Key words: Polycystic Ovary Syndrome, review, Anti-Müllerian Hormone, adolescent, adult, diagnostic accuracy

Abstract

Polycystic ovary syndrome (PCOS) affects 8-13% of women. Rotterdam diagnostic criteria include polycystic ovarian morphology (PCOM) on ultrasound, yet given recognised challenges, serum Anti-Müllerian Hormone (AMH) is proposed as an alternative. To inform international PCOS guidelines, a systematic review was completed. Key identified gaps include large international studies in well-defined populations across the life span, clustering of AMH with PCOS features, relationships to long term health outcomes, improved quality, assays standardisation and sample handling, all needed to determine cut-offs. Here we identify research priorities to address these gaps and enhance AMH utility in PCOS. Once issues are addressed, AMH levels could replace more costly and less accessible ultrasound in PCOS diagnosis

Challenges in ultrasound PCOM detection

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder affecting women of reproductive age with a reported prevalence of 8-13% [1-5]. The condition is heterogeneous [6], and women may present with reproductive, endocrine, metabolic, and psychosocial symptoms which vary across their lifespan [7]. The Rotterdam criteria require that women fulfil two of the following three criteria to be diagnosed with PCOS: oligo- or anovulation, clinical and/or biochemical signs of hyperandrogenism, and/or polycystic ovaries on ultrasound [8-10], with the exclusion of other relevant disorders.

Within the diagnostic criteria, polycystic ovarian morphology (PCOM) on ultrasonography is defined by either total ovarian volume or follicle number per ovary (FNPO). Original cut-offs for PCOM were based on limited evidence [11] and were recently revised in the new International PCOS guidelines, whilst also highlighting the controversy and challenges with this criteria [1-4]. Determining FNPO is operator and equipment-dependent, limiting accuracy and reproducibility. Equipment advances increase sensitivity and in turn FNPO counts [1-4, 12, 13]. Ultrasound involves expensive equipment and trained personnel, leading to increasing costs and impacting on accessibility. The ultrasound approach (transabdominal or transvaginal) impacts on accuracy, and in some women transvaginal ultrasound is unacceptable or may be perceived as invasive. Multi-follicular appearance on ultrasound overlaps with PCOM diagnostic cut offs especially in adolescents, whilst in older women with PCOS cut off values might be considerably lower [11]. Recent international PCOS guidelines now recommend against using ultrasound in PCOS diagnosis within 8 years of menarche and called for greater accuracy in PCOS diagnostic criteria worldwide [1-4].

AMH as a potential alternative to ultrasound PCOM detection

AMH is a polypeptide of the transforming growth factor beta (TGFβ) family, solely secreted by granulosa cells of the pre-antral and small antral ovarian follicles [14]. AMH has been shown in animal models of PCOS to have a possible causal role in development of the disorder through in-utero exposure of the fetus to high AMH levels [15]. In women, AMH inhibits the recruitment of primordial follicles out of the resting oocyte pool and may suppress follicle-stimulating hormone (FSH) action contributing to ovulatory disturbances [16] . Overall, serum AMH levels are significantly higher in women with PCOS compared with normal ovulatory women [17, 18]. These data has led to the hypothesis that AMH could be a valuable surrogate marker or an alternative to ultrasound FNPO count for detection of PCOM or in the overall diagnosing of PCOS [16].

Recognised challenges in the use of AMH measurement in PCOS include variations across the life span and problems with defining PCOM for comparison. AMH assays may also display a differential response to pre-analytical proteolysis, conformational changes of the AMH dimer, or the presence of interfering substances [19]. Appreciable sample-to-sample variability and substantial discrepancies in between-assay conversion factors, suggests assay performance issues. These issues were prioritised and addressed in the recent International evidence-based guideline for the assessment and management of PCOS [1-4]. The aim of this systematic review is to investigate whether AMH is effective for the detection of PCOM and/or diagnosis of PCOS to inform international evidence based guidelines in PCOS.

