APCluster

An R Package for Affinity Propagation Clustering

Ulrich Bodenhofer, Andreas Kothmeier, and Johannes Palme

Institute of Bioinformatics, Johannes Kepler University Linz Altenberger Str. 69, 4040 Linz, Austria *apcluster@bioinf.jku.at*

Version 1.3.0, January 7, 2013

Scope and Purpose of this Document

This document is a user manual for the R package apcluster [1]. It is only meant as a gentle introduction into how to use the basic functions implemented in this package. Not all features of the R package are described in full detail. Such details can be obtained from the documentation enclosed in the R package. Further note the following: (1) this is neither an introduction to affinity propagation nor to clustering in general; (2) this is not an introduction to R. If you lack the background for understanding this manual, you first have to read introductory literature on these subjects.

1 Introduction

Affinity propagation (AP) is a relatively new clustering algorithm that has been introduced by Brendan J. Frey and Delbert Dueck [5].¹ The authors themselves describe affinity propagation as follows:²

"An algorithm that identifies exemplars among data points and forms clusters of data points around these exemplars. It operates by simultaneously considering all data point as potential exemplars and exchanging messages between data points until a good set of exemplars and clusters emerges."

AP has been applied in various fields recently, among which bioinformatics is becoming increasingly important. Frey and Dueck have made their algorithm available as Matlab code.¹ Matlab, however, is relatively uncommon in bioinformatics. Instead, the statistical computing platform R has become a widely accepted standard in this field. In order to leverage affinity propagation for bioinformatics applications, we have implemented affinity propagation as an R package. Note, however, that the given package is in no way restricted to bioinformatics applications. It is as generally applicable as Frey's and Dueck's original Matlab code.¹

Starting with Version 1.1.0, the apcluster package also features *exemplar-based agglomerative clustering* which can be used as a clustering method on its own or for creating a hierarchy of clusters that have been computed previously by affinity propagation. *Leveraged Affinity Propagation*, a variant of AP especially geared to applications involving large data sets, has first been included in Version 1.3.0.

2 Installation

2.1 Installation via CRAN

The R package apcluster (current version: 1.3.0) is part of the *Comprehensive R Archive Network* $(CRAN)^3$. The simplest way to install the package, therefore, is to enter the following command into your R session:

> install.packages("apcluster")

2.2 Manual installation

If, for what reason ever, you prefer to install the package manually, download the package file suitable for your computer system and copy it to your harddisk. Open the package's page at CRAN⁴ and then proceed as follows.

²quoted from http://www.psi.toronto.edu/affinitypropagation/faq.html#def

¹http://www.psi.toronto.edu/affinitypropagation/

³http://cran.r-project.org/

⁴http://cran.r-project.org/web/packages/apcluster/index.html

Manual installation under Windows

- 1. Download apcluster_1.3.0.zip and save it to your harddisk
- 2. Open the R GUI and select the menu entry

Packages | Install package(s) from local zip files...

(if you use R in a different language, search for the analogous menu entry). In the file dialog that opens, go to the folder where you placed apcluster_1.3.0.zip and select this file. The package should be installed now.

Manual installation under Linux/UNIX/MacOS

- 1. Download apcluster_1.3.0.tar.gz and save it to your harddisk.
- 2. Open a shell window and change to the directory where you put apcluster_1.3.0.tar.gz. Enter

R CMD INSTALL apcluster_1.3.0.tar.gz

to install the package.

2.3 Compatibility issues

Both the Windows and the Linux/UNIX/MacOS version available from CRAN have been built using the latest version, R 2.15.2. However, the package should work without severe problems on R versions $\geq 2.10.1$.

3 Getting Started

To load the package, enter the following in your R session:

```
> library(apcluster)
```

If this command terminates without any error message or warning, you can be sure that the package has been installed successfully. If so, the package is ready for use now and you can start clustering your data with affinity propagation.

The package includes both a user manual (this document) and a reference manual (help pages for each function). To view the user manual, enter

```
> vignette("apcluster")
```

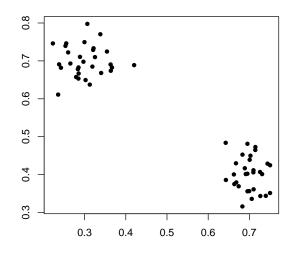

Help pages can be viewed using the help command. It is recommended to start with

> help(apcluster)

Affinity propagation does not require the data samples to be of any specific kind or structure. AP only requires a *similarity matrix*, i.e., given l data samples, this is an $l \times l$ real-valued matrix **S**, in which an entry S_{ij} corresponds to a value measuring how similar sample i is to sample j. AP does not require these values to be in a specific range. Values can be positive or negative. AP does not even require the similarity matrix to be symmetric (although, in most applications, it will be symmetric anyway). A value of $-\infty$ is interpreted as "absolute dissimilarity". The higher a value, the more similar two samples are considered.

To get a first impression, let us create a random data set in \mathbb{R}^2 as the union of two "Gaussian clouds":

```
> cl1 <- cbind(rnorm(30, 0.3, 0.05), rnorm(30, 0.7, 0.04))
> cl2 <- cbind(rnorm(30, 0.7, 0.04), rnorm(30, 0.4, .05))
> x1 <- rbind(cl1, cl2)
> plot(x1, xlab="", ylab="", pch=19, cex=0.8)
```

The package apcluster offers several different ways for clustering data. The simplest way is the following:

```
> apres1a <- apcluster(negDistMat(r=2), x1)</pre>
```

In this example, the function apcluster() first computes a similarity matrix for the input data x1 using the *similarity function* passed as first argument. The choice negDistMat(r=2) is the standard similarity measure used in the papers of Frey and Dueck — negative squared distances.

Alternatively, one can compute the similarity matrix beforehand and call apcluster() for the similarity matrix (for a more detailed description of the differences, see 9.1):

> s1 <- negDistMat(x1, r=2)
> apres1b <- apcluster(s1)</pre>

3 Getting Started

The function apcluster() creates an object belonging to the S4 class APResult which is defined by the present package. To get detailed information on which data are stored in such objects, enter

> help(APResult)

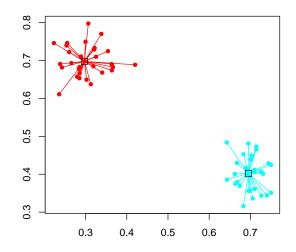

> apres1a

The simplest thing we can do is to enter the name of the object (which implicitly calls show()) to get a summary of the clustering result:

APResult object Number of samples = 60 Number of iterations = 131 Input preference = -0.1416022 Sum of similarities = -0.1955119 Sum of preferences = -0.2832044 Net similarity = -0.4787163 = 2 Number of clusters Exemplars: 25 44 Clusters: Cluster 1, exemplar 25: 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 Cluster 2, exemplar 44: 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60

For two-dimensional data sets, the apcluster package allows for plotting the original data set along with a clustering result:

> plot(apres1a, x1)

In this plot, each color corresponds to one cluster. The exemplar of each cluster is marked by a box and all cluster members are connected to their exemplars with lines.

