**(A) Abstract**

Enhanced management of areas important for marine biodiversity are now obligations under a range of international treaties. Tracking data provide unparalleled information on the distribution of marine taxa, but there are no agreed guidelines that ensure these data are used consistently to identify biodiversity hotspots and inform marine management decisions. Here we develop methods to standardise the analysis of tracking data to identify sites of conservation importance at global and regional scales.

We applied these methods to the largest available compilation of seabird tracking data, covering 60 species, collected from 55 deployment locations ranging from the poles to the tropics.

Key developments include a test for pseudo-replication to assess the independence of two groups of tracking data, an objective approach to define species-specific smoothing parameters ( $h$  values) for kernel density estimation based on area-restricted search behaviour, and an analysis to determine whether sites identified from tracked individuals are also representative for the wider population.

This analysis delineated priority sites for marine conservation for 52 of the 60 species assessed. We compiled 252 data groupings and defined 1052 polygons, between them meeting Important Bird and

1  
2  
3 Biodiversity Area criteria over 1500 times. Other results showed 13% of data groups were  
4 inadequate for site definition and 10% showed some level of pseudo-replication. Between 25 and 50  
5 trips were needed within a data group for data to be considered at least partially representative of  
6 the respective population.  
7

8  
9 Our approach provides a consistent framework for using animal tracking data to delineate areas of  
10 global conservation importance, allowing greater integration into marine spatial planning and policy.  
11 The approaches we describe are exemplified for pelagic seabirds, but are applicable to a range of  
12 taxonomic groups. Covering 4.3% of the oceans, the sites identified would benefit from enhanced  
13 protection to better safeguard the threatened species populations they contain.  
14

### 15 16 **(A) Introduction**

17  
18 Many migratory marine species travel across jurisdictional boundaries and into the High Seas, such  
19 that conventional at-sea survey techniques are impractical at these large spatial scales.  
20 Developments in animal tracking techniques have revolutionized our understanding of the at-sea  
21 distributions, movements, ecology and activity patterns of marine species, with the availability of  
22 small, affordable devices that greatly increase the number of species studied in recent decades  
23 (Gillespie 2001; Tomkiewicz *et al.* 2010). To date, devices have been attached to seabirds (Burger  
24 and Shaffer 2008), seals (McConnell *et al.* 1992), fish (Block *et al.* 1998), turtles (Fossette *et al.* 2007),  
25 whales (Bailey *et al.* 2009) and even jellyfish (Honda *et al.* 2009).  
26  
27

28  
29 The utility of tracking as a tool to inform marine conservation planning is well documented,  
30 facilitating detailed investigations of the spatial overlap of species and their threats, such as fisheries  
31 and marine developments (BirdLife International 2004; Tuck *et al.* 2011). Enhanced spatial  
32 conservation measures to protect species and habitats in marine systems are now obligatory under a  
33 number of international treaties and policy instruments. Consequently there is widespread interest  
34 in using tracking data to identify biodiversity hotspots, particularly to define candidate sites for  
35 formal protection and other forms of management (Block *et al.* 2011; Lascelles *et al.* 2012).  
36 However, there is little consistency in how tracking data are analysed to identify areas of biological  
37 significance and thus how they can be used to inform marine management decisions.  
38  
39

40  
41 Here we demonstrate how the analysis of tracking data from a group of wide-ranging top predators  
42 can be used in combination with objective site selection criteria to delineate areas of global  
43 significance for biodiversity. We use seabirds to demonstrate our approaches because they must  
44 return to land to breed, and are therefore much easier to study than other wide-ranging marine  
45 taxa. Moreover, seabirds are top predators that utilise resources across broad oceanic regions  
46 making them good indicator species, and information on their distributions can therefore provide  
47 surrogates for biodiversity hotspots in marine spatial planning (Zacharias and Roff 2001; Aslan *et al.*  
48 2015). Processing and analysis of tracking data is complex, and previous efforts have typically  
49 developed species- and study-specific methods (Burger and Shaffer 2008). The methods presented  
50 here therefore fulfil the urgent need for a consistent, comparable and repeatable approach to site  
51 identification.

60

1  
2  
3 The Important Bird and Biodiversity Area (IBA) Programme, established by BirdLife International,  
4 uses objective and transparent criteria to define sites of key conservation importance at global and  
5 regional scales (Fishpool and Evans 2001). Terrestrial sites have been identified using these criteria in  
6 over 120 countries, helping guide land-based conservation for over 30 years. More recently the  
7 same broad principles have been applied in the marine environment (BirdLife international 2009a),  
8 and seabird tracking data have been used in a number of national (e.g. Ramirez *et al.* 2008; Arcos  
9 *et al.* 2009; Delord *et al.* 2014) and international (e.g. in Areas Beyond National Jurisdiction, BirdLife  
10 International 2009a) projects to define IBAs and inform spatial management, such as the designation  
11 of Marine Protected Areas. The IBA criteria and thresholds align closely with those used in several  
12 marine policy agreements, such as the European Union's Birds Directive (BirdLife International  
13 2010), the Ramsar Convention (Lynch-Stewart 2008) and the Convention on Biological Diversity  
14 (BirdLife International 2009a).

15  
16  
17  
18  
19 To qualify as an IBA, a site must hold a '*regular presence*' of a '*threshold number of birds (e.g.  $\geq 1\%$  of*  
20 *global or biogeographic population)*'. For globally threatened species with very small populations  
21 (i.e. Critically Endangered or Endangered according to IUCN) regular presence alone may be enough  
22 to warrant designation; however, for other species, abundance thresholds must also be met. IBA  
23 criteria are readily applicable to most threatened and congregatory species during different life-  
24 history stages and can be used to identify areas such as breeding colonies, feeding areas around  
25 colonies, non-breeding congregations, migratory bottlenecks and pelagic feeding aggregations  
26 (Osieck *et al.* 2004). While it is relatively easy to assess seabird breeding colonies against IBA criteria,  
27 it is more difficult to locate areas of aggregation at sea and determine if they warrant designation.  
28 Vessel-based observations cannot adequately describe the at-sea distributions of most seabirds;  
29 tracking data have therefore proved vital in filling this data gap, allowing us to understand where  
30 important areas occur and when these are being used by different species and life-history stages.

