36 **ABSTRACT**
37

38 The Oman – UAE ophiolite is the world’s largest ophiolite. It is divided into twelve
39 separate fault-bounded blocks, of which the northern three lie wholly or partly in the
40 United Arab Emirates (UAE). Extensive mapping has shown that the UAE blocks contain
41 mantle and crustal sections which correspond to the classic ‘Penrose conference’
42 ophiolite definition, but which are cut by a voluminous later magmatic sequence
43 including ultramafic, mafic and felsic components. Samples from the later magmatic
44 sequence are dated at 96.4 ± 0.3 Ma, 95.74 ± 0.3 Ma, and 95.2 ± 0.3 Ma; the early crustal
45 section, which has not been dated directly, is thus constrained to be older than c.96.4 Ma.
46 Petrological evidence shows that the early crustal section formed at a spreading ridge, but
47 the later magmatic sequence was formed from hydrous magmas that produced different
48 mineral crystallisation sequences to normal MORB. Mineral and whole-rock geochemical
49 analyses show that the early crustal rocks are chemically similar to MORB, but the later

4 magmatic sequence has chemical features typically found in supra-subduction zone (SSZ)
5 settings. The ophiolite in the UAE thus preserves clear evidence for two stages of
6 magmatism, an early episode formed at a spreading centre, and a later episode associated
7 with the onset of subduction. Similar two-stage magmatism has been recognised in the
8 Oman sector, but the UAE contains the most voluminous SSZ magmatism yet described
9 from this ophiolite.

25 26 27 **INTRODUCTION AND PREVIOUS WORK**

28 The Oman – UAE Ophiolite (also known as the Semail Ophiolite) is the largest ophiolite
29 complex in the world, and one of the most widely studied. Most of the ophiolite lies in
30 Oman, where it has been mapped and described in great detail; this work has been
31 summarised in a number of special volumes (Glennie et al. 1974; Coleman 1981; Lippard
32 et al. 1986; Robertson et al. 1990; Boudier and Juteau 2000). However, the northern parts
33 of the ophiolite are in the United Arab Emirates (UAE), and have been the subject of a
34 relatively small number of papers (e.g. Peters and Kamber 1994; Reuber 1988; Cox et al.
35 1999; Searle and Cox 1999; Nicolas et al. 2000a,b). This paper presents results from a
36 detailed field and geochemical study of the ophiolite in the UAE, carried out by the
37 British Geological Survey (BGS) under contract to the Ministry of Energy of the UAE
38 (Styles et al. 2006).

45
46
47

48 The Oman – UAE Ophiolite has traditionally been interpreted in terms of the classic
49 ‘Penrose conference’ ophiolite definition (Anonymous 1972), with an ultramafic mantle
50 section, and an overlying oceanic crustal section composed of gabbros, sheeted dykes,
51 and pillow lavas (Lippard et al. 1986). However, many recent studies have recognised the
52 existence of numerous later intrusions into the ophiolite sequence, formed during a later
53 phase of magmatism (Ernewein et al. 1988; Juteau et al. 1988; Shervais 2001; Dilek and
54 Flower 2003; Adachi and Miyashita 2003; Yamasaki et al. 2006; Python et al. 2008;

63
64
65

1
2
3
4 Rollinson 2009). This paper describes the composite nature of the ophiolite in the UAE,
5 and draws upon field, geochronological and geochemical data to propose a model for the
6 development of the ophiolite and the tectonic processes that operated during its formation
7 and accretion.
8
9

10
11 The Oman – UAE Ophiolite was formed during the Cretaceous Period, at around 95 Ma
12 (Tilton et al. 1981; Warren et al. 2005) as part of the Neo-Tethyan ocean floor. Dates on a
13 range of minerals from the metamorphic sole to the ophiolite show that obduction began
14 around a million years after the formation of the youngest magmatic rocks of the
15 ophiolite (Hacker et al. 1996; Warren et al. 2005). The ophiolite belt extends for
16 approximately 600 km and comprises twelve blocks, separated by faults (Glennie et al.
17 1974; Lippard et al. 1986). Of these blocks, the northernmost two - Khor Fakkan and
18 Aswad – lie almost entirely within the UAE (Fig. 1). The northern tip of the Fizh block
19 also extends into the south of the UAE.
20
21
22
23
24
25
26
27
28

29 Many advances have been made in understanding of the Oman – UAE Ophiolite over the
30 last twenty-five years. In the context of our work in the UAE, two particular areas of
31 research are crucial: the Moho Transition Zone (MTZ); and the younger magmatic
32 phases.
33
34
35
36