A heatmap is plotted with heatmap():

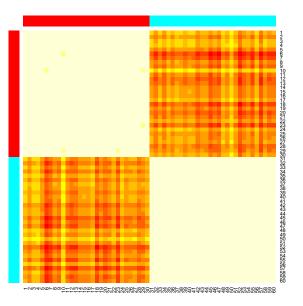

> heatmap(apres1a)

In the heatmap, the samples are grouped according to clusters. The above heatmap confirms again that there are two main clusters in the data. A heatmap can be plotted for the object apres1a because apcluster(), if called for data and a similarity function, by default includes the similarity

3 Getting Started

matrix in the output object (unless it was called with the switch includeSim=FALSE). If the similarity matrix is not included (which is the default if apcluster() has been called on a similarity matrix directly), heatmap() must be called with the similarity matrix as second argument:

```
> heatmap(apres1b, s1)
```

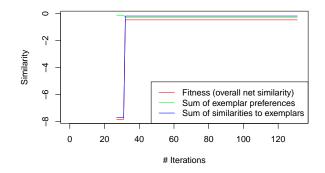

Suppose we want to have better insight into what the algorithm did in each iteration. For this purpose, we can supply the option details=TRUE to apcluster():

```
> apres1c <- apcluster(s1, details=TRUE)</pre>
```

This option tells the algorithm to keep a detailed log about its progress. For example, this allows us to plot the three performance measures that AP uses internally for each iteration:

```
> plot(apres1c)
```

These performance measures are:

- 1. Sum of exemplar preferences
- 2. Sum of similarities of exemplars to their cluster members
- 3. Net fitness: sum of the two former

For details, the user is referred to the original affinity propagation paper [5] and the supplementary material published on the affinity propagation Web page.¹ We see from the above plot that the algorithm has not made any change for the last 100 (of 131!) iterations. AP, through its parameter convits, allows to control for how long AP waits for a change until it terminates (the default is convits=100). If the user has the feeling that AP will probably converge quicker on his/her data set, a lower value can be used:

```
> apres1c <- apcluster(s1, convits=15, details=TRUE)
> apres1c
APResult object
Number of samples
                      =
                         60
Number of iterations =
                         46
Input preference
                      = -0.1416022
Sum of similarities
                      = -0.1955119
Sum of preferences
                      = -0.2832044
Net similarity
                      = -0.4787163
Number of clusters
                      = 2
Exemplars:
   25 44
Clusters:
   Cluster 1, exemplar 25:
      1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26
      27 28 29 30
   Cluster 2, exemplar 44:
      31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53
      54 55 56 57 58 59 60
```

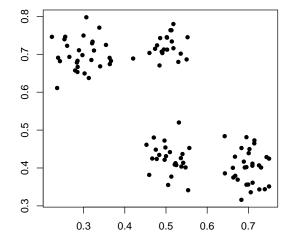

4 Adjusting Input Preferences

Apart from the similarity matrix itself, the most important input parameter of AP is the so-called *input preference* which can be interpreted as the tendency of a data sample to become an exemplar (see [5] and supplementary material on the AP homepage¹ for a more detailed explanation). This input preference can either be chosen individually for each data sample or it can be a single value shared among all data samples. Input preferences largely determine the number of clusters, in other words, how fine- or coarse-grained the clustering result will be.

The input preferences one can specify for AP are roughly in the same range as the similarity values, but they do not have a straightforward interpretation. Frey and Dueck have introduced the following rule of thumb: "*The shared value could be the median of the input similarities (resulting in a moderate number of clusters) or their minimum (resulting in a small number of clusters).*" [5]

Our AP implementation uses the median rule by default if the user does not supply a custom value for the input preferences. In order to provide the user with a knob that is — at least to some extent — interpretable, the function apcluster() provides an argument q that allows to set the input preference to a certain quantile of the input similarities: resulting in the median for q=0.5 and in the minimum for q=0. As an example, let us add two more "clouds" to the data set from above:

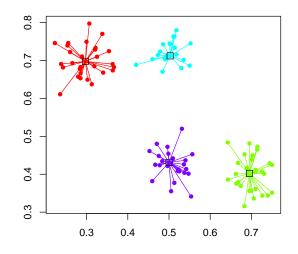

```
> cl3 <- cbind(rnorm(20, 0.50, 0.03), rnorm(20, 0.72, 0.03))
> cl4 <- cbind(rnorm(25, 0.50, 0.03), rnorm(25, 0.42, 0.04))
> x2 <- rbind(x1, cl3, cl4)
> plot(x2, xlab="", ylab="", pch=19, cex=0.8)
```

For the default setting, we obtain the following result:

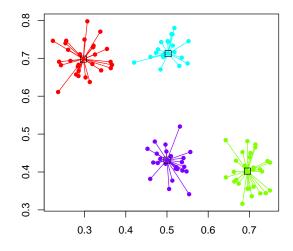

```
> apres2a <- apcluster(negDistMat(r=2), x2)</pre>
```

```
> plot(apres2a, x2)
```

For the minimum of input similarities, we obtain the following result:

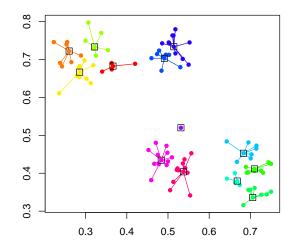

```
> apres2b <- apcluster(negDistMat(r=2), x2, q=0)
> plot(apres2b, x2)
```

So we see that AP is quite robust against a reduction of input preferences in this example which may be caused by the clear separation of the four clusters. If we increase input preferences, however, we can force AP to split the four clusters into smaller sub-clusters:

```
> apres2c <- apcluster(negDistMat(r=2), x2, q=0.8)</pre>
```

```
> plot(apres2c, x2)
```

