equations in reference 53 and assuming the jet to be laminar with nearly normal impingement. The constant in expression (7) is a function of the heating parameter in reference 53. (Value shown is for ratio of a wall temperature to total temperature of 0.5 and a Prandtl number of 0.7.) Good agreement between experimental and calculated values was obtained in reference 6 for a Mach number of 4.6 and  $R_b/\overline{w} \approx 17.5$  by use of this method.

A more detailed method for finding the stagnation point velocity gradient is presented in reference 36, where the Belotserkovskii strip integral method (based on refs. 54 to 56) is used. The velocity gradient is found to be a function of jet Mach number, specific heat ratio, and jet shock standoff distance. However, it was shown in reference 57 that results obtained by use of this method are in error for the low jet Mach numbers ( $M_i < 2.5$ ) which were encountered in the present study.

The velocity gradient used in the present investigation is obtained from an analogy similar to that of reference 6. Even though in reality the jet is impinging on a plane surface when compared with the jet size  $(R_b/\overline{w} >> 1)$ , the stagnation velocity gradient can be approximated by the gradient on a small sphere "jet body" immersed in a supersonic flow field of height equal to the jet width. The flow model of the jet impingement region is shown in figure 10. Flow conditions upstream of the jet bow shock (for example, in region 7 or 8) are known from the previous flow analysis once the jet bow shock location is specified. Inclination of the jet  $\alpha_i$  is assumed to be normal to the wall on the basis of experimental data. The jet bow shock is assumed to be a circular arc of radius  $R_c$ . (See ref. 36.) The orientation of the sonic line relative to the wall and the jet boundary as shown in figure 10 is based on information in references 57 and 58 for  $M_i < 2.8$  at  $\gamma = 1.4$ . Equation (6) is used to calculate the velocity gradient for a specified jet velocity  $u_j$  and Mach number  $M_j$  depending on the region containing the bow shock. The jet-body radius in this case  $\dot{R}_{b,j}$  is computed by using a value of  $\delta_{j,s}/\overline{w}$ ; the calculated width  $\overline{w}$  for a given region, and correlations of  $\delta_{j,s}/R_{b,j}$  as a function of inverse jet normal shock density ratios obtained from reference 59. An approximate value of  $\delta_{j,s}/\overline{w} = 0.45$  was used for calculated jet Mach numbers from 1.2 to 2.5 at  $\gamma = 1.4$ . This value of  $\delta_{j,s}/\overline{w}$  seems to be realistic when compared with calculated values given in reference 56 to normal impingement and jet Mach numbers from 3 to 5. Also, the present schlieren data and data from reference 6 verify this value (0.45) for  $\delta_{j,s}/\overline{w}$ . Therefore, the velocity gradient at the jet stagnation point is calculated once the necessary quantities are known for the given region that includes the jet bow shock.

A sample calculation of the velocity gradient for the jet bow shock located in region 8 for  $M_{\infty} = 6$  and  $\gamma = 1.4$  follows. The calculated jet width, jet velocity, and Mach number ahead of the jet bow shock in region 8 are 0.701 mm, 562.02 m/sec, and 1.53, respectively. The jet bow shock standoff distance  $\delta_{j,s}$  is

$$\delta_{j,s} = \left(\frac{\delta_{j,s}}{\overline{w}}\right)\overline{w} = 0.315 \text{ mm}$$

where  $\frac{\delta_{j,s}}{\overline{w}} = 0.45$ . A value of  $\frac{\delta_{j,s}}{R_{b,j}} = 0.54$  is found in figure 17 of reference 59 by

using the inverse normal shock density ratio for  $M_j = 1.53$ . Then the radius of the jet body is

$$R_{b,j} = \frac{\sigma_{j,s}}{\sigma_{j,s}/R_{b,j}} = 0.584 \text{ mm}$$

Finally, the velocity gradient is obtained from equation (6) modified for jet nomenclature

$$\left(\frac{\mathrm{du}_{\mathrm{W}}}{\mathrm{ds}}\right)_{\mathrm{stag}} = \frac{\mathrm{u}_{\mathrm{j}}}{\mathrm{R}_{\mathrm{b},\mathrm{j}}} \left\{ \frac{\gamma - 1}{\gamma} \left[ 1 + \frac{2}{(\gamma - 1)\mathrm{M}_{\mathrm{j}}^{2}} \right] \left( 1 - \frac{1}{\gamma\mathrm{M}_{\mathrm{j}}^{2}} \right) \right\}^{0.5} = 7.631 \times 10^{5} \; \mathrm{per \; second}$$

The peak heating rate for a given region is calculated by using equation (5) and the calculated flow condition and velocity gradient for that region. In the present study, equations (5) and (6) are also used to calculate the reference stagnation heating on the hemispheric model. The reference pressure is the hemisphere stagnation pressure. It was stated in reference 6 that the peak heating is directly proportional to the square root of the jet width  $\overline{w}$  which, in turn, is dependent on the measured displaced shock length  $L_{SH}$  (fig. 7) as a scale length. A simplified method that would give this length as a function of free-stream conditions and body geometry would relieve the present method from its dependence on experimental measurements of  $L_{SH}$  and  $\delta_{j,S}/\overline{w}$ . Other phenomena that may influence the peak heating, but are not considered in the present study, are the type and growth of the shear layers bounding the jet and jet turbulence. (See ref. 6.)

#### Type V Interference

Type V interference involves the intersection of two oblique shocks of the same family which occurs just above the upper sonic point as illustrated in figures 2 and 11. Type V is analogous to type II with the exception that a thin jet appears at the shock intersection at point A instead of a shear layer and the impinging shock directly influences the flow upstream of the model. The actual increase in pressure and heat transfer on the surface is a result of the shock from point B interacting with the boundary layer. The small jet from point A and the shear layer emanating from the triple point at B (fig. 11) converge as the subsonic flow in region 4 accelerates to sonic velocity. Both the jet and shear layer intermix and may graze the surface and thus cause some increase in heating. (See ref. 6.) Flow conditions and the pressure and heat-transfer rise across

15

the shock—boundary-layer interaction in the supersonic regions near the body are calculated by use of the same procedure as discussed for type II and equation (1) for plane surfaces.

In the present investigation the type V interference pattern was observed on a swept cylindrical leading-edge fin. The pressure rise across the shock—boundary-layer interaction was calculated by using the tangent-cone approximation discussed for type III and the heating rise was calculated by use of equation (1). The undisturbed or reference values used in this case were the laminar stagnation-line pressure and heat transfer on a cylinder. (See ref. 60.)

#### Type VI Interference

The supersonic flow pattern for type VI interference shown in figure 12 consists of the intersection of two weak shocks of the same family and results in a weak bow shock. A shear layer and an expansion fan (that interacts with the boundary layer) are also formed at the intersection (point A). The interaction at the surface results in a local decrease in pressure and heating. (See ref. 61.)

The flow conditions in region 3 are determined by using the oblique shock relations and the specified free-stream conditions and flow angle in a manner similar to that for type I. Once  $\theta_b$  is specified, the flow in region 4 is calculated. An iterative scheme is used to determine the location of the coalesced bow shock that separates regions 1 and 2 to satisfy continuity of the pressures and flow direction across the shear layer between regions 2 and 5. The flow from region 4 must pass through the expansion fan to turn parallel to the shear layer. The relations for a Prandtl-Meyer expansion from reference 40 are used in this iteration to go from region 4 to region 5. In order to turn parallel with the surface, the flow passes through a series of weak reflected expansion waves in going from region 5 to region 6. The total reduction in pressure from region 4 to region 6 is twice the decrease across the first expansion fan for low Mach numbers and small turning angles (ref. 42, p. 451).

The heat-transfer relation (eq. (1)) is used to calculate the reduction in heating by using  $p_6/p_4$ . This procedure is justified since it has been shown in reference 61 that this equation gives a good prediction of the heating reduction for turbulent interactions. A comparison of type VI laminar data from the present investigation with the correlation in reference 38 indicates that the same justification may be used for laminar interactions. The reference values in the present study are the undisturbed values ahead of the interaction on a wedge.