37 The Moho Transition Zone lies between harzburgite of the mantle section and the
38 overlying crustal layered gabbros. It includes dunites, wehrlites, pyroxenites and gabbros,
39 with extremely complicated interrelationships. Broadly speaking, dunite is more common
40 at the base of the MTZ, whereas gabbro is more common toward the top. It has
41 previously been suggested that the ultramafic rocks of this zone simply represent part of
42 the cumulate pile at the base of the crust (e.g. Coleman 1977; Lippard et al. 1986).
43 However, a massive dunite band that forms the upper part of the mantle sequence has
44 been interpreted as having a residual origin, formed by extraction of orthopyroxenes
45 through melting, and this theory was extended to encompass all the dunites of the MTZ
46 by Nicolas and Prinzhofer (1983). Benn et al. (1988) supported this view, and suggested
47 that the transition zone is a composite of residual material, largely dunites that have been
48 ‘impregnated’ by interstitial melt, and gabbroic to ultramafic intrusions. This model for
49 the MTZ has largely been accepted, and developed via detailed field and geochemical

5 2000; Koga et al. 2001).

6
7
8 The tectonic environment in which the Oman – UAE Ophiolite was formed has also been
9 the subject of considerable debate. At first, it was considered to have formed at a fast-
10 spreading mid-ocean ridge (Coleman 1981). However, field mapping has identified a
11 number of different lava units in Oman, associated with late intrusions (Lippard et al.
12 1986). The lavas show a geochemical transition up-sequence, from MORB-like to more
13 island-arc like chemistry, and thus a transition from a spreading-ridge environment to a
14 supra-subduction zone environment has been suggested (Pearce et al. 1981; Alabaster et
15 al. 1982). This model has broadly been accepted by many researchers, and is supported
16 by mineral chemistry data from both gabbros and ultramafic rocks (Umino et al. 1990;
17 Searle and Cox 1999; Shervais 2001; Ishikawa et al. 2002; Dilek and Flower 2003; Arai
18 et al. 2006; Yamasaki et al. 2006; Python et al. 2008; Dare et al. 2009). However, some
19 authors contend that the entire magmatic sequence may have formed at a mid-ocean
20 ridge, with the later magmas being derived from a source that had been contaminated
21 with seawater (Boudier et al. 1988; Boudier et al. 2000; Nicolas and Boudier 2003) or by
22 second-stage melting of a previously-depleted mantle source (Ernewein et al. 1988;
23 Godard et al. 2006). It has been suggested that evidence for a supra-subduction zone
24 environment is stronger in the north-west of the ophiolite (Python et al. 2008), in which
25 case the UAE represents the best place to test this evidence. This paper describes the
26 evidence for voluminous SSZ-type magmatism in the UAE.

46 **GEOLOGICAL SETTING**

47
48 The two most northerly blocks of the Oman – UAE Ophiolite (the Khor Fakkan and
49 Aswad blocks) occur wholly within the UAE, together with the northern tip of the Fizh
50 block (Glennie et al. 1974; Fig. 1). Each of the two northern blocks is divided into two
51 tectonic slices by a major ductile dislocation zone around 1 km below the Moho: the Bani
52 Hamid Shear Zone in the Khor Fakkan block, and the Siji Shear Zone in the Aswad
53 Block (Fig. 2).
54

56
57
58
59
60
61
62
63
64
65

1
2
3
4 The most northerly part of the ophiolite is the Khor Fakkan block, which is some 60 km
5 in length and extends from the town of Dibba in the north to Fujairah in the south. Along
6 its north side, it is separated from deformed sedimentary rocks of the Dibba Zone by the
7 Wadi Sidir Fault Zone. To the west, the Khor Fakkan block is in tectonic contact with the
8 metamorphic rocks of the Masafi-Ismah window, which have typically been interpreted
9 as the metamorphic sole to the ophiolite (Searle and Cox 2002). To the east, the ophiolite
10 continues offshore and can be recognised from aeromagnetic data to extend about 10 km
11 beyond the coastline, where it is either terminated or downfaulted and buried beneath
12 thick sediments. On its southern side, the Khor Fakkan block is bounded by the major
13 NW-SE Wadi Ham Fault Zone.
14
15
16
17
18
19
20
21
22