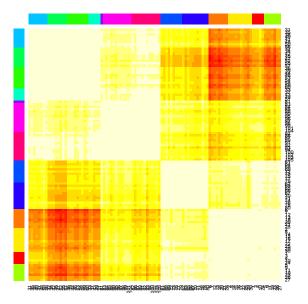

Note that the input preference used by AP can be recovered from the output object (no matter which method to adjust input preferences has been used). On the one hand, the value is printed if the object is displayed (by show or by entering the output object's name). On the other hand, the value can be accessed directly via the slot p:

> apres2c@p

[1] -0.009144609

As noted above already, we can produce a heatmap by calling heatmap() for an APResult object:

> heatmap(apres2c)

The order in which the clusters are arranged in the heatmap is determined by means of joining the cluster agglomeratively (see Section 5 below). Although the affinity propagation result contains 13 clusters, the heatmap indicates that there are actually four clusters which can be seen as very brightly colored squares along the diagonal. We also see that there seem to be two pairs of adjacent clusters, which can be seen from the fact that there are two relatively light-colored blocks along the diagonal encompassing two of the four clusters in each case. If we look back at how the data have been created (see also plots above), this is exactly what is to be expected.

The above example with q=0 demonstrates that setting input preferences to the minimum of input similarities does not necessarily result in a very small number of clusters (like one or two). This is due to the fact that input preferences need not necessarily be exactly in the range of the similarities. To determine a meaningful range, an auxiliary function is available which, in line with Frey's and Dueck's Matlab code,¹ allows to compute a minimum value (for which one or at most two clusters would be obtained) and a maximum value (for which as many clusters as data samples would be obtained):

> preferenceRange(apres2b@sim)

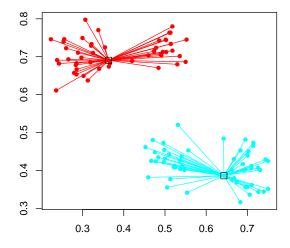

```
[1] -5.136255e+00 -1.818538e-06
```

The function returns a two-element vector with the minimum value as first and the maximum value as second entry. The computations are done approximately by default. If one is interested in exact bounds, supply exact=TRUE (resulting in longer computation times).

Many clustering algorithms need to know a pre-defined number of clusters. This is often a major nuisance, since the exact number of clusters is hard to know for non-trivial (in particular, high-dimensional) data sets. AP avoids this problem. If, however, one still wants to require a fixed number of clusters, this has to be accomplished by a search algorithm that adjusts input preferences in order to produce the desired number of clusters in the end. For convenience, this search

algorithm is available as a function apclusterK() (analogous to Frey's and Dueck's Matlab implementation¹). We can use this function to force AP to produce only two clusters (merging the two pairs of adjacent clouds into one cluster each). Analogously to apcluster(), apclusterK() supports two variants — it can either be called for a similarity measure and data or on a similarity matrix directly.

```
> apres2d <- apclusterK(negDistMat(r=2), x2, K=2, verbose=TRUE)
Trying p = -0.005138071
   Number of clusters: 16
Trying p = -0.05136435
   Number of clusters: 4
Trying p = -0.5136271
   Number of clusters: 4
Trying p = -2.568128 (bisection step no. 1 )
   Number of clusters: 2
Number of clusters: 2 for p = -2.568128
> plot(apres2d, x2)
```

5 Exemplar-based Agglomerative Clustering

The function aggExCluster() realizes what can best be described as "exemplar-based agglomerative clustering", i.e. agglomerative clustering whose merging objective is geared towards the identification of meaningful exemplars. Analogously to apcluster(), aggExCluster() supports two variants — it can either be called for a similarity measure and data or on matrix of pairwise similarities.

5.1 Getting started

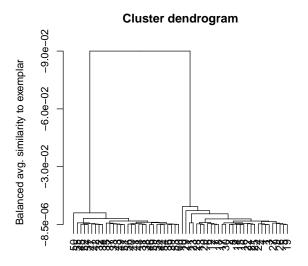

Let us start with a simple example:

```
> aggres1a <- aggExCluster(negDistMat(r=2), x1)
> aggres1a
AggExResult object
```

Number of samples = 60 Maximum number of clusters = 60

The output object aggres1a contains the complete cluster hierarchy. As obvious from the above example, the show() method only displays the most basic information. Calling plot() on an object that was the result of aggExCluster() (an object of class AggExResult), a dendrogram is plotted:

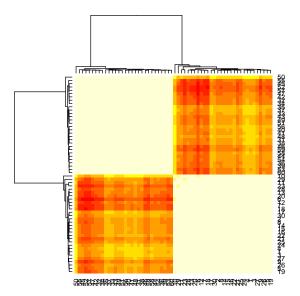

> plot(aggres1a)

The heights of the merges in the dendrogram correspond to the merging objective: the higher the vertical bar of a merge, the less similar the two clusters have been. The dendrogram, therefore, clearly indicates two clusters. Heatmaps can be produced analogously as for APResult objects with the additional property that dendrograms are displayed on the top and on the left:

> heatmap(aggres1a, s1)

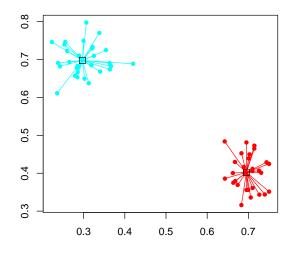

16

Once we have confirmed the number of clusters, which is clearly 2 according to the dendrogram and the heatmap above, we can extract the level with two clusters from the cluster hierarchy. In concordance with standard R terminology, the function for doing this is called cutree():

```
> cl1a <- cutree(aggres1a, k=2)</pre>
> cl1a
ExClust object
Number of samples
                                                60
                                         =
Number of clusters =
                                                2
Exemplars:
      44 25
Clusters:
      Cluster 1, exemplar 44:
            50 55 45 52 57 47 42 32 34 35 37 33 43 49 51 56 40 41 48 31 38 46 59
            58 44 54 36 39 53 60
      Cluster 2, exemplar 25:
            10 \hspace{0.1cm} 29 \hspace{0.1cm} 11 \hspace{0.1cm} 23 \hspace{0.1cm} 28 \hspace{0.1cm} 13 \hspace{0.1cm} 20 \hspace{0.1cm} 6 \hspace{0.1cm} 12 \hspace{0.1cm} 7 \hspace{0.1cm} 18 \hspace{0.1cm} 17 \hspace{0.1cm} 30 \hspace{0.1cm} 2 \hspace{0.1cm} 8 \hspace{0.1cm} 14 \hspace{0.1cm} 15 \hspace{0.1cm} 16 \hspace{0.1cm} 22 \hspace{0.1cm} 21 \hspace{0.1cm} 25 \hspace{0.1cm} 24 \hspace{0.1cm} 4 \hspace{0.1cm} 1 \hspace{0.1cm} 3
            27 9 26 5 19
```

> plot(cl1a, x1)

5.2 Merging clusters obtained from affinity propagation

The most important application of aggExCluster() (and the reason why it is part of the apcluster package) is that it can be used for creating a hierarchy of clusters starting from a set of clusters previously computed by affinity propagation. The examples in Section 4 indicate that it may sometimes be tricky to define the right input preference. Exemplar-based agglomerative clustering on affinity propagation results provides an additional tool for finding the right number of clusters.