31  
32  
33  
34 Here we present a method to derive proposed IBAs (areas representative at the population level)  
35 from raw locations of individuals tracked using a variety of tracking devices. Our approach  
36 objectively defines the spatial scale at which seabirds interact with their marine environment, and  
37 then proceeds to critically assess whether the number of tracked individuals is sufficient for  
38 population-level inference. We use changes in track characteristics (speed or sinuosity) and density  
39 of fixes (locations) to qualify areas as candidate IBAs, and estimate the overall number of individuals  
40 that use those areas based on colony sizes and how representative the tracked birds are of their  
41 respective populations.

42  
43  
44  
45 The approaches we describe are exemplified for pelagic seabirds, but can be used with tracking data  
46 from a range of taxonomic groups. Seabird tracking data are available via several online data portals,  
47 including the *Tracking Ocean Wanderers* database (BirdLife International 2004;  
48 [www.seabirdtracking.org](http://www.seabirdtracking.org)), which is the repository of the data from the 60 species included in our  
49 analysis. This large global dataset covers multiple species and life-history stages and thus provided a  
50 unique opportunity to develop and test consistent methodologies with direct applications to policy.

## 51 52 53 54 55 **(A) Methods**

### 56 57 *(B) Data preparation*

1  
2  
3 This analysis included data from the three most commonly used tracking devices for vertebrates:  
4 Platform Terminal Transmitters (PTT), Global Positioning Systems (GPS) and Geolocators (GLS  
5 loggers). Our methods were applied to raw data consisting of the location (latitude and longitude)  
6 provided by the tracking device at each date and time, and a unique identifier for the individual bird.  
7 We standardised datasets to allow ready combination and comparison where needed (Supplement  
8 1).  
9

10  
11 Most seabirds exhibit changing space-use patterns during different life-history stages and sometimes  
12 between years (e.g. BirdLife International 2004; Riotte-Lambert and Weimerskirch 2013).  
13 Additionally, examples of spatial segregation in foraging areas of separate populations of the same  
14 species are becoming more widespread (Gremillet *et al.* 2004; Wakefield *et al.* 2013). To account for  
15 this variation, we split data into homogenous 'data groups', pooling data from all years and  
16 classifying them into unique combinations of species, colony and life-history stage (Table 1). This  
17 procedure ensures that any spatial aggregation patterns exhibited by a species during a given life-  
18 history stage are captured and not diluted by inclusion of data from other life-history stages with  
19 potentially very different distributions. All analyses described hereafter are undertaken at the level  
20 of the individual data group with data projected into Lambert Equal-Area Azimuthal customised to  
21 each data group (Supplement 1).  
22  
23  
24

25  
26 TABLE 1

27  
28 When breeding, seabirds are central-place foragers that return to their colonies for parental duties,  
29 and tracking data from breeding adults often include multiple foraging trips from the same  
30 individuals. To maximise the use of available data we considered each trip by an individual as an  
31 independent sample, as using only the first foraging trip made by an individual for subsequent  
32 analysis is likely to under-estimate the size of the home range at the population level (Soanes *et al.*  
33 2013). Foraging trips were defined as any occasion where a tracked individual travelled a minimum  
34 specified time and distance from the colony, which varied between species and life-history stages  
35 (BirdLife International 2004).  
36  
37

38  
39 *(B) Test for Site Fidelity*

40  
41 Datasets including multiple trips from a single bird may show pseudo-replication (i.e. if individuals  
42 show site fidelity) and bias results (Giuggioli and Bartumeus 2010; Auge *et al.* 2013). We designed a  
43 test for pseudo-replication that compared the similarity of foraging locations of a single tracked bird  
44 with those of the rest of the data group. This test selected all trips for an individual that had  
45 completed more than one, identified the 50% kernel utilisation distribution (UD, see below) for each  
46 trip, and calculated the Hausdorff distance between these areas, to quantify proximity (Munkres  
47 1999). For each individual, distances between core foraging ranges were calculated between every  
48 combination of its trips, and then compared to a data group reference distribution. To calculate the  
49 reference distribution we randomly selected the same number of trips from each tracked individual,  
50 and calculated the Hausdorff distance for core foraging ranges between individuals. The within  
51 individual distances were then compared against the population-level distances using a Mann-  
52 Whitney U-test. This examined whether the null hypothesis— that the proximity of core areas from  
53 a single individual is similar to the proximity of core areas between different individuals of the same  
54 population and life-history stage—could be rejected, in which case there was some indication of  
55  
56  
57  
58  
59  
60

1  
2  
3 site-fidelity and thus pseudo-replication. This process was repeated 100 times to account for  
4 possible bias in the random sample, and the mean p-value calculated.  
5

6 We used an extremely conservative  $\alpha = 0.25$  to ensure that no data indicating pseudo-replication  
7 were used in subsequent analyses. If pseudo-replication was detected a single trip was randomly  
8 selected from each individual for use in further analyses; otherwise, all data were retained.  
9

#### 10 (B) Defining core-use areas and scales of interaction with the marine environment

11 We used kernel density estimation (KDE), a measure of the probability of occurrence, to define  
12 important areas for six reasons; i) KDE is ideally suited for assessing regularity of use and  
13 determining whether the number of individuals using a site exceeds selection thresholds; ii) core  
14 areas identified by KDE are less influenced by outliers (Hemson *et al.* 2005); iii) comparative studies  
15 have found that KDE omitted fewest key areas of interest (BirdLife International 2009b, Tancell *et al.*  
16 2013); iv) KDE is used widely in the seabird tracking literature, thus facilitating comparison and  
17 integration of results obtained in this and other studies, v) KDE is one of the more straightforward  
18 techniques for analysis of distributions; vi) the outputs of KDE are generally well understood by non-  
19 scientists within policy arenas.  
20