23 The Khor Fakkan block also encloses the high-grade metamorphic rocks of the Bani
24 Hamid Group, which occur in a tectonic window, bounded by thrusts which continue
25 north-west as a major intra-ophiolite shear zone, the Bani Hamid Shear Zone. To the
26 north and west of this shear zone, the block is made up exclusively of mantle harzburgite
27 with subordinate dunite veins (Fig. 2). To the south and east of the shear zone, the Khor
28 Fakkan block encompasses much of the typical ophiolite sequence, from a relatively thin
29 horizon of mantle harzburgite up through the MTZ, into layered gabbro and high-level
30 gabbro. Progressively higher parts of the sequence are encountered toward the east,
31 suggesting that the whole block is gently inclined eastwards. The uppermost parts of the
32 crustal section (sheeted dyke complex and pillow lavas) are not present in the Khor
33 Fakkan block.
34
35
36
37
38
39
40
41
42
43

44 To the south, the Aswad block is one of the largest blocks in the Oman – UAE Ophiolite
45 (Fig. 2). It extends approximately 70 km from north to south, and approaches 40 km in
46 exposed east – west width. It is separated from the Khor Fakkan block to the north-east
47 by the Wadi Ham Fault Zone and the Masafi-Ismah Metamorphic Window, and from the
48 Fizh block to the south by the Hatta Zone. To the west, the Aswad block extends beneath
49 the desert sands of the UAE, whereas to the east it continues for several kilometres
50 beneath the Indian Ocean. A ductile thrust (the Siji Shear Zone) close to the base of the
51 crustal section separates the northern part of the Aswad block, which is entirely
52 composed of ultramafic mantle rocks, from the larger southern part. The latter consists
53 chiefly of rocks of the crustal section (up to and including pillow lavas), together with the
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 upper part of the mantle. The high-level gabbro, sheeted dykes and pillow lavas occur on
5 the eastern side of the block, passing westwards into layered gabbro and then into
6 ultramafic rocks, indicating that the Aswad block also has an overall dip to the east.
7
8 However, in the central part of the block dips appear to be gentle to flat (as described by
9 Nicolas et al. 2000b), and as a result the hills commonly have rocks of the MTZ exposed
10 at their bases, capped by layered gabbro. The transition from the layered to the high-level
11 gabbro is obscured in many areas by voluminous bodies of younger gabbro, as discussed
12 below.
13
14
15
16
17
18

19 The Fizh block lies almost entirely within Oman, and only its northernmost tip extends
20 into the UAE. This block is separated from the Aswad block to the north by the deformed
21 sedimentary and metamorphic rocks of the Hatta Zone. The Fizh block in the UAE
22 chiefly consists of mantle harzburgite, with only a small area of gabbro.
23
24
25
26
27
28

29 **OPHIOLITE UNITS IN THE UAE**

30
31
32 Our mapping has shown that the rocks of the ophiolite in the UAE can be divided into
33 three broad groups, namely: the mantle section; the early crustal section, and the later
34 magmatic sequence. The mantle and early crustal sections together represent the classic
35 ‘Penrose conference’ ophiolite succession; they are separated by a gradational boundary
36 zone (the MTZ). The later intrusive magmatic sequence encompasses a range of
37 compositions, from ultramafic to felsic, and a range of forms, from large plutons to dykes
38 and sheets, which cross-cut the earlier parts of the ophiolite.
39
40
41
42
43
44

45 **Harzburgite and dunite of the mantle section**

46
47 The mantle rocks of the Oman – UAE Ophiolite have been described in detail elsewhere
48 (e.g. Lippard et al. 1986; Styles et al. 2006). In the UAE, they form the greater part of the
49 Khor Fakkan block and the northern part of the Aswad and Fizh blocks. They also occur
50 along the western fringe of, and in a small fault-bounded horst in the centre of, the Aswad
51 block. They consist of coarse-grained harzburgite with subordinate dunite bands. The
52 harzburgite is crudely foliated and lineated, as described by Nicolas et al. (2000b). Across
53 much of the mantle section, the dunite forms networks of anastomosing veins that vary in
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 width from about 10 cm to 1 m, and have gradational (over about 1 cm) contacts with the
5 harzburgite. These dunite veins are considered to represent channels through which melt
6 migrated towards the crust (Kelemen et al. 1995). In some areas, larger, irregular masses
7 of dunite up to tens of metres across are seen.
8
9