#### COMPARISON OF CALCULATED AND EXPERIMENTAL RESULTS

In this section typical examples of experimental center-line pressure and heattransfer distributions, primarily peak values, are compared with calculated levels for the six types of interference patterns. Flow-visualization photographs are presented to indicate the type of interference and details of the flow field. Experimental models used in this investigation included hemispheres, a cylindrical leading-edge fin, and a 30<sup>0</sup> wedge. Surface static pressures were measured by using conventional electrical strain-gage transducers and heat-transfer coefficients were obtained by use of the phase-change coating technique. In the interest of clarity, details concerning the models, test conditions, and experimental techniques are discussed in the experimental study along with tabulations and plots of experimental data not shown in the analysis. In general, the discussion presented in this section also covers the experimental results. The pressure and heat-transfer data are presented in nondimensional form, stagnation-point values  $\left(p_{stag} \text{ and } Q_{stag}\right)$  being used for the hemisphere data. Stagnation-line pressure and heat-transfer values  $(p_{cyl})$  and  $Q_{cyl}$  are used for the fin data. The reference pressure for the wedge  $p_{wedge}$  is the calculated wedge value without interference. Reference heating for the wedge  $Q_{wedge}$  is arbitrarily chosen as the local laminar value at the midpoint of the wedge (X = 0.5) with the exception of type VI where the reference value is taken as the maximum measured wedge value ahead of the interaction.

#### Type I Interference

Type I interferences on the  $30^{\circ}$  wedge at  $\alpha = 0^{\circ}$  (wedge center line parallel with flow) for  $\theta_i = 10^{\circ}$  and  $\theta_i = 15^{\circ}$  are shown in figures 13 and 14, respectively. Measured peak pressure for both shock generator angles  $\theta_i$  is approximately 10 to 15 percent higher than the calculated value. This difference is probably due to the extensive separation of the laminar boundary layer on the wedge (caused by the shock—boundary-layer interaction) and the resulting complex shock system which allows a greater pressure recovery than the nonseparated case). Differences between the measured and calculated peak heating levels are probably also influenced by the separated flow.

#### Type II Interference

An example of a type II interference pattern on the  $30^{\circ}$  wedge at  $\alpha = 25^{\circ}$  and  $\theta_i = 15^{\circ}$  is presented in figure 15. The reflected shock that occurs at the upper triple point in the bow shock interacts with the wedge boundary layer and causes the increase in pressure and heat transfer. A region of transonic flow exists behind the reflected shock between the surface and the shear layer. (See, for example, refs. 32 and 33.) Calculated peak pressure levels shown in figure 15 are obtained by assuming (1) a Mach

reflection with a normal shock loss at the wall (upper line) and (2) the pressure rise for an attached shock corresponding to the upstream Mach number  $M_2$ . A pressure spike was not measured, evidently because of the finite pressure tap spacing since the measured value should have occurred between the two calculated levels. The peak heat-transfer level was underpredicted.

#### Type III Interference

Examples of type III interference on a 0.051-meter-diameter hemisphere at Mach 6 with  $\theta_i = 14.8^{\circ}$  are shown in figures 16 and 17. The basic difference between these two examples is that the shear layer attaches at a lower point in figure 17 than in figure 16. The measured pressure peaks are underpredicted approximately 15 percent probably because of viscous effects (shear layer deflection and growth and three-dimensional flow). As expected, heating peaks, in general, are underpredicted approximately 50 to 65 percent by use of the constants of reference 50. Better agreement is obtained by using the constants from the correlation of reference 38 (based upon the present data) and the calculated laminar and turbulent shear layer thicknesses. The maximum heating amplification measured in this study for a type III interference (14 times stagnation heating) is shown in figure 16(c).

Typical results of tests conducted in the other three facilities with a 0.025-meterdiameter hemisphere are presented in figures 18 to 20. The type of interference was determined from the location of the shock intersection and the shape of the peaks. In general, the agreement between measured and calculated pressure and heat-transfer peaks was not as good as that for the Mach 6 results, probably because of errors incurred in measuring parameters from photographs and the finite pressure tap spacing  $(10^{\circ})$  on the model. Viscous effects, in addition to these reasons, may explain the poor agreement in the nitrogen tests. (See fig. 18.) Flow condensation due to a low stagnation temperature may have influenced the pressure measurements in the CF<sub>4</sub> facility. A good indication of how the surface flow is affected by an attaching shear layer can be seen in figure 20(c).

#### Type IV Interference

Since the type IV interference results in the most severe heating (ref. 6), an extensive investigation was conducted by using the 0.051-meter-diameter hemisphere, the  $30^{\circ}$  wedge, and the fin model in the Mach 6 air tunnel. Additional tests were conducted with the 0.025-meter-diameter hemisphere in the other facilities.

Typical examples of type IV interference on the 0.051-meter-diameter hemisphere at Mach 6 for  $\theta_i = 5^{\circ}$ ,  $10^{\circ}$ , and  $15^{\circ}$  are shown in figures 21 to 23. Jet impingement

occurs between 20<sup>°</sup> and 30<sup>°</sup> below the axis of the hemisphere with nearly normal impingement. In general, calculations based on conditions in regions 7 and 8 and the measured value at  $\frac{\delta_{j,s}}{\overline{w}} = 0.45$  bracket the measured peak pressure and heat transfer. Comparisons of the measured and calculated (no interference) pressures and heat-transfer distributions on the hemisphere indicate the strong influence of the jet flow along the surface.

Results in helium at Mach 20.2 and nitrogen at Mach 19.8 obtained on the 0.025-meter-diameter hemisphere are presented in figures 24 and 25. Agreement between the measured and calculated peak values was not as good as the Mach 6 results, large differences occurring in the nitrogen tests. Better agreement would probably result if the proper values of  $\delta_{j,s}/\overline{w}$  were known for each gas. Oblique jet impingement and shear layer growth could also explain the lower measured peak values. However, the predicted values provide conservative estimates.

Comparisons of measured and calculated values on the  $30^{\circ}$  wedge at  $\alpha = 50.3^{\circ}$  and at Mach 6 are presented in figure 26. Good agreement exists between the pressure results whereas the heating peak is underpredicted. The high measured heating peak may be the result of turbulent jet impingement. (See ref. 6.)

An example of a type IVa interference (grazing jet) on the unswept cylindrical fin at Mach 6 is shown in figure 27. The plane of symmetry of the fin and the leading edge of the shock generator are perpendicular. In this case the supersonic jet curls upward because of the higher pressure differential across the jet than that encountered on the hemisphere or wedge. The peaks and dips observed in the pressure and heat transfer are the result of shocks and expansions in the grazing jet interacting with the fin boundary layer. Agreement between the data and the calculated stagnation line values on the lower part of the fin is only fair, probably because of the curved bow shock.

#### Type V Interference

A type V interference pattern occurred on the cylindrical fin when it was swept back  $25^{\circ}$  (center line at  $65^{\circ}$  to free-stream flow) as shown in figure 28. Good agreement between measured and calculated heating peaks was obtained for all type V tests. Since the fin bow shock was detached, the predicted heating value was calculated by use of the measured bow shock angle  $\beta_3$  below the shock intersection and the maximum angle  $\theta_6$  for a regular shoer seflection at the wall. The secondary heating peak occurring near X = 0.6 is a result of the thinning of the boundary layer by the grazing jet and shear layer.

#### Type VI Interference

An example of type VI interference on the upper surface of the  $30^{\circ}$  wedge is shown in figure 29. The theoretical pressure reduction from the expansion-fan impingement agrees well with the experimental level. Although equation (1) was developed for shock boundary-layer interactions, the use of the laminar form and the calculated pressure reduction gives a good indication of the amount of local heat-transfer reduction. The reason for the first dip in the heating distribution is unknown. Unlike the other wedge data, the reference heating is taken as the maximum measured value ahead of the interaction.

#### Summary of Comparisons of Calculated and Experimental Data

In summary, for most cases calculations made for the different types of interference were in fair to good agreement with measured peak values for gases where real-gas effects are negligible and good flow-visualization photographs were available. (See table II.)

#### Empirical Inputs for Methods of Prediction

The main problem that exists in using these local two-dimensional methods is their dependency on measurements (see table III) from flow-visualization photographs or other empirical sources. These inputs along with the specified upstream flow conditions, surface geometry, and pressure and heat-transfer distributions without interference can be used to calculate interference heating on complex configurations. Other problem areas include the effects of (1) shear layer growth, (2) oblique jet impingement, (3) jet bow shock standoff distance, (4) gas chemistry, and (5) three-dimensional flow on interference heating.

#### PARAMETRIC STUDY USING COMPUTATIONAL METHODS

Calculations were carried out for each type of shock interference at a variety of flow conditions to determine the dependence of peak pressure and heating on the specific heat ratio  $\gamma$ , free-stream Mach number  $M_{\infty}$ , and impinging shock strength (shock generator angle  $\theta_i$ ). Body angle  $\theta_b$ , shear layer angle  $\bar{\theta}_5$ , and shock displacement length  $L_{SH}$  were also varied to determine their effect on the peaks for some types of interference. The free-stream total conditions and wall temperature remained fixed for all types. These calculations were made by assuming impingement on a wedge at  $X_i = 0.305$  meter for types I, II, V, and VI and on a 0.305-meter-diameter sphere for types III and IV. The heating results were calculated by use of a recovery factor of  $\left(N_{Pr}\right)^{0.5}$  for laminar and  $\left(N_{Pr}\right)^{0.33}$  for turbulent  $\left(N_{Pr} = 0.72\right)$ . Also these calculations are based on ideal gas relations and do not account for real-gas effects.