21 We estimated kernel utilisation distributions (UD) for every individual trip and, following previous  
22 studies, defined the 50% isopleth as the 'core-use area' for each trip (Fig. 5) (Arcos *et al.* 2009;  
23 Ramirez *et al.* 2008; Soanes *et al.* 2013). To assess regularity of use we overlapped the 50% UD of  
24 each trip onto a  $0.01 \times 0.01^\circ$  grid projected into a customized Lambert Equal-Area Azimuthal  
25 projection, and assumed that a grid cell was in the core area of an individual trip if it intersected the  
26 50% UD. To identify core-use areas where multiple trips co-occurred, we summarised how often  
27 each  $0.01 \times 0.01^\circ$  cell was included in a core-use area of individual trips (Fig. 6).  
28

29 To estimate density, KDE assumes an area of influence around each point (the smoothing factor  $h$ ).  
30 The results of KDE are extremely sensitive to this value, which must be defined *a priori*. However,  
31 despite considerable debate (Worton 1989; Wand and Jones 1995), there is no consensus and values  
32 are frequently set arbitrarily. To assign smoothing factors to GPS and PTT data in a justifiable and  
33 consistent way, we employ a novel approach based on area-restricted search behaviour (ARS – e.g.  
34 Weimerskirch *et al.* 2007), assessed via First Passage Time (FPT) analysis, to determine the spatial  
35 scales individuals interact with different aspects of the environment (Suryan *et al.* 2006). We used  
36 the average ARS exhibited across all trips within a data group to define the  $h$  value - see Supplement  
37 1. For GLS data, we used  $h=186$ , which corresponds to the average error of the locations in  
38 kilometres (Phillips *et al.* 2004).  
39

#### 40 (B) Assessing representativeness

41 Generally only a fraction of a population is tracked; therefore the representativeness of such data  
42 needs to be evaluated if inferences are to be drawn at the population level (Lindberg and Walker  
43 2007). Small sample sizes may be insufficient to capture the variability among individuals in space  
44 use (Lindberg and Walker 2007) and debate continues over the appropriate sample size required to  
45 account for variability in behaviour and distribution of the wider population (Seaman *et al.* 1999;  
46 Soanes *et al.* 2013; Delord *et al.* 2014). Therefore, the analysis of unrepresentative samples risks  
47 placing false emphasis on areas, particularly for species that show high variability in distribution  
48  
49  
50  
51  
52  
53

1  
2  
3 within and between individuals or have broad habitat preferences (Delord *et al.* 2014). In order to  
4 assess whether data were representative and allow inferences to be drawn about the spatial use  
5 patterns of a population, we examined how core area distribution (based on inclusion rather than  
6 spatial coverage) changes with increasing sample size—an approach similar to those applied to  
7 species discovery curves (Bebber *et al.* 2007) and chick growth rates (Scheckerman *et al.* 2003). We  
8 randomly selected individual trips iteratively, and compared the randomly selected (the ‘sampled’)  
9 with the unselected (the ‘unsampled’) data. For each sample size, a 50% UD was calculated from the  
10 sampled data, using an average ARS scale to define the smoothing factor (Fig. 3). We then assessed  
11 what proportion of the unsampled data was located within this 50% UD. This ‘inclusion value’ is a  
12 metric indicating how well the sampled data explain the space use of individuals in the unsampled  
13 data (details in Supplement 1). These assessments allowed us to determine a) whether a tracked  
14 sample was representative of the wider population, and b) what correction factors should be used to  
15 assess the number of individuals using an area.  
16  
17  
18

#### 19 (B) Defining sites at the population level

20  
21 IBAs require not only evidence that areas are used regularly, but also that a certain proportion of a  
22 population is found there. It is therefore necessary to determine the number of individuals using a  
23 site. Such information cannot be estimated directly from tracking data unless the tracked sample is  
24 representative of the wider population. For those data groups that were considered to be  
25 representative (Table S3), we determined the number of individuals using each grid cell by  
26 multiplying the size of the overall population by the proportion of the tracked population which had  
27 a core-use area in this grid cell (Fig. 7). We use this assessment to assign correction factors to infer  
28 abundance estimates from the tracking data. These correction factors were set conservatively to  
29 reduce the probability of errors of commission.  
30  
31  
32  
33  
34  
35

#### 36 (A) Results

37  
38 Our global analysis assessed tracking data from 125 deployments at 55 locations, covering 60  
39 species, collected over a 20 year period (1992-2012). Data were homogenised into 252 ‘data groups’  
40 (i.e. pooling data from all years and classifying them into unique combinations of species, colony and  
41 life-history stage) which between them included over 8000 individual tracks made up of over 2  
42 million data points. The species assessed included albatrosses (21 species; 140 data groups),  
43 shearwaters (11; 34), *Pterodroma* petrels (12; 27), giant-petrels (2; 18), *Procellaria* petrels (5; 17),  
44 sulids (5; 7), tropicbirds (2; 6), and frigatebirds (2:3).  
45  
46  
47

48 In total 1052 polygons were defined for 52 of the 60 species included in the analysis, with between 1  
49 and 36 polygons (mean 4.4) resulting for each data group (Fig. 1). These polygons were assessed  
50 against three IBA criteria, with A1 (regular presence of a threatened species) triggered 715 times,  
51 A4ii (areas holding  $\geq 1\%$  of global population) triggered 687 times and A4iii (areas holding  $\geq 10,000$   
52 pairs seabirds) triggered 128 times (Supplement 2). Note that polygons can trigger more than one  
53 criterion. The resulting polygons can be viewed in Fig 1 and, along with other IBAs for seabirds, at  
54 [www.birdlife/datazone/marine](http://www.birdlife/datazone/marine).  
55  
56  
57

58 Figure 1  
59  
60

1  
2  
3 Some data groups (48; 19%) were inadequate for IBA assessment due to them either a) not being  
4 representative enough of the wider population (i.e. <70% representative – 22 data groups; 10%), b)  
5 no polygons were defined during the analysis (15 data groups; 7%) due to wide habitat preferences  
6 or c) where polygons resulting did not meet IBA criteria (11 data groups; 5%) because small source  
7 populations were tracked or the polygons held below threshold numbers.  
8  
9