Methods

This systematic review was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) Statement [20] and was prepared to

inform recommendations in the updated and expanded evidence-based guideline for the assessment and management of PCOS [4].The methodology used for development of this guideline is aligned with Australia's National Health and Medical Research Council (NHMRC) [21], the European Society of Human Reproduction and Embryology (ESHRE) [22], and the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) methodology [23], and is described in detail in the full guideline [4].

This systematic review addressed the evidence for the following two clinical questions:

1: Is AMH effective to diagnose PCOS?

2: Is AMH effective to detect PCOM?

Systematic search for evidence

A systematic search strategy was designed to identify the best available evidence to answer the two clinical questions [24]. The search string comprised terms related to PCOS, PCOM, diagnosis, and AMH, and was developed to retrieve articles addressing women with PCOS in all cultural, geographical and socioeconomic backgrounds and settings. The search strategy was limited to English language studies in humans, and there were no limits on year of publication. A study design filter was not used.

Selection criteria

The Population of interest, Intervention, Comparison, and Outcome (PICO) framework was used to guide the selection criteria for each clinical question presented in this systematic review, and these were developed *a priori* by the multi-disciplinary guideline development group [24]. These included reporting of results in the format of threshold, sensitivity, specificity, area under the curve, and precision.

Databases

The following electronic databases were searched on June 26th 2017; Medline (Ovid)- Ovid MEDLINE(R) In-Process & Other Non-Indexed Citations, Ovid MEDLINE(R) and Ovid OLDMEDLINE(R) 1950 to Present; EMBASE (Ovid); All EBM (Ovid)- including The Cochrane Database of Systematic Reviews, DARE, CENTRAL and ACP Journal Club; PsycInfo (Ovid) and CINAHL

Evidence processing

Studies were selected and appraised by one highly experienced reviewer (MM) in consultation with colleagues using study selection criteria [24] established *a priori*. The retrieved articles were first reviewed by title and abstract, and then full articles will be retrieved for further assessment if the information given suggests that the study meets the inclusion criteria.

Assessment of methodological quality

Methodological quality (i.e. risk of bias) of each of the included studies was assessed by one reviewer for the adolescent studies (EB) and one reviewer for the adult studies (ECT), using a critical appraisal template developed *a priori* [25]. Individual quality items were investigated using a descriptive component approach that assessed attrition bias, reporting bias, selection bias, performance bias, potential confounding, and appropriateness of the statistical analysis. Any disagreement or uncertainty was resolved by a discussion with a third reviewer (MM) and within the team of authors of this manuscript. Using this approach each study was allocated a risk of bias rating of either low, moderate, or high.

Data extraction

Data were extracted directly into customized tables for characteristics of included studies and results by one reviewer (MM). Information was extracted on general study characteristics (lead author, year of publication, study design, country), participants (number, age category (adolescents or adults), BMI, AMH, PCOS diagnostic criteria, medication status), and diagnostic accuracy results (threshold, sensitivity, specificity, area under the curve, and precision). Due to the timeline intensive nature of conducting evidence-synthesis for an international guideline, authors were not contacted in instances of missing data or for data conversions.

Data synthesis

Due to the heterogeneity in diagnostic criteria and/or threshold/cut off values, meta-analyses (for pooled sensitivity and specificity estimates) have not been performed and thus the study data are presented narratively and in tabular form. True and false positive, and true and false negative, values for the diagnostic accuracy of AMH for PCOS and PCOM were calculated in Review Manager 5.3 using the sensitivity and specificity data extracted from included studies (MM and ECT). AMH data presented as ng/ml were converted to SI units, pmol/L (conversion factor of 7.1429).

Results

A total of 313 potentially relevant studies were identified in the electronic database search, of which 41 duplicates were excluded. The remaining 272 articles were reviewed by title and abstract and 230 were excluded. Forty-two articles were retrieved for full-text screening, of which 29 studies [16, 26-53] addressed diagnostic accuracy of AMH for PCOS and/or PCOM and thus met the inclusion criteria for the clinical questions presented in this review, whilst

13 full-text articles were excluded **(Figure 1).** A table of the excluded studies with reasons for their exclusion can be found in section 1.5 of the technical report for the International evidence-based guideline for the assessment and management of polycystic ovary syndrome [24].