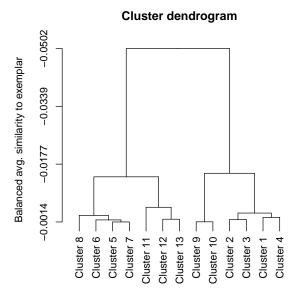

Let us revisit the four-cluster example from Section 4. We can apply aggExCluster() to an affinity propagation result if we run it on the affinity propagation result supplied as second argument x:

```
> aggres2a <- aggExCluster(x=apres2c)
> aggres2a
AggExResult object
Number of samples = 105
Maximum number of clusters = 13
```

The result apres2c had 13 clusters. aggExCluster() successively joins these clusters until only one cluster is left. The dendrogram of this cluster hierarchy is given as follows:

> plot(aggres2a)

> heatmap(aggres2a)

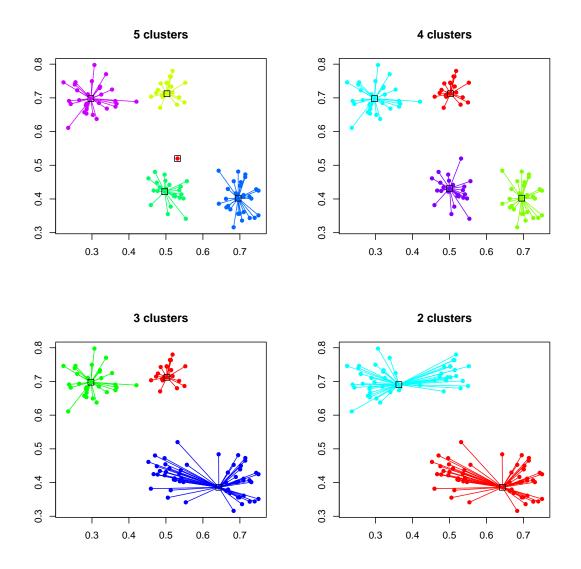

The following heatmap coincides with the one shown in Section 4 above. This is not surprising, since the heatmap plot for an affinity propagation result uses aggExCluster() internally to arrange the clusters:

027-022018140-407407407000

Once we are more or less sure about the number of clusters, we extract the right clustering level from the hierarchy. For demonstation purposes, we do this for $k = 5, \ldots, 2$ in the following plots:

```
> par(mfrow=c(2,2))
> for (k in 5:2)
+ plot(aggres2a, x2, k=k, main=paste(k, "clusters"))
```

There is one obvious, but important, condition: applying aggExCluster() to an affinity propagation result only makes sense if the number of clusters to start from is at least as large as the number of true clusters in the data set. Clearly, if the number of clusters is already too small, then merging will make the situation only worse.

5.3 Details on the merging objective

Like any other agglomerative clustering method (see, e.g., [6, 10, 12]), aggExCluster() merges clusters until only one cluster containing all samples is obtained. In each step, two clusters

are merged into one, i.e. the number of clusters is reduced by one. The only aspect in which aggExCluster() differs from other methods is the merging objective.

Suppose we consider two clusters for possible merging, each of which is given by an index set:

$$I = \{i_1, \dots, i_{n_I}\}$$
 and $J = \{j_1, \dots, j_{n_J}\}$

Then we first determine the potential *joint exemplar* ex(I, J) as the sample that maximizes the average similarity to all samples in the joint cluster $I \cup J$:

$$\operatorname{ex}(I,J) = \operatorname{argmax}_{i \in I \cup J} \frac{1}{n_I + n_J} \cdot \sum_{j \in I \cup J} S_{ij}$$

Recall that S denotes the similarity matrix and S_{ij} corresponds to the similarity of the *i*-th and the *j*-th sample. Then the merging objective is computed as

$$\operatorname{obj}(I,J) = \frac{1}{2} \cdot \Big(\frac{1}{n_I} \cdot \sum_{j \in I} S_{\operatorname{ex}(I,J)j} + \frac{1}{n_J} \cdot \sum_{k \in J} S_{\operatorname{ex}(I,J)k}\Big),$$

which can be best described as "balanced average similarity to the joint exemplar". In each step, aggExCluster() considers all pairs of clusters in the current cluster set and joins that pair of clusters whose merging objective is maximal. The rationale behind the merging objective is that those two clusters should be joined that are best described by a joint exemplar.

6 Leveraged Affinity Propagation

Leveraged affinity propagation is based on the idea that, for large data sets with many samples, the cluster structure is already visible on a subset of the samples. Instead of evaluating the similarity matrix for all sample pairs, the similarities of all samples to a subset of samples are computed — resulting in a non-square similarity matrix. Clustering is performed on this reduced similarity matrix allowing for clustering large data sets more efficiently.

In this form of clustering, several rounds of affinity propagation are executed with different sample subsets — iteratively improving the clustering result. The implementation is based on the Matlab code of Frey and Dueck provided on the AP Web page¹. Apart from dynamic improvements through reduced amount of distance calculations and faster clustering, the memory consumption is also reduced not only in terms of the memory used for storing the similarity matrix, but also in terms of memory used by the clustering algorithm internally.

The two main parameters controlling leveraged AP clustering are the fraction of data points that should be selected for clustering (parameter frac) and the number of sweeps or repetitions of individual clustering runs (parameter sweeps). Initially, a sample subset is selected randomly. For the subsequent repetitions, the exemplars of the previous run are kept in the sample subset and the other samples in the subset are chosen randomly again. The best result of all sweeps with the highest net similarity is kept as final clustering result.