10 Over 50% of the species (n=31) assessed are listed by IUCN as globally threatened (i.e. Critically  
11 Endangered, Endangered or Vulnerable), with a further 10 species listed as Near Threatened and the  
12 remainder (n=19) Least Concern (Table 2). The analysis of the 122 data groups (48% of total) for  
13 globally threatened species resulted in the definition of over 660 polygons (63% of total) with IBA  
14 criteria triggered 1191 times (77% of total).  
15

16  
17 Table 2  
18

19 While the analysis was undertaken on each data group individually, when looking across the entire  
20 dataset (i.e. results for all species, sites and life-history stages combined) there was often overlap  
21 amongst the polygons defined (Fig 1 insets). Dissolving the overlapping polygons highlighted 7.6%  
22 (c.30 million km<sup>2</sup>) of the oceans as feeding areas for seabirds, with c. 18 million km<sup>2</sup> of this being  
23 found in Areas Beyond National Jurisdiction. When only looking at polygons that were shown to  
24 meet the IBA criteria and thresholds the area of the ocean highlighted reduced to 4.3% (c. 17 million  
25 km<sup>2</sup>).  
26  
27

28 Other outputs from the analysis showed that 10% of data groups included individuals that exhibited  
29 some level of site-fidelity. The number of trips within a data group ranged from 5 to 299 and ARS  
30 scales determined for PTT and GPS data groups ranged from 11-135km (Table S2). The assessment of  
31 representativeness indicated that between 25 and 50 trips were generally needed for a data group  
32 to be considered at least partially representative (i.e. ≥70%) of the wider population (Table S3).  
33  
34

35 To demonstrate our approach, we provide an example using PTT data for the Wandering Albatross  
36 (*Diomedea exulans*), obtained during the incubation period at Bird Island, South Georgia  
37 (Supplement 3). We defined a trip as any occasion where a tracked individual travelled for >25 km  
38 from the colony for >12 hours, providing a sample size of 27 trips (Fig. 4). We assessed interaction  
39 with the marine environment by exploring scales from 10 - 250 km at 5 km intervals, and our FPT  
40 analysis indicated ARS behaviour at a radius of 45.3 km (Fig. 3). We used this value as the kernel  
41 smoothing factor to estimate core-use areas for each trip (Fig. 5), and aggregated these to quantify  
42 the frequency of usage for 0.01 degree grid cells (Fig. 6). By sub-sampling 1 to 26 trips from the data  
43 set, we estimated that the tracked population represented 83.4% of the locations that would have  
44 been used by the entire population (Fig. 2), and the data were therefore suitable for population level  
45 inference. For each polygon that was used by >12.5% of the tracked population, we then assessed  
46 whether abundance thresholds for IBA criteria were met by multiplying the size of the colony (2406  
47 individuals) by the proportion of tracked birds using this polygon, and by the correction factor of  
48 0.75 (Table S3). For example, one polygon was used by at least 15% of tracked birds and was  
49 therefore considered to be used by  $2406 * 0.15 * 0.75 = 271$  birds. The four polygons identified (Fig. 7)  
50 were then assessed against IBA thresholds, with all four qualifying for the regular presence of a  
51 globally threatened species (Wandering Albatross is listed as Vulnerable by IUCN) and two polygons  
52 also qualifying by holding >1% of the global population (>241 individual Wandering Albatrosses).

### (A) Discussion

Our approach provides a consistent framework to delineate areas of global conservation importance based on animal tracking data and internationally accepted criteria. It offers an objective yet pragmatic tool that uses a set of well-established statistical approaches for the analysis of tracking data. Although the approach is both ecologically and statistically sound, it is also flexible enough to account for variation between species, geographic distributions and tracking technologies; and provides intuitive outputs that can inform management processes. Such a tool should help convince policy makers of the utility of tracking data for identifying key marine areas for conservation. The approach described here can be adapted for other marine or terrestrial central-place foragers with known population sizes.

Our approach is robust and applicable to a wide range of species and scenarios, and minimises the inclusion of arbitrary threshold values. All thresholds and correction factors presented here are extremely conservative, supported by decades of seabird research, and based on the ecological characteristics of the species involved. We tested all thresholds and correction factors across multiple datasets to ensure that our approach avoids erroneous designation of sites that do not meet international criteria. Critically, our approach assesses objectively whether data are appropriate for population-level inference, and identifies important areas only when a species exhibited behaviour appropriate for site-based conservation approaches.

Nonetheless there are plausible refinements to the analysis to account for additional variation. Most of the tracking data pertained to medium-sized to large procellariiform species, i.e., albatrosses and petrels (93% of data groups). Application of this methodology to smaller or less mobile marine species (e.g. penguins, terns, seals, otters) will require different definitions for the length of trips, and other species-specific amendments which are required as input parameters in the R code.

Further improvements may also be possible by additional rigorous tests of the various analytical components underlying our approach (Supplement 1). We encourage the scientific community to conduct sensitivity analyses of the various thresholds and approaches presented here to further validate and improve the analysis of tracking data to inform marine spatial planning.

For data groups that were inadequate for IBA assessment or where resulting polygons did not meet IBA criteria this was either due to the very small sample of tracked individuals, because the tracking was undertaken at a colony where the population size was already below the IBA threshold, or because at-sea distributions were too dispersed to show spatial aggregation.

1  
2  
3 The total area of the IBAs identified during this analysis amounts to 4.3% of the world's oceans and  
4 with over 50% of the species assessed threatened with extinction, the network of sites are of key  
5 important for marine conservation efforts. Together these sites show where species can be most  
6 effectively conserved as a group and where potential threats may have population level impacts.  
7 Best practice management of activities that negatively affect seabirds in these areas, such as  
8 through the designation of Marine Protected Areas, would make a vital contribution to the  
9 conservation of seabirds (and other marine life found in these areas) and help halt and reverse the  
10 declines many species have undergone in recent decades.