INSERT FIGURE 1 HERE

Figure 1: PRISMA flow diagram

One of the 29 studies identified was a systematic review [34] and included nine of the studies identified here. However, it also included studies that did not meet the inclusion criteria for this evidence review, and was missing additional studies published more recently that were identified by this review's search; therefore, it was not used in this systematic review.

Characteristics of included studies

Supplementary table 1 includes key characteristics of included studies with four addressing diagnostic accuracy of AMH for PCOS and PCOM [31, 32, 38, 43], and one addressing PCOM only [48]. Of the 28 studies, six studies included adolescent participants for diagnosis of PCOS [32, 36, 45, 46, 48, 51] and one of these addressed PCOS and PCOM [32]. The remaining 21 studies [16, 26-31, 33, 37-44, 47, 49, 50, 52, 53] included adult participants for diagnosis of PCOS, where three of these addressed PCOS and PCOM [31, 38, 43]; the remaining 18 studies addressed PCOS alone [16, 26-30, 33, 37, 39-42, 44, 47, 49, 50, 52, 53]. Of the studies in adolescents, one was in overweight and obese participants [35], and in one study BMI was unclear [51]. Of the studies in adults, one included lean and obese participants [27], and five studies [26, 31, 37, 52, 53] included overweight and obese participants.

Participant numbers ranged from 31 to 633 participants for adolescents, and from 44 to 606 for adults. The studies were conducted across a range of settings including university departments, outpatient hospital clinics and laboratories, in countries including Australia, Indonesia, South Korea, Iran, Chile, USA, Turkey, Italy, Taiwan, Croatia, France, Norway, UK, Germany, Denmark, China and India.

Quality appraisal of included studies

The six studies which included adolescent participants ranged in quality from low to high risk of bias, whilst the majority of adult studies were at high risk of bias [24]. Reasons for these ratings include: selection criteria were not explicitly stated; it was unclear whether participants were entered into the study appropriately (randomly or consecutively); case-control design; inclusion of PCOM cases among controls; and inadequacies around application of index and reference tests, in particular, suboptimal choice about the best compromise between sensitivity and specificity by receiver operating characteristic (ROC) curve analysis. Moderate or high risk of bias was noted in interpretation of the results.

Diagnostic accuracy of AMH for PCOS

In adolescents, there were five studies, of which one was found to have a low risk of bias [32], two were of moderate risk of bias [35, 36, 46] and two were of high risk of bias [45, 51], demonstrating areas under the ROC curve of AMH for the diagnosis of PCOS, ranging from 0.5 to 0.88 (**Table 1**); the threshold cut-off values ranged from 25 to 44 pmol/L.

In adults, there were 21 studies, of which five were found to have a moderate risk of bias [29, 41-43, 49] and 16 were of high risk of bias [16, 26-28, 30, 31, 33, 37-40, 44, 47, 50, 52, 53], demonstrating areas under the ROC curve of AMH for the diagnosis of PCOS ranging from 0.66 to 0.994 (**Table 1**); the threshold cut-off values ranged from 10 to 57 pmol/L. Although mean serum AMH levels in adolescent and adult PCOS women were significantly higher than those of non-PCOS participants in all studies, there was significant overlap between the cases and controls. The sensitivity, specificity and AUC was generally higher in adults than in adolescents, acknowledging that the evidence is of limited quality and that study populations

varied widely across studies in terms of recruitment and definitions of both PCOS and control populations.