#### Type I Interference

The results of a parameter variation study for type I interference are presented in figures 30 and 31 for laminar and turbulent boundary layers with a fixed impingement location and body angle. Figure 30 presents the variation of pressure and heat-transfer amplification with shock generator angle for several free-stream Mach numbers and specific heat ratios. Both the pressure and heat-transfer amplification increase with increasing impinging shock strength and free-stream Mach number until the transition from a regular reflection to a Mach reflection takes place. Beyond this point the amplification remains constant until the beginning of a type II interference. For a given Mach number and  $\theta_i$ , the amplification decreases with increasing  $\gamma$ . The high heat-transfer amplification for the laminar case (fig. 30(b)) is the result of the low heating rates ahead of the shock—boundary-layer interaction  $Q_2$  for  $X_i = 0.305$  meter. Figure 31 shows that the amplification and for a fixed  $M_{\infty}$ ,  $\gamma$ , and  $\theta_i$ . The reason for this decrease is that the reflected shock becomes weaker with increasing  $\theta_b$  and thus results in a lower pressure rise from region 2 to region 6.

#### Type II Interference

The variation of the pressure and heat-transfer (laminar and turbulent) amplification with body angle is shown in figure 32 for a type II interference at several values of  $M_{\infty}$  and  $\gamma$  for a regular shock reflection. Calculations of the flow near the wedge are independent of  $\theta_i$ . The amplification decreases with increasing body angles and specific heat ratio for the same reason as type I. For a given  $\theta_b$ , the amplification also increases with Mach number.

#### Type III Interference

Pressure and laminar and turbulent heat-transfer amplification as a function of shock generator angle are shown in figure 33 for attaching shear layers. The shock displacement length  $L_{SH}$  and shear layer angle  $\bar{\theta}_5$  are fixed. Heat-transfer peak calculations are based on constants from reference 38 as discussed previously. The maximum amplification occurs between  $\theta_i = 10^\circ$  to  $\theta_i = 20^\circ$  depending on the Mach number and  $\gamma$ . The pressure amplification increases and the heat-transfer amplification decreases with increasing Mach number for a given  $\theta_i$  and  $\gamma$ . Actually, the heating amplification will follow the same trend as the pressure. (See ref. 6.) This reverse trend for the heating in the present study is the result of using constant total pressure and temperature for  $M_{\infty}$  and  $\gamma$  instead of varying these conditions for each  $M_{\infty}$  and  $\gamma$ . For a given  $\theta_i$  and  $M_{\infty}$ , the amplifications decrease with increasing  $\gamma$ . The variation of the stagnation reference values with  $M_{\infty}$  and  $\gamma$  is shown in figure 34.

The effects of variations in shear layer angle and shock displacement length (shear layer thickness) on the pressure and heat-transfer amplifications for  $M_{\infty} = 10$  and  $\gamma = 1.4$  are shown in figures 35 and 36, respectively.

#### Type IV Interference

The variation of the pressure and heating amplification with the shock generator angle for an impinging laminar jet is presented in figure 37 for a constant shock displacement length. These calculations are made by assuming the jet bow shock in

region 8,  $\frac{\delta_{j,S}}{\overline{w}} = 0.45$ , and jet impingement normal to the wall. Both the pressure and heat-transfer amplifications increase with increasing Mach number for a given  $\theta_i$ , a maximum occurring between  $\theta_i = 10^{\circ}$  and  $\theta_i = 20^{\circ}$ , whereas the amplification decreases with increasing  $\gamma$  for a given  $M_{\infty}$  and  $\theta_i$ . The large increases in pressure and heat-ing amplification at different  $\gamma$  values are primarily due to the decrease in reference values shown in figure 34. The reduction in heating due to increasing the shock displacement length (or jet scale length) is shown in figure 38.

#### Type V Interference

The pressure and heat-transfer amplification as a function of  $\theta_i$  is presented in figure 39 for a regular shock reflection at the wall. Both the pressures and heating amplification increase with increasing  $\theta_i$  and  $M_{\infty}$ . At a constant  $M_{\infty}$  and  $\theta_i$ , the amplification decreases with an increase in  $\gamma$ . The effect of increasing body angle on the amplification is shown in figure 40.

#### Type VI Interference

Pressure and heat-transfer reduction rates as a function of  $\theta_i$  for an expansionfan—boundary-layer interaction (laminar and turbulent) are shown in figure 41. The largest reduction occurs between  $\theta_i = 7^{\circ}$  and  $\theta_i = 9^{\circ}$ . For a given  $\theta_i$  the amount of reduction becomes larger with increasing Mach number, whereas for a given  $M_{\infty}$  and  $\theta_i$  the reduction is lower for an increase in  $\gamma$ .

#### EXPERIMENTAL STUDY

#### OBJECTIVE

The objective of the experimental phase of the study was to determine the type of interference pattern generated for a given shock configuration and to investigate the effects of Mach number, unit Reynolds number, specific heat ratio, and strength of the impinging shock on the center-line peak pressure and heat transfer on basic shapes.

#### APPARATUS AND TEST CONDITIONS

#### **Test Facilities**

#### A brief outline of the tunnels used in this study is presented in table IV:

Facility	Test gas	γ	M∞	( <sup>p</sup> t,∞) <sub>max</sub> , N/cm <sup>2</sup>	(T <sub>t,∞</sub> ) <sub>max</sub> , K	Facility description in reference
Langley 20-inch Mach 6 tunnel	Air	1.40	6	362	561	62
Langley 22-inch helium tunnel	Helium	1.67	20	2069	533	63
Langley hypersonic nitrogen tunnel	Nitrogen	1.40	19	6895	2222	64 and 65
Pilot $CF_4$ facility at the Langley Research Center	$\begin{array}{c} {\rm Tetrafluoromethane} \\ \left( {{\rm CF}_4} \right) \end{array}$	*1.27	*8.9	2000	500	66

#### TABLE IV.- TEST FACILITIES

 $M_{\infty}$  and  $\gamma$  are effective values calculated by using the method of reference 66. At  $T_{t,\infty} = 291 \text{ K}$  some flow condensation was present.

#### Models

The experimental setup shown in figure 42(a) was designed to use interchangeable models and was employed in the Mach 6 air, Mach 20 helium, and Mach 19 nitrogen tests. A slightly different arrangement was used for the pressure test in the smaller scale  $CF_4$  facility. (See fig. 42(b).)

The interchangeable models included a 0.025-meter-diameter hemisphere, a 0.051-meter-diameter hemisphere, a 0.025-meter-diameter cylindrical leading-edge fin, and a  $30^{\circ}$  included angle wedge. Both pressure and heat-transfer models were constructed for each configuration. Pressure models were constructed of stainless steel and the heat-transfer models were constructed of silica base epoxy material. Solid stainless-steel (type 347) heat-transfer models were also used to measure peak heating in some facilities. Sketches of the models showing the center-line pressure tap locations are in figure 43.

The thermophysical properties (specific heat, thermal conductivity, and density) were measured on samples of material for each heat-transfer model. The value of  $\sqrt{\rho ck}$  used was approximately 1.80  $\frac{kW-sec^{1/2}}{m^2}$  for the epoxy models and 7.26  $\frac{kW-sec^{1/2}}{m^2}$  for the stainless-steel models.

#### **Test Parameters**

A summary of the models used, type of test, nominal flow conditions, and types of interference patterns studied is presented in table V.

Test	Model	Type of test	Shock generator angles and plate size	M <sub>∞</sub>	γ	p <sub>t,∞</sub> , N/cm <sup>2</sup>	T <sub>t,∞</sub> , K	N <sub>Re,∞</sub> /m	Types of interference

#### TABLE V.- SUMMARY OF TEST PARAMETERS

#### EXPERIMENTAL TECHNIQUES AND DATA ACCURACY

The method of testing used in all facilities was to measure the center-line pressure distribution on the model and at the same time photograph the shock patterns by use of schlieren, shadowgraph, or electron-beam techniques. The hemispheric model position relative to the impinging shock was varied vertically while the shock generator angle remained fixed. The hemisphere was moved in small increments to measure as close as possible the peak pressure and to form various shock interference patterns. The fin model was mounted vertically and positioned so that impingement occurred at approximately the same location on the model for both the unswept  $(0^{\circ})$  and swept  $(25^{\circ})$  cases. Various types of interference flows were studied with the  $30^{\circ}$  wedge by varying the wedge angle of attack. Conditions for the heat-transfer runs were selected after evaluating the pressure and flow-visualization data.