### 14 15 16 **(A) Acknowledgments**

17  
18 This work was possible due to funding from the AV Jensen Foundation and the Lenfest Ocean  
19 Program. Particular thanks to all contributors of data to *Tracking Ocean Wanderers: the global*  
20 *seabird tracking database* without which this analysis would not have been possible. To see the full  
21 list of contributors and datasets visit [www.seabirdtracking.org/mapper/about.php](http://www.seabirdtracking.org/mapper/about.php).  
22  
23

24 Thanks to Jose-Manuel Arcos, Mark Balman, John Croxall, Lincoln Fishpool, Autumn-Lynne Harrison,  
25 Vitor Paiva, David Pinaud, Ivan Ramirez, Norman Ratcliffe and Phil Trathan for their assistance in  
26 various phases of the analysis development. Thanks also to those who attended workshops at CNRS  
27 Chize, France in 2009, and Coimbra University, Portugal in 2011 which helped further advance the  
28 methodology.  
29

### 30 31 **(A) Data accessibility**

32  
33 A compilation of customized R scripts needed to undertake the analysis described here is available in  
34 Supplement 4, along with a sample dataset in Supplement 3. The script package, and assistance with  
35 its use, can also be requested by emailing [seabirds@birdlife.org](mailto:seabirds@birdlife.org). All tracking data assessed in this  
36 project is housed in the Tracking Ocean Wanderers database, and can be viewed and requested via  
37 [www.seabirdtracking.org](http://www.seabirdtracking.org).

## Tables

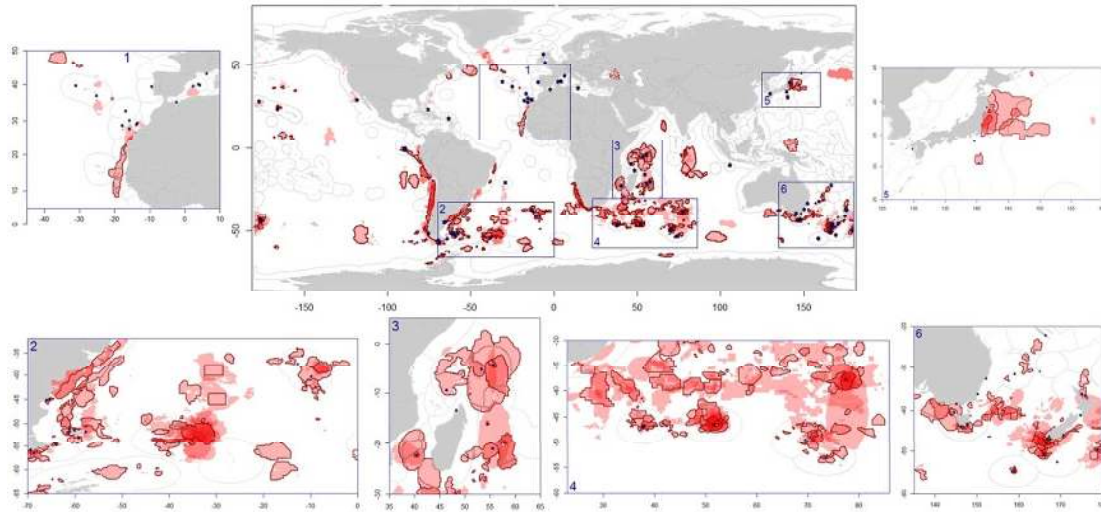

Life-history stages	Description	No. data groups
Breeding	Covering the entire breeding period. Used when it was not possible to define more detailed life-history stages.	39
Pre-egg	The period prior to breeding during which adults may visit the colony, copulate and spend time at-sea feeding in preparation for egg production and incubation.	7
Incubation	The period when adults are alternating incubation of eggs and undertaking maintenance trips to sea.	43
Brood-guard <sup>1</sup>	The period when adults are feeding small chicks. Adults alternate staying with the chick to brood or guard it against predators while the other forages at sea.	38
Post-guard	The period when adults are feeding large chicks. The chick is generally left alone during this time with both adults feeding at sea.	44
Fledging	Young birds leaving the colony for the first time.	3
Immature <sup>2</sup>	Young birds which are not yet old enough to breed. For many seabirds this period can last several years.	13
Non-breeding	Adult birds outside of the breeding season during which time they do not need to return to the colony.	61
Sabbatical	Adult birds with breeding experience that have skipped breeding that season.	4

**Table 1:** Description of seabird life-history stages included within this analysis and the number of data groups assessed within each. <sup>1</sup> Includes sulid data data groups classed as chick-rearing. <sup>2</sup> Includes all data groups classed as juveniles.

IUCN Status	No. Species	No. data groups	No. polygons resulting	No. polygons A1	No. polygons A4ii	No. polygons A4iii
CR	5	16	132	127	126	4
EN	9	36	212	195	136	17
VU	17	70	317	301	257	28
NT	10	72	257	92	109	50
LC	19	58	134	0	61	31
<b>Total</b>	<b>60</b>	<b>252</b>	<b>1052</b>	<b>715</b>	<b>689</b>	<b>130</b>

**Table 2:** IUCN Red List status of species included within the analysis, the number of data groups assessed and the polygons resulting along with the IBA criteria triggered within these. A1 = *Globally threatened species* - The site is known or thought regularly to hold significant numbers of a globally threatened species, or other species of global conservation concern. A4ii = *Congregations* - Site known or thought to hold, on a regular basis, >1% of the global population of a congregatory seabird or terrestrial species. A4iii = *Congregations* - Site known or thought to hold, on a regular basis, > 20,000 waterbirds or >10,000 pairs of seabirds of one or more species.

## Figures

**Figure 1:** Polygons resulting from the analysis of all 252 data groups. Polygons are aggregated to show areas of overlap between data groups (darker areas), with insets providing further detail on those with greatest convergence. Also shown are the 55 deployment locations (blue stars) and Exclusive Economic Zones.