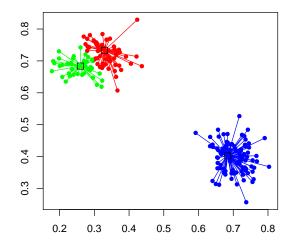

When called with a similarity measure and a dataset the function apclusterL() performs both the calculation of similarities and leveraged affinity propagation. In the example below, we use 10% of the samples and run 5 repetitions. The function implementing the similarity measure can either be passed as a function or as a function name (which must of course be resolvable in the current environment). Additional parameters for the distance calculation can be passed to apclusterL() which passes them on to the function implementing the similarity measure via the ... argument list. In any case, this function must be implemented such that it expects the data in its first argument x (a subsettable data structure, such as, a vector, matrix, data frame, or list) and that it takes the selection of "column objects" as a second argument sel which must be a set of column indices. The functions negDistMat(), expSimMat(), linSimMat(), corSimMat(), and linKernel() provided by the apcluster package also support the easy creation of parameterfree similarity measures (in R terminology called "closures"). We recommend this variant, as it is safer in terms of possible name conflicts between arguments of apclusterL() and arguments of the similarity function.

Here is an example that makes use of a closure for defining the similarity measure:

```
> cl5 <- cbind(rnorm(100, 0.3, 0.05), rnorm(100, 0.7, 0.04))
> cl6 <- cbind(rnorm(100, 0.70, 0.04), rnorm(100, 0.4, 0.05))
> x3 <- rbind(c15, c16)
> apres3 <- apclusterL(s=negDistMat(r=2), x=x3, frac=0.1, sweeps=5, p=-0.2)</pre>
> apres3

> plot(apres3, x3)

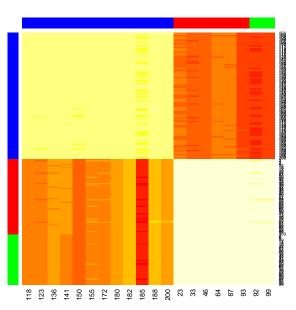

The function apclusterL() creates a result object of S4 class APResult that contains the same information as for standard AP. Additionally, the selected sample subset, the associated rectangular similarity matrix for the best sweep (provided that includeSim=TRUE) and the net similarities of all sweeps are returned in this object.

> dim(apres3@sim) [1] 200 20 > apres3@sel 99 118 123 136 141 150 155 172 180 182 185 23 33 46 64 87 92 93 23 33 46 64 87 92 93 99 118 123 136 141 150 155 172 180 182 185 188 200 188 200 > apres3@netsimLev

 $[1] \ -1.292973 \ -1.288784 \ -1.271729 \ -1.266257 \ -1.269638 \\$

The APResult object returned by apclusterL() also contains the slot sel with the selected samples of the best run and the slot netsimLev which contains the net similarities of the individual sweeps. These slots are not displayed by the show() method. The result returned by leveraged affinity propagation can be used for further processing in the same way as a result object returned from apcluster(), e.g., merging of clusters with agglomerative clustering can be performed.

For heatmap plotting either the parameter includeSim=TRUE must be set in apcluster() or apclusterL() to make the similarity matrix available in the result object or the similarity matrix must be passed as second parameter to heatmap() explicitly. The heatmap for leveraged AP looks slightly different compared to the heatmap for affinity propagation because the number of samples is different in both dimensions.

> heatmap(apres3)

Often selected samples will be chosen as exemplars because, only for them, the full similarity information is available. This means that the fraction of samples should be selected in a way such that a considerable number of samples is available for each expected cluster. Please also note that a data set of the size used in this example can easily be clustered with regular affinity propagation. The data set was kept small to keep the package build time short and the amount of data output in the manual reasonable.

For users requiring a higher degree of flexibility, e.g., for user-specific distance calculations or user-specific selection of the sample subset apclusterL() called with a rectangular similarity matrix provides the possibility to perform affinity propagation on a rectangular similarity matrix. See the source code of apclusterL() with signature s=function and x=any for an example how to embed apclusterL() into a complete loop performing leveraged AP. The package-provided functions for distance calculation support the generation of rectangular similarity matrices (see Chapter 8).

7 A Toy Example with Biological Sequences

As noted in the introduction above, one of the goals of this package is to leverage affinity propagation in bioinformatics applications. In order to demonstrate the usage of the package in a biological application, we consider a small toy example here.

The package comes with a toy data set ch22Promoters that consists of sub-sequences of promoter regions of 150 random genes from the human chromosome no. 22 (according to the human genome assembly hg18). Each sequence consists of the 1000 bases upstream of the transcription start site of each gene. Suppose we want to cluster these sequences in order to find out whether groups of promoters can be identified on the basis of the sequence only and, if so, to identify exemplars that are most typical for these groups.

```
> data(ch22Promoters)
> names(ch22Promoters)[1:5]
[1] "NM_001169111" "NM_012324"
                               "NM_144704"
                                            "NM_002473"
[5] "NM_001184970"
> substr(ch22Promoters[1:5], 951, 1000)
                                    NM_001169111
"GCACGCGCTGAGAGCCTGTCAGCGGCTGCGCCCGTGTGCGCATGCGCAGC"
                                       NM_012324
NM_144704
"GTGCTGGGCCCGCGGGCTCCCCGGCCGCAGTGCAAACGCAGCGCCAGACA"
                                       NM_002473
"CAGGCTCCGCCCCGGAGCCGGCTCCCGGCTGGGAATGGTCCCGCGGCTCC"
                                    NM_001184970
"GGGGCGGGGCTCGGTGTCCGGTAGCCAATGGACAGAGCCCAGCGGGAGCG"
```

Obviously, these are classical nucleotide sequences, each of which is identified by the RefSeq identifier of the gene the promoter sequence stems from.

In order to compute a similarity matrix for this data set, we choose (without further justification, just for demonstration purposes) the simple *spectrum kernel* [8] with a sub-sequence length of k = 6. We use the implementation from the kernlab package [7] to compute the similarity matrix in a convenient way:

```
> library(kernlab)
> promSim <- kernelMatrix(stringdot(length=6, type="spectrum"), ch22Promoters)
> rownames(promSim) <- names(ch22Promoters)
> colnames(promSim) <- names(ch22Promoters)</pre>
```

Now we run affinity propagation on this similarity matrix:

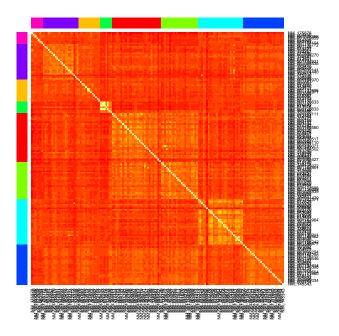