INSERT TABLE 1 HERE

Diagnostic accuracy of AMH for PCOM

In adolescents, there was one study of low risk of bias demonstrating an area under the ROC of AMH for the diagnosis of PCOM of 0.87 [48] (**Table 2**); the threshold cut-off value was 50 pmol/L. In adults, there were four relevant studies, one of which was found to have a low risk of bias [32], one of moderate risk of bias [43] and two of high risk of bias [31, 38], demonstrating areas under the ROC of AMH for the diagnosis for PCOM of 0.67 to 0.92 (**Table 2**). The threshold ranged from 20 to 30 pmol/L. Although serum AMH levels in adolescent and adult PCOM women are significantly higher than those of non-PCOM counterparts in all studies, there is significant overlap between cases and controls.

INSERT TABLE 2 HERE

Identified gaps in the AMH literature

This systematic review presents the most up to date, rigorous synthesis of peer-reviewed literature assessing whether AMH is effective for the detection of PCOM and diagnosis of PCOS, in both adolescents and adults, with results informing the international guideline on assessment and management of PCOS. The 28 included studies were rated with the majority having a moderate, or high risk of bias. Heterogeneity was significant with identified challenges including poorly defined study populations, variation across the life span, ill-defined approaches to AMH cut offs and challenges with aligning with PCOM and assay evolution and technical challenges.

The systematic review revealed significant heterogeneity in the accuracy of AMH in reflecting PCOM and in assisting the diagnosis of PCOS. Key contributors to this heterogeneity include the inappropriate selection of participants and the lack of well-defined study populations (those with or without PCOS or features of PCOS in the control populations). It is crucial that participants are entered into studies based on explicit, well defined and transparent selection criteria. Study populations need to be generalisable and ideally community recruited, rather than from high risk subgroups including those presenting with infertility. Comparators or controls need to be very clearly and consistently defined. Entrance to the studies needs to be either random or consecutive and studies need to be adequately powered to detect the specified outcome. The majority of available studies fail to fulfil these criteria leading to a moderate to high risk of bias and poor reliability. This needs to be addressed before progress can be made in understanding the role of AMH assays in PCOS.

Follicle development varies across the life span and is increased in adolescence, falling subsequently until menopause, when oocytes are depleted. There is a need for age specific cut offs for both PCOM and AMH. Here the sensitivity, specificity and area under the ROC curve suggests greater accuracy of AMH in PCOS diagnosis in adults than in adolescents and it may be that the role of AMH in PCOS diagnosis will align with that of PCOM. The new international guidelines now recommend against the use of ultrasound in the diagnosis of PCOS until 8 years post menarche (Box 1) [1-4], however more research is needed to determine age specific cut offs and acceptable accuracy at given life stages. Given that AMH is also not appropriate for diagnosis in adolescents or adults at present, both hyperandrogenism and ovulatory dysfunction are currently required for diagnosis in adolescents.

Another key challenge with the literature is the significant variably in the way the cut-off values were defined. Traditionally in determining cut-off values in biochemical tests as "normal" range, a cut-off of the 95th centile is applied to deliver 95% specificity. However, this is not appropriate for defining diagnostic cut offs for a clinical condition. Here more important considerations include clustering with other clinical features such as hirsutism, hyperandrogenism and oligo-anovulation, or prediction of long term health outcomes such as fertility. For example, establishing gestational diabetes, hypertension, or obesity cut-offs were based on long-term health risks, not simply percentiles [54-56]. In the case of AMH, the majority of studies defined the cut-offs at the 95th centile which is not a valid biological cut off. Further research on clustering of AMH with other features of PCOS and the relationship between AMH and long-term health outcomes is now vital.

Other considerations were the significant variability in follicle numbers and development, in PCOM and in AMH across the lifespan. Levels are high in adolescence and overlap considerably with those who do not have other features of PCOS. This makes it very difficult to differentiate PCOS from controls on AMH levels [57]. Levels fall in later life, especially after menopause [58]. Age specific reference ranges are thus vital [59] and it is likely that aligned with PCOM as a diagnostic feature of PCOS, AMH will be of most use where overlap is least notable, beyond the early post menarche years.