#### **Pressure Tests**

Conventional wind-tunnel pressure-measuring techniques were used for all tests. Electrical strain-gage pressure transducers were used for model static, tunnel freestream pitot, and tunnel stagnation pressure measurements.

All pressure transducers were calibrated to an accuracy of 0.25 percent of full scale. Based on this calibration accuracy and the repeatability of data, the pressure ratios measured in air and helium have a maximum deviation of  $\pm 0.08$ . The maximum deviations in the nitrogen and CF<sub>4</sub> tests are somewhat greater. The reason for this deviation is that the models were instrumented primarily to measure the peak value and not the lower pressures on the undisturbed regions of the model.

#### Heat-Transfer Tests

The heat-transfer tests were conducted by using the phase-change coating technique and methods described in reference 67. Because of the highly nonuniform heat-transfer distribution on the models, some models were tested with two or more temperature coatings. In some cases, peak heating was so high that the coating needed was near  $T_{aw}$ ; thus, short melt times and the possibility of large errors were indicated. To measure these peaks, the stainless-steel model with its large value of  $\sqrt{\rho ck}$  was used. This procedure permitted the use of a lower melt temperature coating and resulted in longer melt times.

Heat-transfer data are subject to numerous and often large sources of error. Errors in measuring the thermophysical properties of the model material, the melt temperatures and times, the initial model wall temperature, and the initial time at exposure to the free stream can affect the accuracy of the heat-transfer data. A very important source of error in most heat-transfer tests is in determining the adiabatic wall temperature distribution. For the present test,  $T_{aW}$  was assumed to be equal to the freestream total temperature, since it is very difficult to determine the adiabatic wall temperature in such complex flow patterns as occur in shock interference regions. An analysis of these combined errors indicates that the peak heating ratios measured at Mach 6 in air may have a maximum error of about 29 percent (25 percent at Mach 20 in helium). The errors in the heat-transfer data in other areas will be less. Inaccuracies due to errors in  $T_{aW}$ ,  $T_m$ , and  $T_{init}$  would be less in the nitrogen tests since  $T_{t,\infty}$ was higher.

A semi-infinite slab solution of the general heat conduction equation is used to reduce the heating data. (See ref. 67.) In order for this assumption to be valid, the radius of curvature must be much greater than the depth of heat penetration (ref. 67). As stated in reference 68, the heat-penetration depth for the semi-infinite slab is approximately independent of the aerodynamic heat-transfer coefficient and depends only on the thermal diffusivity of the wall material and the thermal diffusion time. The minimum distance from peak heating for which the semi-infinite slab solution is valid can also be determined by using the melt time. (See ref. 68.) The expression for this distance is shown in figure 44 for Mach 6 test conditions. For example, for a heating amplification of 10 at a melt temperature of 394 K, the minimum distance over the body diameter is 0.0084. Although this method does not account for lateral conduction errors, this figure does indicate where these errors can occur.

#### Flow Visualization

Schlieren, shadowgraph, or electron-beam photographs were taken in all tests. For the Mach 6 air and the Mach 20 helium tests, details of the interference region were observed by using the schlieren technique. The electron-beam flow-visualization technique described in reference 69 was used in the Mach 19 nitrogen tunnel. Shadowgraphs using nonparallel light were obtained in the  $CF_4$  tests. Oil-flow patterns were also made in this facility with the use of a mixture of titanium dioxide and silicon oil.

The best flow-visualization photographs were obtained in the Mach 6 air facility. Details observed in the Mach 6 photographs were used to determine the type of interference from photographs taken in the lower density facilities.

#### PRESENTATION OF EXPERIMENTAL RESULTS

Pressure and heat-transfer data not included in the analysis are presented as data plots (see table VI) or in tabular form. Tabulations of the test flow conditions, reference pressures, and lengths measured from flow-visualization photographs for all pressure

tests are given in table VII. These lengths include the shock displacement length  $L_{SH}$ and the coordinates  $x_i, y_i$  of the intersection of the impinging shock and the heimsphere bow shock. All lengths have been nondimensionalized with respect to the hemisphere nose radius  $R_b$ . Wall temperatures  $(T_w = T_m)$ , reference heat-transfer rates, and model material are presented in table VIII for all heat-transfer tests. Peak heating values measured in the Mach 19 nitrogen tunnel (test 16) are also presented in table VIII(d). Pressure data not plotted are given in table IX in nondimensional form. The reference pressure for the hemisphere tests is the stagnation pressure on the nose or the free-stream pitot pressure  $p_{stag}$ . On the fin the calculated stagnation-line value on the cylindrical leading edge  $p_{cvl}$  is used. The wedge reference pressure  $p_{wedge}$  is the calculated value on the wedge without interference with the exception of the  $\alpha = 50^{\circ}$  case where the measured free-stream pitot pressure is used. The reference heating for the hemisphere  $Q_{stag}$  is calculated by using equations (5) and (6). (See ref. 51.) Stagnationline values  $\tilde{Q}_{cvl}$  obtained from an expression in reference 60 are used for the cylindrical fin. The reference heating for the wedge  $Q_{wedge}$  was calculated by using an expression in reference 49 and was arbitrarily chosen as the value at the midpoint of the wedge (X = 0.5). Tables VII to IX are presented before the figures.

The plotted data (figs. 45 to 79) are grouped by configuration, Mach number, specific heat ratio, and type of interference as outlined in table VI.

Calculated peak pressure and heat-transfer levels obtained from the analytical methods are shown in the figures for comparative purposes. The dashed curves shown on the hemisphere figures (figs. 45 to 57, 69 to 79) are the pressure (modified Newtonian) and laminar heat-transfer distributions without interference and the solid curves are data fairings. Undisturbed pressure and heat-transfer levels (dashed lines in figs. 58 to 67) for the cylindrical fin were calculated by use of the stagnation-line expressions in reference 60 by assuming that the bow shock is parallel with the leading edge. The pressure calculation shown in figure 68(a) are the total and static pressures behind a normal shock.

#### TABLE VI.- INDEX TO PRESSURE AND HEAT-TRANSFER FIGURES

#### CONCLUDING REMARKS

An extensive analytical and experimental study of shock-interference heating has been conducted on simple shapes. This study covered a wide range of free-stream Mach numbers, specific heating ratios, Reynolds numbers, and location and strength of the impinging shock.

In most cases, calculations based on semiempirical methods developed in the present paper gave reasonable estimates of the measured peak pressures and heating for the six types of interferences (for test gases where real-gas effects are negligible). Correlations of pressure and heat transfer based on previous studies gave fair estimates of the heating levels for shock—boundary-layer interactions (types I, II, and V interferences). Correlations of the present data indicate that heating levels for attaching shear layers (type III interference) are from 50 to 65 percent higher than the peak heating for reattaching separated boundary layers. Calculations for peak heating due to an impinging supersonic jet (type IV interference) were made by assuming that the flow is analogous to the stagnation heating on a small sphere submerged in the jet flow.

The highest experimental pressure and heating amplification were obtained in the Mach 6 air investigations (along with good-quality flow-visualization photographs). Amplification factors up to 11.7 and 14.8 times the undisturbed wedge pressure and laminar heating, respectively, were measured for shock—boundary-layer interactions. Peak heating 13.9 times the laminar stagnation point value was measured on a 0.051-meterdiameter hemisphere for the shear layer attachment. Peak pressures 7.5 times the free-stream pitot pressure and peak heating 16.8 times the stagnation point heating were measured on the hemisphere for the supersonic jet impingement. Pressure and heating reductions of approximately 20 and 14 percent of the wedge values ahead of the disturbance occurred for the expansion-fan—boundary-layer interaction (type VI inter-ference). Results of the investigation conducted in the other facilities were affected by the limitations of the flow-visualization techniques and the smaller model size.

The theoretical parametric study showed that shock interference heating is strongly influenced by free-stream Mach number, specific heat ratio, impinging shock strength, and model geometry. In general, pressure and heat-transfer amplification for shock—boundary-layer interactions increase with increasing Mach number and shock strength and decrease with increasing specific heat ratio. For a fixed Mach number, specific heat ratio, and shock strength, the amplification decreases with increasing body angle. Pressure amplification for shear layer attachment increases with increasing Mach number whereas the heating decreases. This condition is primarily a result of the magnitude of the actual peaks and the reference values used. Both the pressure and heat-transfer amplification increase with increasing Mach number and decrease with

à

increasing specific heat ratio for jet impingement. These results indicate that because of real-gas effects, interference heating on the actual flight vehicle may be considerably higher than that measured in a wind tunnel.