```
> promAP <- apcluster(promSim, q=0)</pre>
> promAP
APResult object

```

So we obtain 8 clusters in total. The corresponding heatmap looks as follows (note that we have to supply the similarity matrix, as it is not included by default if apcluster() is called with the similarity matrix; the reason is that, for large data sets, it is more memory-efficient not to make multiple copies of the similarity matrix; see also 9.1):

> heatmap(promAP, promSim)

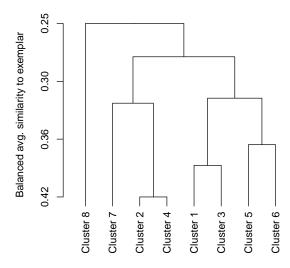

Let us now run agglomerative clustering to further join clusters.

> promAgg <- aggExCluster(promSim, promAP)</pre>

The resulting dendrogram is given as follows:

> plot(promAgg)

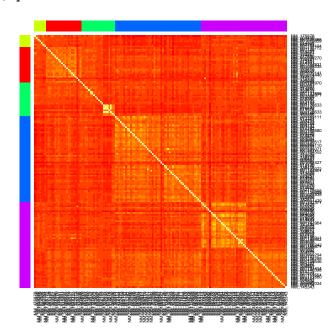

The dendrogram does not give a very clear indication about the best number of clusters. Let us adopt the viewpoint for a moment that 5 clusters are reasonable.

```
> prom5 <- cutree(promAgg, k=5)</pre>
> prom5

The final heatmap looks as follows:

> heatmap(prom5, promSim)

8 Similarity Matrices

Apart from the obvious monotonicity "the higher the value, the more similar two samples", affinity propagation does not make any specific assumption about the similarity measure. Negative squared distances must be used if one wants to minimize squared errors [5]. Apart from that, the choice and implementation of the similarity measure is left to the user.

Our package offers a few more methods to obtain similarity matrices. The choice of the right one (and, consequently, the objective function the algorithm optimizes) still has to be made by the user.

All functions described in this section assume the input data matrix to be organized such that each row corresponds to one sample and each column corresponds to one feature (in line with the standard function dist). If a vector is supplied instead of a matrix, each single entry is interpreted as a (one-dimensional) sample.

8.1 The function negDistMat()

The function negDistMat(), in line with Frey and Dueck, allows for computing negative distances for a given set of real-valued data samples. If called with the first argument x, a similarity matrix with pairwise negative distances is returned:

> s <- negDistMat(x2)</pre>

The function negDistMat() is a simple wrapper around the standard function dist(), hence, it allows for a lot more different similarity measures. The user can make use of all variants implemented in dist() by using the options method (selects a distance measure) and p (specifies the exponent for the Minkowski distance, otherwise it is void) that are passed on to dist(). Presently, dist() provides the following variants of computing the distance $d(\mathbf{x}, \mathbf{y})$ of two data samples $\mathbf{x} = (x_1, \ldots, x_n)$ and $\mathbf{y} = (y_1, \ldots, y_n)$:

Euclidean:

$$d(\mathbf{x}, \mathbf{y}) = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2}$$

use method="euclidean" or do not specify argument method (since this is the default);

Maximum:

$$d(\mathbf{x}, \mathbf{y}) = \max_{i=1}^{n} |x_i - y_i|$$

use method="maximum";

Sum of absolute distances / Manhattan:

$$d(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} |x_i - y_i|$$

use method="manhattan";

Canberra:

$$d(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} \frac{|x_i - y_i|}{|x_i + y_i|}$$

summands with zero denominators are not taken into account; use method="canberra";

Minkowski:

$$d(\mathbf{x}, \mathbf{y}) = \left(\sum_{i=1}^{n} (x_i - y_i)^p\right)^{\frac{1}{p}}$$

use method="minkowski" and specify p using the additional argument p (default is p=2, resulting in the standard Euclidean distance);

We do not consider method="binary" here, since it is irrelevant for real-valued data.

The function negDistMat() takes the distances computed with one of the variants listed above and returns -1 times the *r*-th power of it, i.e.,

$$s(\mathbf{x}, \mathbf{y}) = -d(\mathbf{x}, \mathbf{y})^r.$$
 (1)

The exponent r can be adjusted with the argument r. The default is r=1, hence, one has to supply r=2 to obtain negative squared distances as in the examples in previous sections.

Here are some examples. We use the corners of the two-dimensional unit square and its middle point $(\frac{1}{2}, \frac{1}{2})$ as sample data:

```
> ex <- matrix(c(0, 0.5, 0.8, 1, 0, 0.2, 0.5, 0.7,
+ 0.1, 0, 1, 0.3, 1, 0.8, 0.2), 5, 3,byrow=TRUE)
> ex
```

Minkowski distance for p = 3 (3-norm):

> negDistMat(ex, method="minkowski", p=3)