The relationship between AMH with PCOM was also an important consideration (Box 1). Investigators have used the PCOS definition established in 2003 at the Rotterdam conference [60], i.e. 12 follicles of 2-9mm diameter per ovary, to define this PCOS diagnostic criteria. This cut-off suffers from the same challenges of applying the 95th centile cut offs to define PCOM and is highly variable by life stage and dependent on advancing ultrasound equipment. Therefore, with the latest ultrasound equipment, the new international guidelines have redefined the PCOM cut offs to a threshold of ≥20 FNPO and have specified that ultrasound defined PCOM is no longer appropriate in PCOS diagnosis within 8 years post menarche, given the overlap between PCOS and controls [1-4, 12, 13]. With similar challenges in defining PCOM (cut-offs at the 95th centile, changes across the life stage and technical challenges mandate further research on clustering of PCOM with other features of PCOS and the relationship between PCOM and long-term health outcomes.

INSERT BOX 1 HERE

In addition, there are technical issues regarding the assays for serum AMH, leading to further heterogeneity in results. About one-half of the studies were performed using either the

Diagnostic Systems Lab (DSL) or Immunotech (IOT) assays, for which concordance in values is problematic. Furthermore, these assays are not marketed anymore. There is very little data with the new automated platform assays [41]. There is rising awareness on the impact of sample handling, transport, and storage conditions, factors which are under-reported in the literature. There is also a clear need for an international reference standard for AMH and for robust independent evaluation of commercial assays in routine clinical samples with well-defined sample handling and processing protocols [19]. Overall there is an urgent need for international standardisation in order to improve comparability amongst assays, the challenge of determining the optimal assay and the issues concerning sample storage and processing need to be addressed before clinical utility can be recommended (Box 2) [1-4].

INSERT BOX 2 HERE

Limitations

A single protocol document for all 40 systematic reviews completed as part of the international PCOS guideline was developed and signed off by all 70 Guideline development group expert, consumer and health professional members. These protocols are publically available at https://www.monash.edu/__data/assets/pdf_file/0020/1412282/PCOS-Guideline_Technical-report.pdf, however each individual protocol was not registered. This review was limited to studies published in English, thus putting the review at risk of language bias. Also, we did not contact study authors for missing information or data conversions.

Concluding remarks

AMH may play a key role in the pathogenesis of PCOS, however key issues must be addressed before it can be applied clinically to the detection of PCOM or in the diagnosis of PCOS. These include consistently defined and appropriate study and control populations, biologically relevant cut-off values that reflect clustering of clinical features and are relevant to health outcomes, are life stage specific, more clearly defining PCOM on ultrasound, and improved accuracy and standardisation of assays and handling procedures. With improved standardisation of emerging assays and established internationally approved cut-off levels/thresholds based on large scale validation in defined populations of different ages, AMH may become useful in the clinical detection of PCOM and the diagnosis of PCOS. However, until these issues are addressed, AMH is not clinically applicable and useful in detecting PCOM or diagnosing PCOS and is not recommended outside research in the new International evidence based guidelines for the assessment and management of PCOS [1-4].

Acknowledgements

We thank Estifanos Baye for performing the critical appraisals of the adolescent studies included in this review.

Author's roles

M.M with input from all authors designed the search strategy, M.M ran the database searches, screened articles, selected articles, performed data extraction, performed data conversions, completed the statistical analyses, and contributed to the write up of the manuscript. E.C.T critically appraised articles and contributed to the write up of the manuscript. H.T, contributed to the write up of the manuscript. All authors assisted in interpretation of the synthesised literature, critically revised the manuscript and approved the final version for submission.

Funding

The guideline and associated systematic reviews were primarily funded by the Australian National Health and Medical Research Council of Australia (NHMRC) supported by a partnership with the European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine. Guideline development group members did not receive payment. Travel expenses were covered by the sponsoring organisations.

Disclosure statement

HT received NHMRC grant funding to the institution to undertake this work. RA is a consultant for Medtronics, Ansh Labs, Spruce Biosciences, and Longitude Capital, and on the advisory board of Martin PET Imaging. JSEL has received grants from Ferring and Euroscreen. MM, ECT, DD, EHN, RJN, MA, SF, KH, SH, SO, DS, FH, SO, PD have nothing to declare.