The present methods of predicting peak heating are dependent on length scale measurements from flow-visualization data. Semiempirical methods are needed to relax this requirement. Other problem areas that require considerable investigations are the effects of shear layer growth, oblique jet impingement, and jet bow shock standoff distance as well as gas chemistry and three-dimensional flow on shock interference heating.

Langley Research Center,

National Aeronautics and Space Administration, Hampton, Va., January 22, 1973.

#### APPENDIX

## INTERFERENCE HEATING ON A TYPICAL SPACE

## SHUTTLE CONFIGURATION

A limited analysis of heating along a typical space shuttle ascent trajectory indicates that interference heating can occur in several locations on a mated shuttle configuration as illustrated in figure 80. Depending on the relative positions of the bodies, the free-stream conditions, and the angle of attack, one or more of the six types of interference may appear on the nose of the orbiter, between the fuel tank and the orbiter, and between the fuel tank and the rocket motors. Heating due to interfering shocks may also appear on the leading edge of wings and control surfaces depending on the amount of sweep. An example of how the type of interference pattern and its location can vary on the nose sections of a mated configuration is illustrated in figure 81 for a typical shuttle ascent trajectory. Initially, there will be little or no shock interference between the bodies. As the vehicle accelerates, type V or type VI interference appears on the upper surface of the orbiter. With further increase in Mach number, the shock interaction moves downward on the nose of the orbiter and types IV and III interferences will develop. Here the largest heating will develop as shown in the present study. A further increase in Mach number leads to a type II and finally a type I pattern. The reflected shocks can reflect back and forth several times in the region between the bodies to produce hot spots over an extended region on both surfaces. Some areas of interference heating can be eliminated by the proper spacing and placement of components and by sweeping back wings and control surfaces.

(b) Test 6358, fin model, Mach 6 air

\*The values of  $\rm p_{cyl}$  are the calculated stagnation line pressure on an infinite cylinder without interference. In all other runs,  $\rm p_{cyl}$  is the measured free-stream pitot pressure.

\*\*No interference.

(c) Test 6358,  $30^{\circ}$  wedge, Mach 6 air

\*Calculated wedge pressure without interference. \*\*No interference. \*\*\*Calculated wedge pressure including pressure rise across impinging shock. All other values of pwedge are measured free-stream pitot pressure. Shear layer did not attach to wedge in runs 25, 26, or 27.

(d) Test 357, 0.025-m-diameter hemisphere, Mach 20 helium.	Values of	<sup>p</sup> stag	are measured
free-stream pitot pressure.

(b) Test 6363, fin model, Mach 6 air.  $Q_{cyl}$  is the calculated stagnation line value on an infinite cylinder without interference.

\*Reference value for the calculated peak as well as the experimental data.

(c) Test 6363, 30<sup>0</sup> wedge, Mach 6 air. Q<sub>wedge</sub> is the calculated heating at the midpoint of the wedge without interference for all runs except runs 63 and 64. For runs 63 and 64, Q<sub>wedge</sub> is based on the maximum heating ahead of the expansion-fan—boundary-layer interaction.

Figure 54.- Type IV interference on a 0.051-m-diameter hemisphere at Mach 5.94 in air.  $\theta_i \approx 20^{\circ}; N_{\text{Re},\infty}/\text{m} \approx 7.6 \times 10^6; \gamma = 1.4.$ 

Figure 55.- Type IV interference on a 0.051-m-diameter hemisphere at Mach 5.94 in air.  $\theta_i \approx 25^{\circ}; N_{\text{Re},\infty}/m \approx 7.8 \times 10^6; \gamma = 1.4.$ 

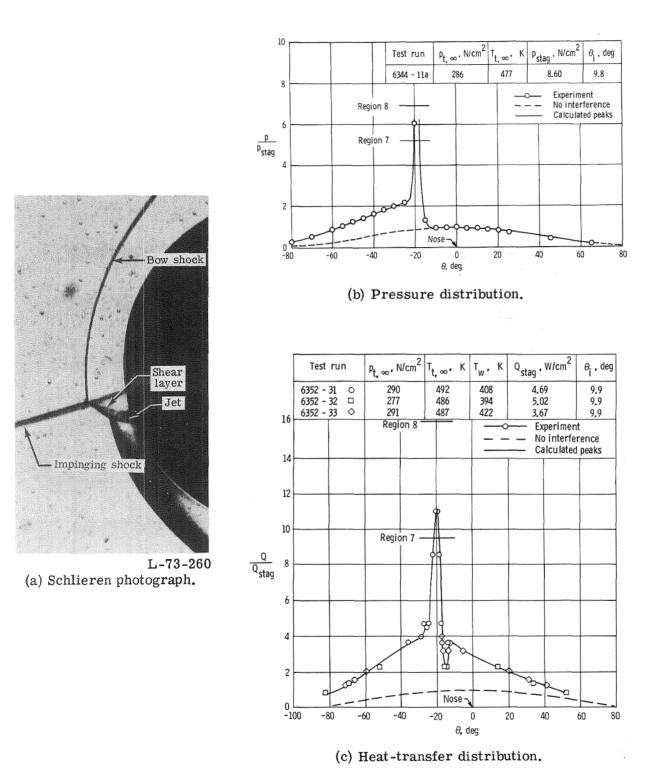

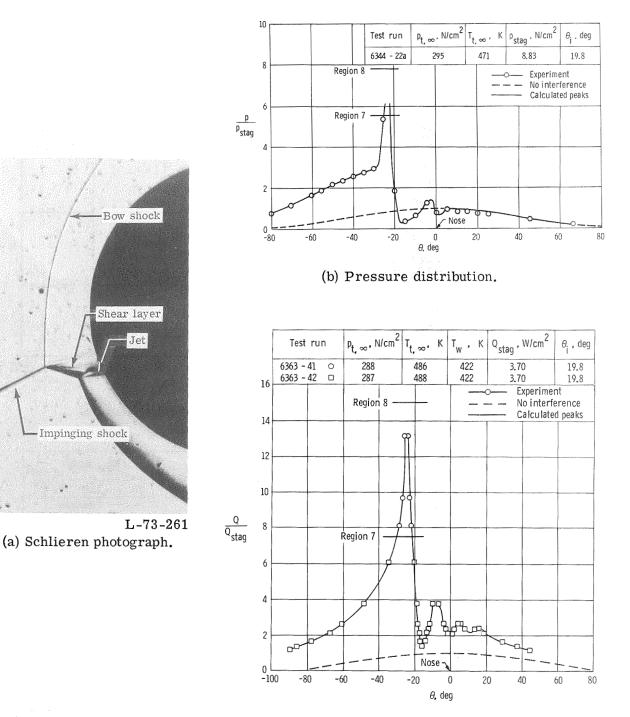

Figure 56.- Type IV interference on a 0.051-m-diameter hemisphere at Mach 6.00 in air.  $\theta_i = 9.8^{\circ}; N_{\text{Re},\infty}/m \approx 25.0 \times 10^{6}; \gamma = 1.4.$ 

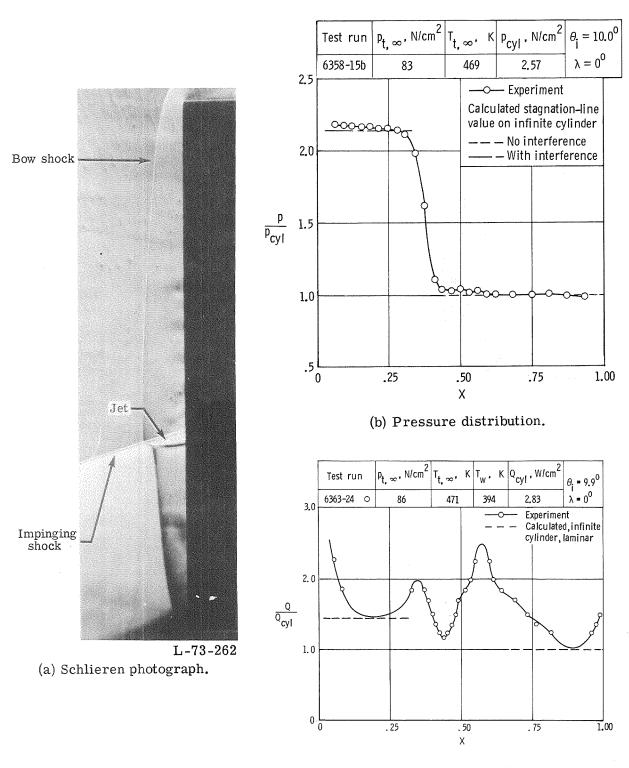

Figure 57.- Type III interference on a 0.051-m-diameter hemisphere at Mach 6.00 in air.  $\theta_i = 19.8^{\circ}; N_{\text{Re},\infty}/m \approx 25.6 \times 10^6; \gamma = 1.4.$ 

(c) Heat-transfer distribution.