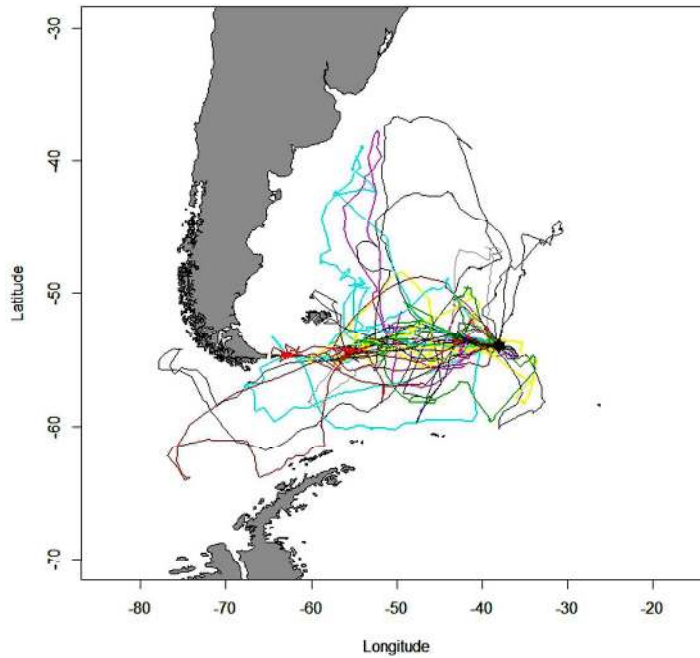

The following figures show the results from the analysis of a single data group; PTT data for the Wandering Albatross (*Diomedea exulans*) during the incubation period at Bird Island, South Georgia (Supplement 3). Data courtesy of the British Antarctic Survey.

**Figure 2:** Assessing the representativeness of the data group to determine if population-level inference is possible. The graph indicates what proportion of out-of-sample locations were located within the 50% core-use areas estimated from sampled locations (Inclusion value) for 100 random draws of sample sizes from 1 to 26 trips. Grey bars indicate variability of inclusion value for 100 random data selections, and the solid line represents a non-linear regression line. Inclusion rate (and thus representativeness of the tracking data set) is based on the estimated asymptote of the nonlinear regression.

**Figure 3:** Characterizing the Area Restricted Search patterns of the data group. Each black line shows the log variance in First Passage Time at each scale for an individual foraging trip, dotted red lines show the peak scales for each individual foraging trip (i.e. the ARS scale), assessed from 10 - 250 km at 5 km intervals, solid red line shows the average ARS scale for the data group which was then used as kernel smoothing factor ( $h$  values) for home range estimation.

**Figure 4:** Individual foraging trips (each trip coloured differently) of Wandering Albatross during the incubation period at Bird Island, South Georgia. We defined a trip as any occasion where a tracked individual travelled for >25 km from the colony for >12 hours, giving us a sample size of 27 trips.

**Figure 5:** Identification of “core-use areas” for each trip (coloured as Fig. 4) from the 50% kernel density utilisation distributions. The kernel smoothing factor ( $h$  value) was based on the result of the ARS assessment in Fig. 3.

**Figure 6:** Count surface showing the frequency of inclusion of 0.01 degree grid cells in individual 50% UD isopleths. The colour scale indicates the proportion of foraging trips with a core-use area in a given grid cell and thus indicates the important areas at the population level.

**Figure 7:** Resulting IBAs identified for the example data group, including the percentage of tracked birds occurring in each site. Population estimates for each polygon were determined by multiplying the number of birds breeding at Bird Island (2406 individuals), by the percentage of birds using a site and the appropriate correction factor determined from the representativeness analysis in Fig. 2 and Table S3 (in this case 0.75). Polygons were therefore shown to be holding *the regular presence of a threatened species or > 1% of the global population* (241 individuals), thus qualify as IBAs for this species.

## Supplement 1

Additional details of the methods employed in this analysis, please use this in combination with that contained in the main text.

### A. Data standardisation

This analysis included data from the three most commonly used tracking devices for vertebrates: Platform Terminal Transmitters (PTT), Global Positioning Systems (GPS) and Geolocators (GLS loggers). Our methods were applied to raw data consisting of the location (latitude and longitude) provided by the tracking device at each date and time, and a unique identifier for the individual bird.

Data from PTTs were standardised using a speed filter to remove erroneous locations (BirdLife International 2004; Douglas *et al.* 2012). A maximum realistic velocity was set at 100 km/h for albatross and petrel species; calculations from Pennycuik (1997) were used for other species. GPS devices have a high spatial accuracy and hence all data points were retained (Costa *et al.* 2010). Both PTT and GPS data were resampled to provide a location at hourly intervals (McConnell *et al.* 1992) because original locations were intermittent (Tremblay *et al.* 2006). Homogenisation of the sampling interval allowed PTT and GPS datasets to be combined in subsequent analysis. GLS data were processed, filtered, and standardised by data owners before submission to the database, interpolated to two fixes per day, and were then analysed separately due to their greater error (Phillips *et al.* 2004; Shaffer *et al.* 2005).

### B Projections

Data were projected into Lambert Equal-Area Azimuthal projections customised to each data group. For data relating to movements during the breeding period, the projection was centred on the colony, during the non-breeding period on the centroid of all locations, and for birds showing circumpolar movements on the relevant pole.

### C Defining Kernel smoothing parameters

The most important at-sea areas for seabirds are arguably those where they obtain food. However, most assessments of tracking data cannot identify prey ingestion events and thus rely on the assumption that feeding takes place within regions of area-restricted search (ARS – e.g. Weimerskirch *et al.* 2007). This assumption has been tested using additional devices that can provide data on true feeding events, with results indicating that First Passage Time (FPT) analysis appears to provide a useful proxy for identifying areas where feeding events are likely (Pinaud 2008; Dragon *et al.* 2012).