Highlights

- This systematic review investigates whether serum Anti-Müllerian Hormone (AMH) is an effective alternative for detection of PCOM and/or diagnosis of PCOS
- There is significant heterogeneity in studies conducted in adolescents and adults, with a number of limitations identified
- Studies have lacked well-defined PCOS and control populations that varied across the life-span; used inconsistent methods for defining cut offs, variably defined PCOM in comparator studies and had methodological assay and sample handling challenges

Outstanding Questions

- Consistently defined and appropriate study and control populations, biologically relevant cut-off values that reflect clustering of clinical features and are relevant to health outcomes, are life stage specific, more clearly defining PCOM on ultrasound, with improved accuracy and standardisation of assays and handling procedures are needed in future studies

Box 1. Ultrasound and PCOM recommendations- International Evidence-based Guideline [1-4]

Ultrasound should not be used for the diagnosis of PCOS in those with a gynaecological age of < 8 years (< 8 years after menarche), due to the high incidence of multi-follicular ovaries in this life stage **(CCR)**

- The threshold for PCOM should be revised regularly with advancing ultrasound technology, and age-specific cut off values for PCOM should be defined **(CCR)**
- The transvaginal ultrasound approach is preferred in the diagnosis of PCOS, if sexually active and if acceptable to the individual being assessed **(CCR)**
- Using endovaginal ultrasound transducers with a frequency bandwidth that includes 8MHz, the threshold for PCOM should be on either ovary, a follicle number per ovary of ≥20 and/or an ovarian volume ≥ 10ml, ensuring no corpora lutea, cysts or dominant follicles are present **(CCR)**
- If using older technology, the threshold for PCOM could be an ovarian volume ≥ 10ml on either ovary **(CPP)**
- In patients with irregular menstrual cycles and hyperandrogenism, an ovarian ultrasound is not necessary for PCOS diagnosis; however, ultrasound will identify the complete PCOS phenotype **(CPP)**
- In transabdominal ultrasound reporting is best focused on ovarian volume with a threshold of ≥ 10ml, given the difficulty of reliably assessing follicle number with this approach **(CPP)**
- Clear protocols are recommended for reporting follicle number per ovary and ovarian volume on ultrasound. Recommended minimum reporting standards include:
    - Last menstrual period
    - Transducer bandwidth frequency
    - Approach/route assessed
    - Total follicle number per ovary measuring 2-9mm
    - Three dimensions and volume of each ovary
    - Reporting of endometrial thickness and appearance is preferred – 3-layer endometrial assessment may be useful to screen for endometrial pathology
    - Other ovarian and uterine pathology, as well as ovarian cysts, corpus luteum, dominant follicles ≥ equal 10mm **(CPP)**
- There is a need for training in careful and meticulous follicle counting per ovary, to improve reporting **(CPP)**

555 CCR= clinical consensus recommendations; CPP= clinical practice point

Box 2. AMH recommendations- International Evidence-based Guideline [1-4].

- Serum AMH levels should not yet be used as an alternative for the detection of PCOM or as a single test for the diagnosis of PCOS **(EBR)**
- There is emerging evidence that with improved standardisation of assays and established cut off levels or thresholds based on large scale validation in populations of different ages and ethnicities, AMH assays will be more accurate in the detection of PCOM **(CPP)**

Future steps for AMH in PCOS

- PCOM needs to be consistently defined and follow international guidelines to allow comparison with AMH levels
- The inclusion of controls with PCOM should be avoided, as previously mentioned. This requires a particular statistical approach (cluster analysis). Age-stratified thresholds need to be defined.
- Standardized optimal assays need to be applied
- AMH is a potential future substitute for detecting PCOM, however further research is needed including establishing universal threshold for elevated serum AMH level that requires validation in large populations of different ages and ethnicities.

556 EBR= evidence-based recommendation; CPP= clinical practice point