Figure 58.- Type IVa interference on a fin at Mach 5.94 in air.  $\theta_i \approx 10^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 8.1 \times 10^{6}$ ;  $\gamma = 1.4$ .

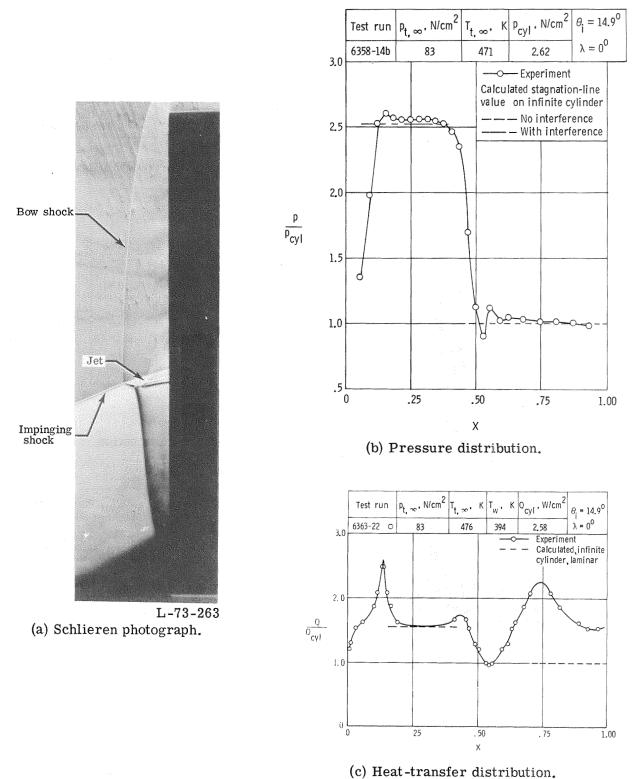

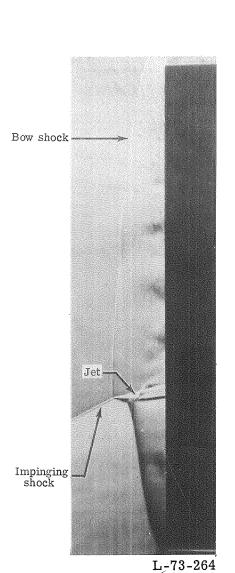

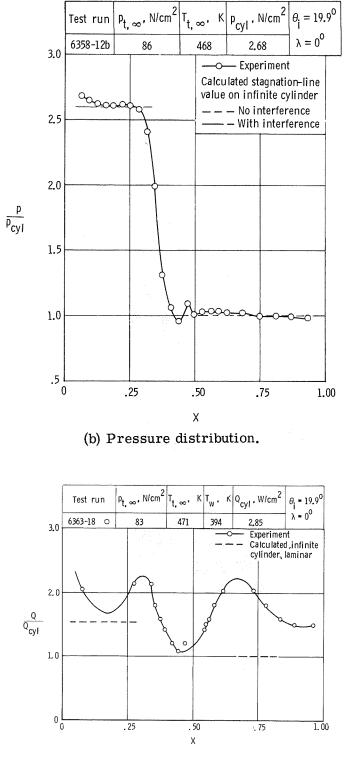

Figure 59.- Type IVa interference on a fin at Mach 5.94 in air.  $\theta_i = 14.9^{\circ}$ ;  $N_{\text{Re},\infty}/m \approx 7.7 \times 10^{6}$ ;  $\gamma = 1.4$ .

(a) Schlieren photograph.

(c) Heat-transfer distribution.

Figure 60.- Type IVa interference on a fin at Mach 5.94 in air.  $\theta_i = 19.9^{\circ}$ ;  $N_{\text{Re},\infty}/m \approx 7.9 \times 10^{6}$ ;  $\gamma = 1.4$ .

in Ri K

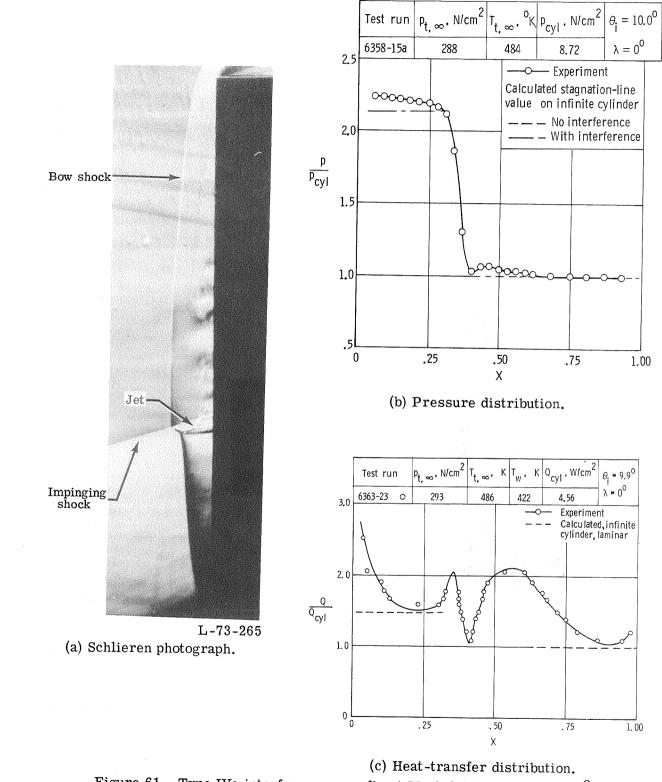

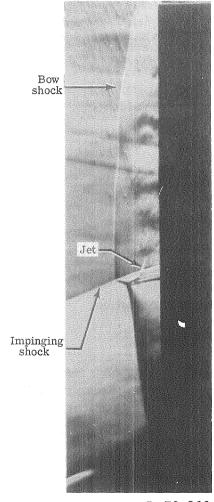

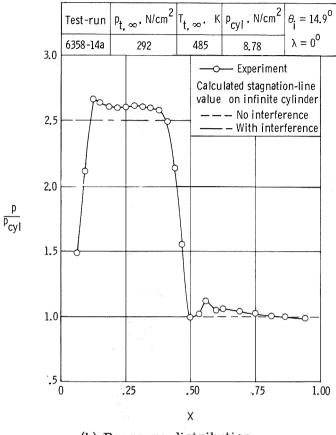

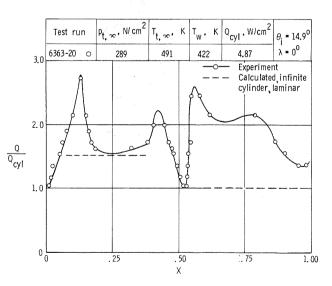

Figure 61.- Type IVa interference on a fin at Mach 6.00 in air.  $\theta_i \approx 10^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 26.2 \times 10^{6}$ ;  $\gamma = 1.4$ .

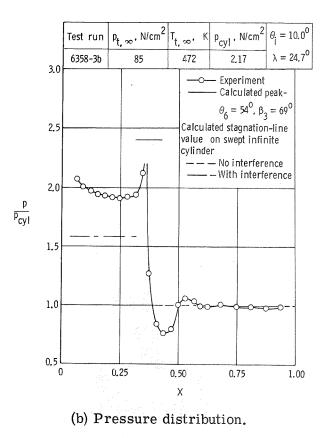

L-73-266 (a) Schlieren photograph.

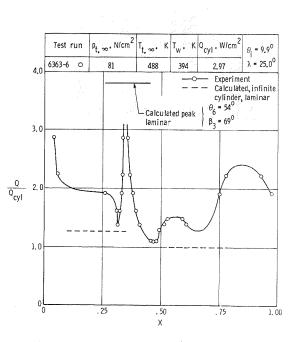

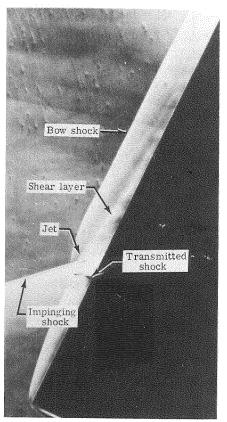

(c) Heat-transfer distribution. Figure 62.- Type IVa interference on a fin at Mach 6.00 in air.  $\theta_i = 14.9^{\circ}$ ;  $N_{\text{Re},\infty}/m \approx 25.4 \times 10^6$ ;  $\gamma = 1.4$ .