If called without the data argument x, a function object is returned that can be supplied to clustering functions — as in the majority of the above examples:

```
> sim <- negDistMat(r=2)</pre>
> is.function(sim)
[1] TRUE
> apcluster(sim, x1)

8.2 Other similarity measures

The package apcluster offers four more functions for creating similarity matrices for real-valued data:

Exponential transformation of distances: the function expSimMat() is another wrapper around the standard function dist(). The difference is that, instead of the transformation (1), it uses the following transformation:

$$s(\mathbf{x}, \mathbf{y}) = \exp\left(-\left(\frac{d(\mathbf{x}, \mathbf{y})}{w}\right)^r\right)$$

Here the default is r=2. It is clear that r=2 in conjunction with method="euclidean" results in the well-known *Gaussian kernel / RBF kernel* [4, 9, 11], whereas r=1 in conjunction with method="euclidean" results in the similarity measure that is sometimes called *Laplace kernel* [4, 9]. Both variants (for non-Euclidean distances as well) can also be interpreted as *fuzzy equality/similarity relations* [2].

Linear scaling of distances with truncation: the function linSimMat() uses the transformation

$$s(\mathbf{x}, \mathbf{y}) = \max\left(1 - \frac{d(\mathbf{x}, \mathbf{y})}{w}, 0\right)$$

which is also often interpreted as a fuzzy equality/similarity relation [2].

- **Correlation:** the function corSimMat() interprets the rows of its argument x (matrix or data frame) as multivariate observations and computes similarities as pairwise correlations. The function corSimMat() is actually a wrapper around the standard function cor(). Consequently, the method argument allows for selecting the type of correlation to compute (Pearson, Spearman, or Kendall).
- **Linear kernel:** scalar products can also be interpreted as similarity measures, a view that is often adopted by kernel methods in machine learning. In order to provide the user with this option as well, the function linKernel() is available. For two data samples $\mathbf{x} = (x_1, \ldots, x_n)$ and $\mathbf{y} = (y_1, \ldots, y_n)$, it computes the similarity as

$$s(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} x_i \cdot y_i$$

The function has one additional argument, normalize (by default FALSE). If normalize=TRUE, values are normalized to the range [-1, +1] in the following way:

$$s(\mathbf{x}, \mathbf{y}) = \frac{\sum_{i=1}^{n} x_i \cdot y_i}{\sqrt{\left(\sum_{i=1}^{n} x_i^2\right) \cdot \left(\sum_{i=1}^{n} y_i^2\right)}}$$

Entries for which at least one of the two factors in the denominator is zero are set to zero (however, the user should be aware that this should be avoided anyway).

For the same example data as above, we obtain the following for the RBF kernel:

> expSimMat(ex)

1234511.0000000.19988760.45840600.60653070.234570320.19988761.0000000.47236660.13398870.527292430.45840600.47236661.00000000.68386140.763379540.60653070.13398870.68386141.00000000.349937750.23457030.52729240.76337950.34993771.000000

Linear kernel:

> linKernel(ex[2:5,])

Normalized linear kernel:

All of these functions work in the same way as negDistMat(): if called with argument x, a similarity matrix is returned, otherwise a function is returned.

8.3 Rectangular similarity matrices

With the introduction of leveraged affinity propagation, distance calculations are entirely performed within the apcluster package. The code is based on a customized version of the dist() function from the stats package. In the following example, a rectangular similarity matrix of all samples against a subset of the samples is computed:

```
> sel <- sort(sample(1:nrow(x1), ceiling(0.08 * nrow(x1))))</pre>
> sel
[1] 13 29 33 34 44
> s1r <- negDistMat(x1, sel, r=2)</pre>
> dim(s1r)
[1] 60 5
> s1r[1:7,]
            13
                          29
                                     33
                                                 34
                                                            44
1 -0.014603013 -0.022549737 -0.1737253 -0.2223371 -0.1933647
2 -0.001699832 -0.006817446 -0.2206123 -0.2733747 -0.2455206
3 -0.015345081 -0.022217640 -0.1672119 -0.2149003 -0.1866619
4 -0.014703942 -0.020312110 -0.1641115 -0.2112203 -0.1837830
5 -0.008328025 -0.021148694 -0.2247310 -0.2795651 -0.2470108
6 -0.004504812 -0.018396781 -0.3125267 -0.3753219 -0.3411642
7 -0.003460584 -0.016865771 -0.2822221 -0.3424318 -0.3088750
```

The rows correspond to all samples, the columns to the sample subset. The sel parameter specifies the sample indices of the selected samples in increasing order. Rectangular similarity calculation is provided in all distance functions of the package. If the parameter sel is not specified, the quadratic similarity matrix of all sample pairs is computed.

8.4 Defining a custom similarity measure for leveraged affinity propagation

As mentioned in Section~6 above, leveraged affinity propagation requires the definition of a similarity measure that is supplied as a function or function name to apclusterL(). For vectorial data, the similarity measures supplied with the package (see above) may be sufficient. If other similarity measures are necessary or if the data are not vectorial, the user must supply his/her own similarity measure. The user can supply any function as argument s to apclusterL(), but the following rules must be obeyed in order to avoid errors and to ensure meaningful results:

- 1. The data must be supplied as first argument, which must be named x.
- 2. The second argument must be named sel and must be interpreted as a vector of indices that select a subset of data items in x.
- 3. The function must return a numeric matrix with similarities. If sel=NA, the format of the matrix must be length(x)×length(x). If sel is not NA, but contains indices selecting a subset, the format of the returned similarity matrix must be length(x)×length(sel).
- 4. Although this is not a must, it is recommended to properly set row and column names in the returned similarity matrix.

As an example, let us revisit the sequence clustering example presented in Section~7. Let us first define the function that implements the similarity measure:

```
> spectrumK6 <- function(x, sel=NA)</pre>
+ {
+
       if (any(is.na(sel)))
       {
+
           s <- kernelMatrix(stringdot(length=6, type="spectrum"), x)</pre>
+
           rownames(s) <- names(x)</pre>
+
           colnames(s) <- names(x)</pre>
+
       }
+
       else
+
+
       {
+
           s <- kernelMatrix(stringdot(length=6, type="spectrum"), x, x[sel])</pre>
           rownames(s) <- names(x)</pre>
+
           colnames(s) <- names(x)[sel]</pre>
+
       }
+
+
+
       s
+ }
```

Now we run leveraged affinity propagation on the ch22Promoters data set using this similarity measure

```
> promAPL <- apclusterL(s=spectrumK6, ch22Promoters, frac=0.1, sweeps=10,</p>
                         p=promAP@p)
> promAPL

   NM_032608
```

So we obtain 10 clusters in total.

9 Miscellaneous

9.1 Convenience vs. efficiency

In most of the above examples, we called a clustering method by supplying it with a similarity function and the data to be clustered. This is undoubtedly a convenient approach. Since the resulting output objects (unless the option includeSim=FALSE is supplied) even includes the similarity matrix, we can plot heatmaps and produce a cluster hierarchy on the basis of the clustering result without the need to supply the similarity matrix explicitly.

For large data sets, however, this convenient approach has some disadvantages:

- If the clustering algorithm is run several times on the same data set (e.g., for different parameters), the similarity matrix is recomputed every time.
- Every clustering result (depending on the option includeSim) usually includes a copy of the similarity matrix.

For these reasons, depending on the actual application scenario, users should consider computing the similarity matrix beforehand. This strategy, however, requires some extra effort for subsequent processing, i.e. the similarity must be supplied as an extra argument in subsequent processing.

9.2 Clustering named objects

The function apcluster() and all functions for computing distance matrices are implemented to recognize names of data objects and to correctly pass them through computations. The mechanism is best described with a simple example:

```
> x3 <- c(1, 2, 3, 7, 8, 9)
> names(x3) <- c("a", "b", "c", "d", "e", "f")
> s3 <- negDistMat(x3, r=2)</pre>
```

So we see that the names attribute must be used if a vector of named one-dimensional samples is to be clustered. If the data are not one-dimensional (a matrix instead), object names must be stored in the row names of the data matrix.

All functions for computing similarity matrices recognize the object names. The resulting similarity matrix has the list of names both as row and column names.

> s3

```
а
        b
            с
                d
                        f
                    е
    0
      -1
          -4 -36 -49 -64
а
        0
           -1 -25 -36 -49
Ъ
   -1
  -4 -1
            0 -16 -25 -36
с
d -36 -25 -16
               0
                   -1
                       -4
e -49 -36 -25
              -1
                    0 -1
f -64 -49 -36
              -4
                        0
                  -1
> colnames(s3)
[1] "a" "b" "c" "d" "e" "f"
```

The function apcluster() and all related functions use column names of similarity matrices as object names. If object names are available, clustering results are by default shown by names.

```
> apres3a <-apcluster(s3)</pre>
> apres3a
APResult object
Number of samples
                      =
                         6

2 5
> apres3a@clusters
[[1]]
a b c
1 2 3
[[2]]
d e f
4 5 6

9.3 Computing a label vector from a clustering result

For later classification or comparisons with other clustering methods, it may be useful to compute a label vector from a clustering result. Our package provides an instance of the generic function labels() for this task. As obvious from the following example, the argument type can be used to determine how to compute the label vector.

```
> apres3a@exemplars
b e
2 5
> labels(apres3a, type="names")
[1] "b" "b" "b" "e" "e" "e"
> labels(apres3a, type="exemplars")
[1] 2 2 2 5 5 5
> labels(apres3a, type="enum")
[1] 1 1 1 2 2 2
```

The first choice, "names" (default), uses names of exemplars as labels (if names are available, otherwise an error message is displayed). The second choice, "exemplars", uses indices of exemplars (enumerated as in the original data set). The third choice, "enum", uses indices of clusters (consecutively numbered as stored in the slot clusters; analogous to the standard implementation of cutree() or the clusters field of the list returned by the standard function kmeans()).

9.4 Implementation and performance issues

Prior to version 1.2.0, apcluster() was implemented in R. Starting with version 1.2.0, the main iteration loop of apcluster() has been implemented in C++ using the Rcpp package [3], which has led to a speedup in the range of a factor or 9–10.

Note that details=TRUE requires quite an amount of additional memory. If possible, avoid this for larger data sets.

The asymptotic computational complexity of aggExCluster() is $O(l^3)$ (where l is the number of samples or clusters from which the clustering starts). This may result in excessively long computation times if aggExCluster() is used for larger data sets without using affinity propagation first. For real-world data sets, in particular, if they are large, we recommend to use affinity propagation first and then, if necessary, to use aggExCluster() to create a cluster hierarchy.

10 Future Extensions

We currently have no implementation that exploits sparsity of similarity matrices. The implementation of *sparse AP* which is available as Matlab code from the AP Web page¹ is left for future extensions of the package. Presently, we only offer a function sparseToFull() that converts similarity matrices from sparse format into a full $l \times l$ matrix.

11 Special Notes for Users Upgrading from Previous Versions

Version 1.3.0 has brought several fundamental changes to the architecture of the package. We tried to ensure backward compatibility with previous versions where possible. However, there are still some caveats the users should take into account:

- The functions apcluster(), apclusterK(), and aggExCluster() have been re-implemented as S4 generics, therefore, they do not have a fixed list of arguments anymore. For this reason, users are recommended to name all optional parameters.
- Heatmap plotting has been shifted to the function heatmap() which has now been defined as an S4 generic method. Previous methods for plotting heatmaps using plot() are partly still available, but deprecated.

12 Change Log

Version 1.3.0:

- added Leveraged Affinity Propagation Clustering
- re-implementation of main functions as S4 generic methods in order to facilitate the convenient internal computation of similarity matrices
- for convenience, similarity matrices can be stored as part of clustering results

- heatmap plotting now done by heatmap() which has been defined as S4 generic
- extended interface to functions for computing similarity matrices
- added function corSimMat()
- implementation of length() method for classes APResult, AggExResult, and ExClust
- added accessor function to extract clustering levels from AggExResult objects
- correction of exemplars returned by apcluster for details=TRUE in slot idxAll of returned APResult object
- when using data stored in a data frame, categorical columns are now explicitly omitted, thereby, avoiding warnings
- all clustering methods now store their calls into the result objects
- updates and extensions of help pages and vignette

Version 1.2.0:

- reimplementation of apcluster() in C++ using the Rcpp package [3] which reduces computation times by a factor of 9-10
- obsolete function apclusterLM() removed
- updates of help pages and vignette

Version 1.1.1:

- updated citation
- minor corrections in help pages and vignette

Version 1.1.0:

- added exemplar-based agglomerative clustering function aggExCluster()
- added various plotting functions for dendrograms and heatmaps
- extended help pages and vignette according to new functionality
- added sequence analysis example to vignette along with data set ch22Promoters
- re-organization of variable names in vignette
- added option verbose to apclusterK()
- numerous minor corrections in help pages and vignette

Version 1.0.3:

- Makefile in inst/doc eliminated to avoid installation problems
- renamed vignette to "apcluster"

Version 1.0.2:

- replacement of computation of responsibilities and availabilities in function apcluster() by pure matrix operations (see 9.4 above); traditional implementation à la Frey and Dueck still available as function apclusterLM;
- improved support for named objects (see 9.2)

- new function for computing label vectors (see 9.3)
- re-organization of package source files and help pages

Version 1.0.1: first official release, released March 2, 2010

13 How to Cite This Package

If you use this package for research that is published later, you are kindly asked to cite it as follows:

U. Bodenhofer, A. Kothmeier, and S. Hochreiter (2011). APCluster: an R package for affinity propagation clustering. *Bioinformatics* **27**(17):2463–2464. DOI: 10.1093/bioinformatics/btr406.

Moreover, we insist that, any time you cite the package, you also cite the original paper in which affinity propagation has been introduced [5].

To obtain BibT_EX entries of the two references, you can enter the following into your R session:

```
> toBibtex(citation("apcluster"))
```