By calculating FPT values at several scales it is possible to identify at which scale searching behaviour appears to occur (Fauchald and Tveraa 2003; Pinaud and Weimerskirch 2005), and thus the scale at which the individual is interacting with different aspects of the environment (Suryan *et al.* 2006). Using the *fpt* function in *adehabitatLT* package in R (Calenge 2009), FPT values were calculated for each trip within a data group at scales from 10 to 250 km at 5 km intervals. The variance in FPT was calculated as a function of radius, and maxima in the log-transformed variance indicated the scale at which the bird interacted with the environment (Suryan *et al.* 2006; Pinaud and Weimerskirch 2005). This value was averaged across all trips, considered as the scale at which this data group showed

searching behaviour, and was used subsequently to determine the kernel smoothing factor for data collected with GPS or PTT devices (Fig. 3 and S1). For GLS data, we used  $h=186$ , which corresponds to the average error of the locations in kilometres (Phillips *et al.* 2004). ARS scales varied considerably between species, devices and seasons (Table S2).

Figure 3 and S1: Characterizing the Area Restricted Search patterns of the data group. Each black line shows the log variance in First Passage Time at each scale for an individual foraging trip, dotted red lines show the peak scales for each individual foraging trip (i.e. the ARS scale), assessed from 10 - 250 km at 5 km intervals, solid red line shows the average ARS scale for the data group which was then used as kernel smoothing factor ( $h$  values) for home range estimation.

Device/season	No. data groups	Min ARS Scale	Max ARS Scale	Ave ARS Scale
GPS or PTT Breeding	111	11.67	135.87	47.75
GPS or PTT Non-Breeding	12	20	98.19	51.15
<b>Grand Total</b>	<b>123</b>	<b>11.67</b>	<b>135.87</b>	<b>48.08</b>
GLS Breeding	50	186	186	186
GLS Non-Breeding	39	186	186	186
<b>Grand Total</b>	<b>89</b>	<b>186</b>	<b>186</b>	<b>186</b>

Table S2: Summary of results for Area Restricted Search analyses, showing the number of data groups for the breeding and non-breeding seasons split by data capture device types. ARS values for GPS and PTT are the minimum and maximum exhibited within the device/season combination, as well as the average value across all data groups. For GLS 186km was set as a default, rather than calculated, following Phillips *et al.* 2004.

#### D. Assessing representativeness

In order to assess whether data were representative and allow inferences to be drawn about the spatial use patterns of a population, we examined how core area distribution changes with increasing sample size. We randomly selected individual trips iteratively, and compared the

randomly selected (the 'sampled') with the unselected (the 'unsampled') data. For each sample size, a 50% UD was calculated from the sampled data, using an average ARS scale to define the smoothing factor (Fig. S1). We then assessed what proportion of the unsampled data was located within this 50% UD. Inclusion values were calculated 100 times using different random samples, to assess variability due to random sample selection. Thus, 100 estimates of the inclusion value were obtained for each sample size (i.e. from one to the total number of trips in the data group). A nonlinear regression was used to estimate the sample size needed for a data group to be considered completely representative, even when the inclusion value did not reach an asymptote. The sample size at which a data group is assumed to fully represent the wider population is reached at the point where the rate of increase of the regression function decreases to zero (i.e. when adding new samples simply replicates distributions already sampled). The maximum inclusion value achieved by a data group was calculated as a percentage of the estimated asymptote value to provide a measure of the data group's representativeness. The values obtained from the analysis of representativeness were then used to set the correction factors used when assigning overall populations to a site (Table S3).

**Table S3:** Values obtained from the analysis of representativeness of the tracking data sets and how this translates into the areas selected, and the correction factors used when assigning overall populations to a site. For example in a data group shown to be 70-80% representative only areas used by at least 20% of tracked individuals were selected and were conservatively assumed to be used by up to 50% of the wider population.

Representativeness value	Core-use threshold	Correction Factor
>90%	10%	0.9
80%-90%	12.5%	0.75
70%-80%	20%	0.5
<70% or n trips < 15	NA	NA

#### E Future improvements to methodology

Further improvements may also be possible by additional rigorous tests of the various analytical components underlying our approach. For example, evaluating a species-specific definition of 'core use area' may be useful to further account for variations in ecology and environmental interactions. Integration of data from tracking with data from other devices, such as wet/dry sensors, stomach sensors and accelerometers, may also lead to more accurate definitions of activity patterns and behaviours at sea.

We found ARS scales to vary considerably between species, sites and life-history stages, providing further justification for splitting the analysis into data groups. We used the average ARS scale within

1  
2  
3 a data group to assign kernel smoothing values; however ARS assessments often show multiple  
4 peaks (e.g. Paiva *et al.* 2010), reflecting small and large scale searching behaviours or differences  
5 between devices, and future analysis could explore how to choose the most effective ARS value for  
6 capturing feeding events and assigning kernel smoothing factors.  
7

8  
9 Further, more complex modelling of the raw location data may help to identify more discrete sites.  
10 We relied on data providers to process and filter GLS data before submission, but the distribution  
11 inferred from GLS data could be improved via state space modelling (Block *et al.* 2011; Jonsen *et al.*  
12 2003; Winship *et al.* 2012), or by comparing temperature data recorded by the same loggers with  
13 maps of sea surface temperatures measured by satellite (Shaffer *et al.*, 2005).