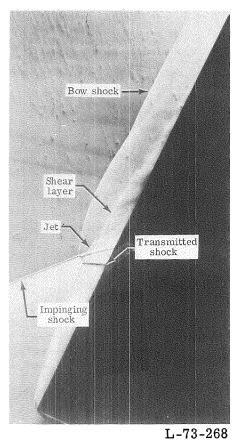

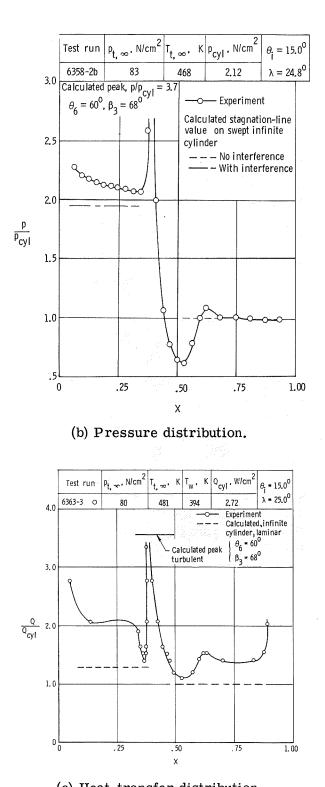

L-73-267 (a) Schlieren photograph.

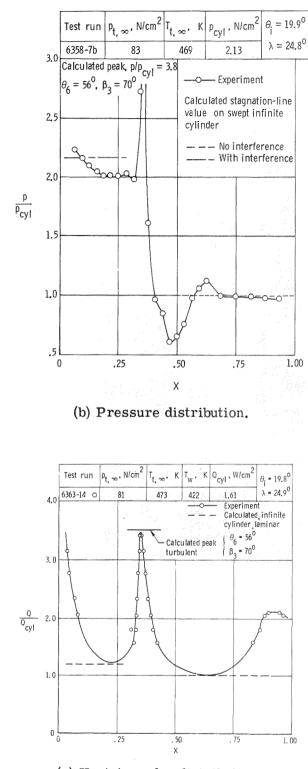

(c) Heat-transfer distribution. Figure 63.- Type V interference on a fin at Mach 5.94 in air.  $\theta_i \approx 10^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 7.2 \times 10^{6}$ ;  $\gamma = 1.4$ .

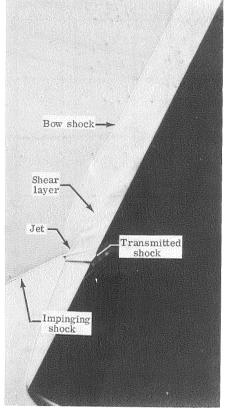

(a) Schlieren photograph.

(c) Heat-transfer distribution. Figure 64.- Type V interference on a fin at Mach 5.94 in air.  $\theta_i = 15^{\circ}$ ;  $N_{\text{Re},\infty}/m \approx 7.3 \times 10^6$ ;  $\gamma = -1.4$ .

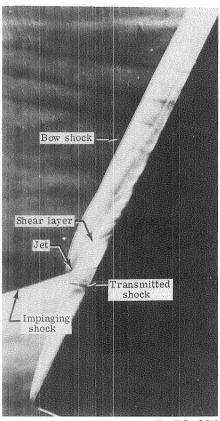

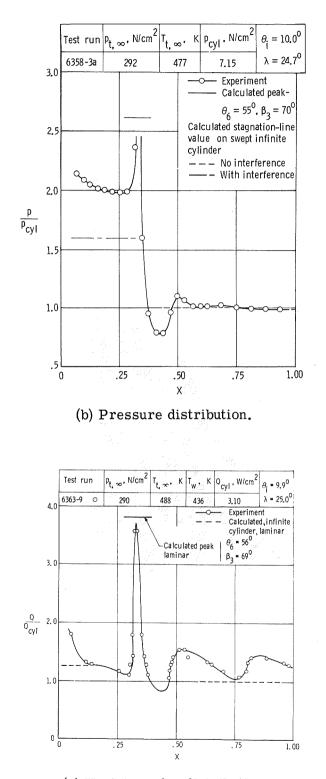

L-73-269 (a) Schlieren photograph.

(c) Heat-transfer distribution.

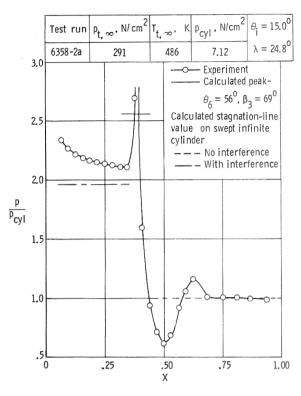

Figure 65.- Type V interference on a fin at Mach 5.94 in air.  $\theta_i \approx 20^{\circ}$ ;  $N_{\text{Re},\infty}/m \approx 7.6 \times 10^{6}$ ;  $\gamma = 1.4$ .

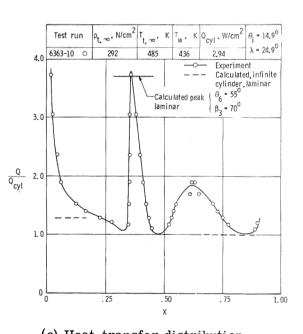

L-73-270 (a) Schlieren photograph.

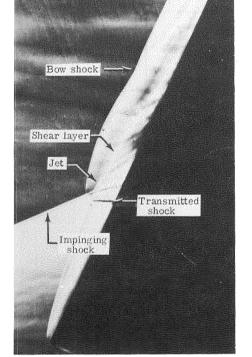

(c) Heat-transfer distribution. Figure 66.- Type V interference on a fin at Mach 6.00 in air.  $\theta_i \approx 10^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 25.7 \times 10^{6}$ ;  $\gamma = 1.4$ .

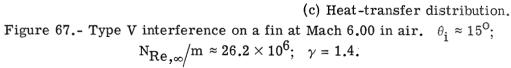

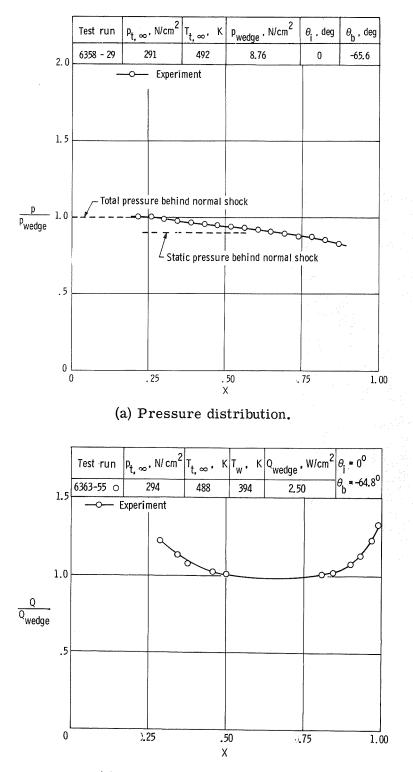

(b) Pressure distribution.

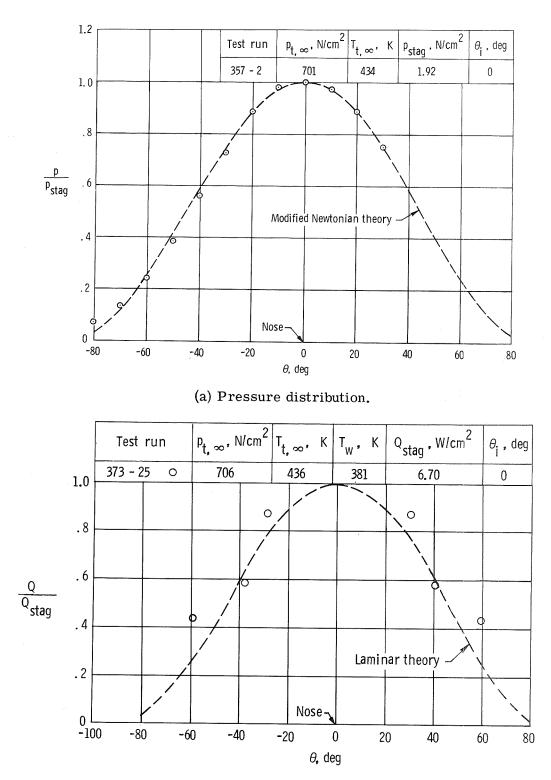

L-73-271 (a) Schlieren photograph.