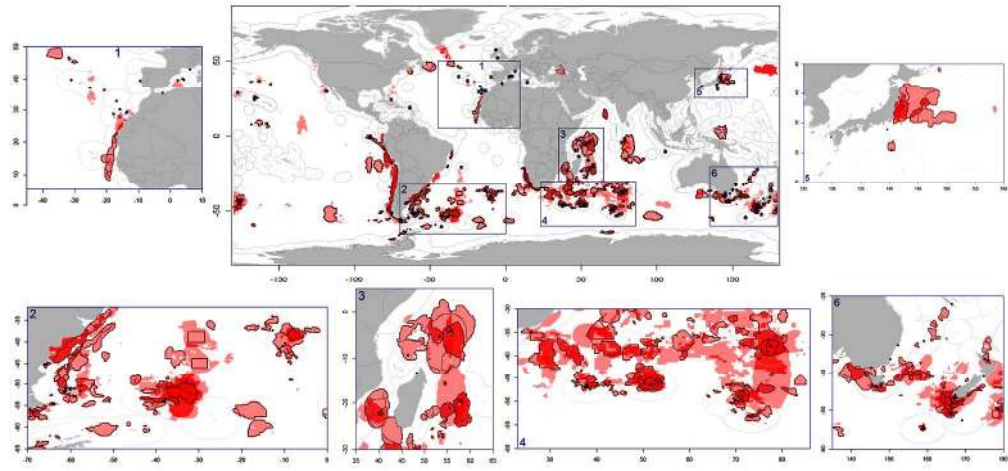

Figure 1: Polygons resulting from the analysis of all 252 data groups. Polygons are aggregated to show areas of overlap between data groups (darker areas), with insets providing further detail on those with greatest convergence. Also shown are the 55 deployment locations (blue stars) and Exclusive Economic Zones.

Figure 2: Assessing the representativeness of the data group to determine if population-level inference is possible. The graph indicates what proportion of out-of-sample locations were located within the 50% core-use areas estimated from sampled locations (Inclusion value) for 100 random draws of sample sizes from 1 to 26 trips. Grey bars indicate variability of inclusion value for 100 random data selections, and the solid line represents a non-linear regression line. Inclusion rate (and thus representativeness of the tracking data set) is based on the estimated asymptote of the nonlinear regression.

Figure 3: Characterizing the Area Restricted Search patterns of the data group. Each black line shows the log variance in First Passage Time at each scale for an individual foraging trip, dotted red lines show the peak scales for each individual foraging trip (i.e. the ARS scale), assessed from 10 - 250 km at 5 km intervals, solid red line shows the average ARS scale for the data group which was then used as kernel smoothing factor (h values) for home range estimation.  
194x194mm (72 x 72 DPI)

Figure 4: Individual foraging trips (each trip coloured differently) of Wandering Albatross during the incubation period at Bird Island, South Georgia. We defined a trip as any occasion where a tracked individual travelled for >25 km from the colony for >12 hours, giving us a sample size of 27 trips.  
271x271mm (72 x 72 DPI)

Figure 5: Identification of "core-use areas" for each trip (coloured as Fig. 4) from the 50% kernel density utilisation distributions. The kernel smoothing factor (h value) was based on the result of the ARS assessment in Fig. 3.  
271x271mm (72 x 72 DPI)

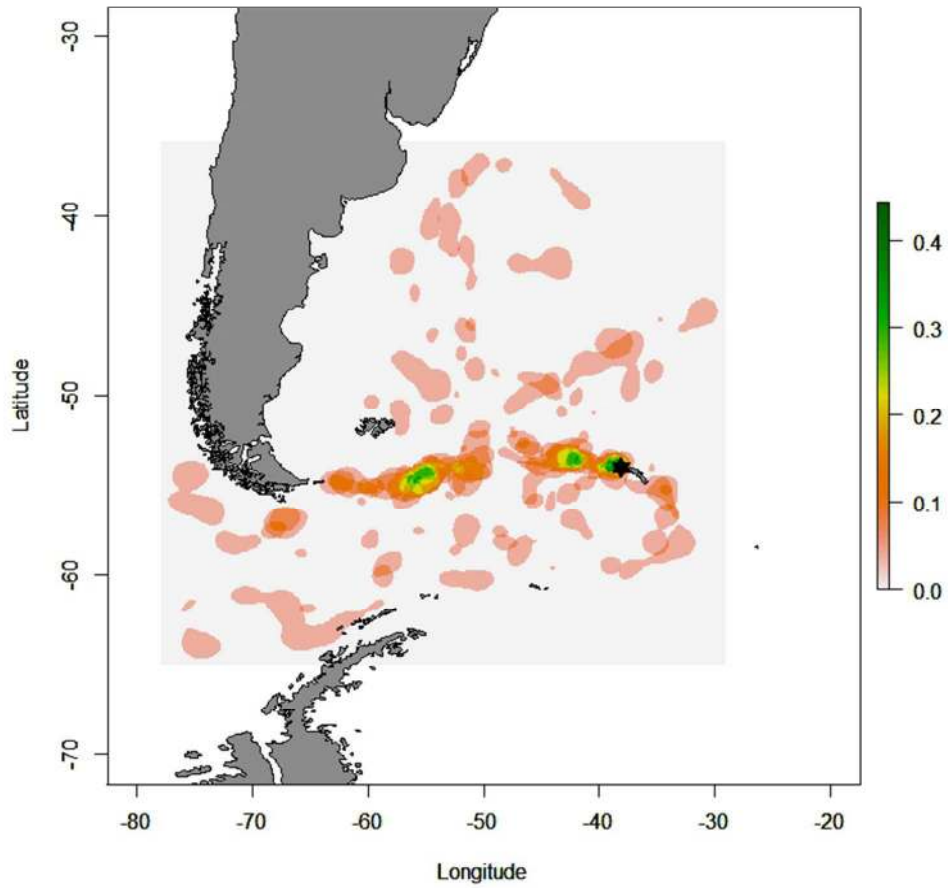

Figure 6: Count surface showing the frequency of inclusion of 0.01 degree grid cells in individual 50% UD isopleths. The colour scale indicates the proportion of foraging trips with a core-use area in a given grid cell and thus indicates the important areas at the population level.  
271x271mm (72 x 72 DPI)

Figure 7: Resulting IBAs identified for the example data group, including the percentage of tracked birds occurring in each site. Population estimates for each polygon were determined by multiplying the number of birds breeding at Bird Island (2406 individuals), by the percentage of birds using a site and the appropriate correction factor determined from the representativeness analysis in Fig. 2 and Table S3 (in this case 0.75). Polygons were therefore shown to be holding the regular presence of a threatened species or > 1% of the global population (241 individuals), thus qualify as IBAs for this species.

271x271mm (72 x 72 DPI)