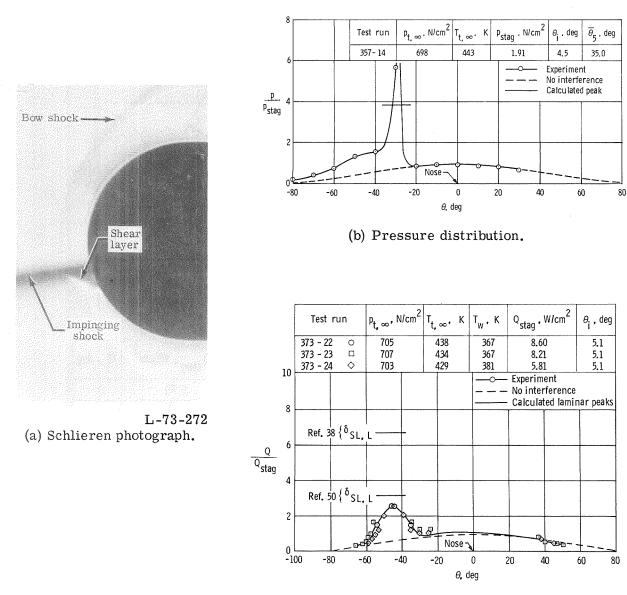

(b) Heat-transfer distribution.

(b) Heat-transfer distribution.

Figure 69.- Pressure and heat-transfer distribution on a 0.025-m-diameter hemisphere at Mach 20.2 in helium.  $\theta_i = 0^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 9.6 \times 10^{6}$ ;  $\gamma = 1.67$ .

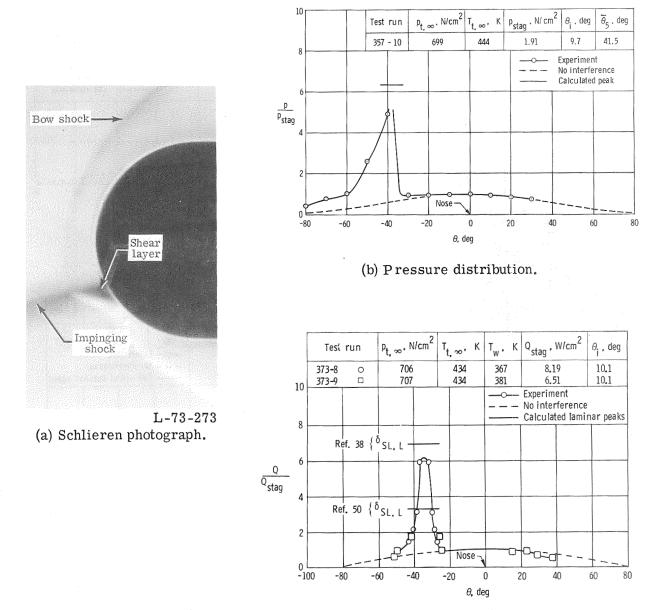

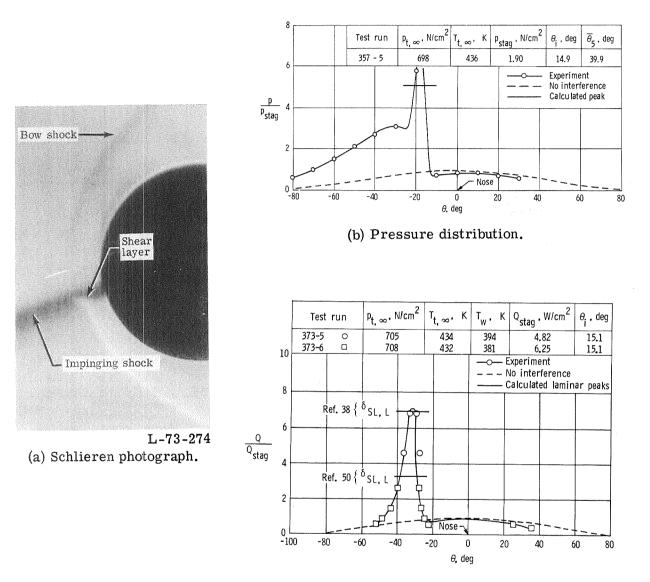

Figure 70.- Type III interference on a 0.025-m-diameter hemisphere at Mach 20.2 in helium.  $\theta_i \approx 5^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 9.7 \times 10^{6}$ ;  $\gamma = 1.67$ .

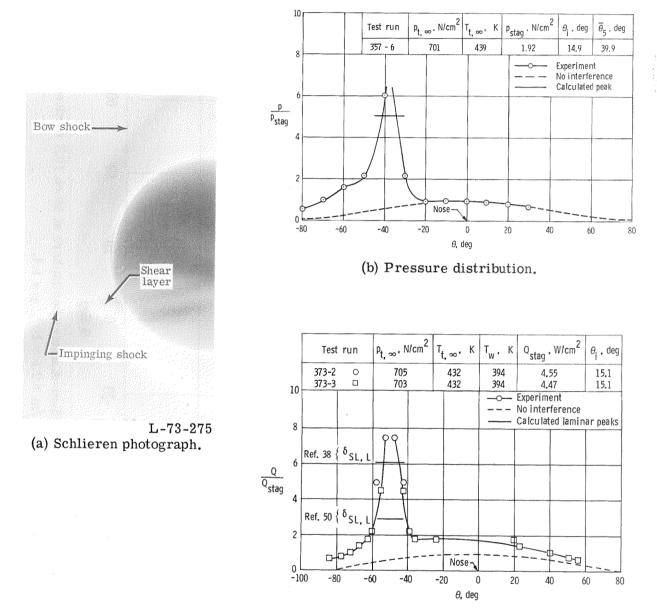

Figure 72.- Type III interference on a 0.025-m-diameter hemisphere at Mach 20.2 in helium.  $\theta_i \approx 15^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 9.8 \times 10^{6}$ ;  $\gamma = 1.67$ .

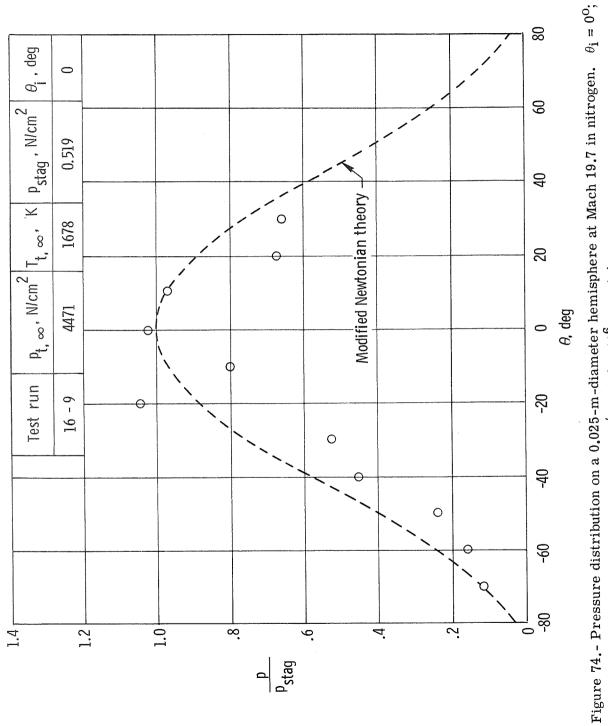

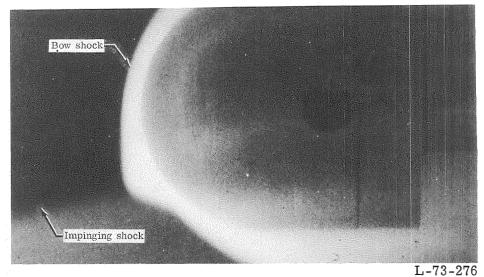

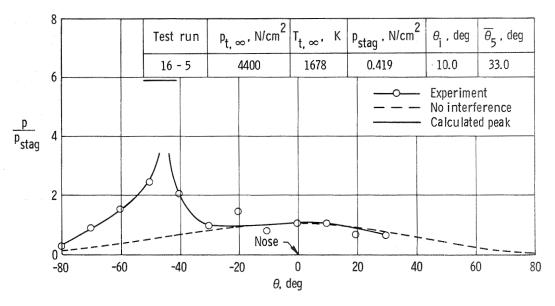

Figure 73.- Type III interference on a 0.025-m-diameter hemisphere at Mach 20.2 in helium.  $\theta_i \approx 15^{\circ}$ ;  $N_{\text{Re},\infty}/\text{m} \approx 9.8 \times 10^{6}$ ;  $\gamma = 1.67$ .

"The aeronautical and space activities of the United States shall be conducted so as to contribute ... to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

-NATIONAL AERONAUTICS AND SPACE ACT OF 1958

## NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

## TECHNICAL MEMORANDUMS:

Information receiving limited distribution because of preliminary data, security classification, or other reasons. Also includes conference proceedings with either limited or unlimited distribution.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

**TECHNICAL TRANSLATIONS: Information** published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include final reports of major projects, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

## TECHNOLOGY UTILIZATION

PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Technology Surveys.

Details on the availability of these publications may be obtained from: SCIENTIFIC AND TECHNICAL INFORMATION OFFICE NATIONAL AERONAUTICS AND SPACE ADMINISTRATION Washington, D.C. 20546