10
11 Close to the major bounding thrusts and shear zones of the ophiolite, the dunite occurs as
12 tabular, parallel bands in the harzburgite, which define a distinct layering. This ‘banded
13 unit’ has also been described in Oman (Boudier et al. 1988) and is considered to have
14 formed through emplacement-related deformation. The shear zones that separate the
15 tectonic slices within the blocks are characterised by intense recrystallisation, producing
16 ‘recrystallised harzburgite’ with a grain size of less than 1 mm. The shear zones also
17 contain rocks with a higher clinopyroxene content than typical harzburgite, possibly
18 indicating some infiltration of magmas. The top of the mantle section is marked by a
19 discontinuous zone of massive dunite, which represents the base of the MTZ.
20
21
22
23
24
25
26
27
28

29 **The Moho Transition Zone**

30
31 The MTZ constitutes the zone of transition between the mantle harzburgite and the
32 layered gabbro at the base of the crustal section. It is well exposed along the eastern side
33 of the high mountains of the Khor Fakkan block, and also in the western and central parts
34 of the Aswad block.
35
36
37
38

39 Most authors have described the MTZ of the ophiolite in Oman as largely composed of
40 dunite, with an increasing amount of gabbroic sills up-section, and locally containing
41 wehrlite, pyroxenite and troctolite bodies of various dimensions and geometries (Nicolas
42 and Prinzhofer, 1983; Benn et al. 1988; Boudier and Nicolas 1995; Korenaga and
43 Kelemen, 1997; Jousselin and Nicolas, 2000; Nicolas and Boudier 2000). In the UAE, we
44 have delimited two separate components of the MTZ: a massive dunite unit, at the top of
45 the mantle section; and an overlying layer that we have termed the Mixed Unit, which
46 comprises varying quantities of dunite, wehrlite, pyroxenite, troctolite and gabbro (Fig.
47 3). Both layers are of very variable thickness, and in some areas one or the other layer
48 may be almost entirely absent.
49
50
51
52
53
54
55
56

57
58 The massive dunite layer is a discontinuous zone that locally attains a thickness of several
59 hundreds of metres, although large lateral variations occur over distances of a few
60
61
62
63
64
65

1
2
3
4 kilometres. The base of the massive dunite unit is defined as the point at which dunite
5 consists of >90% of the outcrop; above this point, harzburgite only occurs as relict
6 patches. Chromite-rich zones are common, and locally layered.
7
8

9
10 The massive dunite unit is overlain by the Mixed Unit, which varies in thickness from a
11 few metres up to around 1000 metres. Although it is laterally variable, a general
12 stratigraphy can be recognised (Fig. 3). The base of the Mixed Unit is taken where
13 patches rich in coarse grains of clinopyroxene and/or plagioclase feldspar begin to appear
14 at the top of the massive dunite. These areas are known as ‘impregnated dunite’ (Benn et
15 al. 1988). Continuing up-section, the proportion of plagioclase and/or clinopyroxene in
16 the dunite increases, grading upwards into wehrlite and, less commonly, troctolite. In
17 many areas the orange-brown dunite and impregnated dunite are cross-cut by coarse-
18 grained, irregular intrusions of green clinopyroxenite and olivine clinopyroxenite, and
19 dark brown wehrlite.
20
21
22
23
24
25
26
27
28

29 Higher in the Mixed Unit, wehrlite and pyroxenite dominate. These are associated with
30 scattered tabular sheets and enclaves of gabbro, which vary from a few tens of
31 centimetres up to tens of metres in size (Fig. 4). The gabbro is typically coarse-grained
32 and shows modal layering, similar to that seen in the crustal layered gabbros. The
33 layering is most commonly parallel to that in the overlying layered gabbros, but in many
34 enclaves the layering is randomly orientated. Wehrlite and pyroxenite intrusions locally
35 transgress the gabbro layering, clearly indicating that they were intruded into already-
36 layered gabbro. The margins of the gabbro sheets and xenoliths vary from sharp to
37 diffuse; in the latter case, there is a gradation over a few centimetres, from layered
38 gabbro, through troctolite or melagabbro with ‘ghost’ layering, into wehrlite. This
39 gradation indicates partial assimilation of the gabbroic rocks by the intruding wehrlite
40 and pyroxenite.
41
42
43
44
45
46
47
48
49
50

51 The volume of gabbro increases higher up the succession, with a concomitant decrease in
52 intrusive wehrlite. Pyroxenite becomes less common, and the feldspar content of the
53 wehrlite increases, grading into melagabbro (> 10% plagioclase; Koga et al. 2001). The
54 contact between the Mixed Unit and the overlying layered gabbro unit is generally very
55 difficult to define, but is taken at the point where the gabbro appears as the dominant rock
56
57
58
59
60
61
62
63
64
65

1
2
3
4 body, rather than as a stack of xenoliths within a wehrlite mass. This point roughly
5 equates to layered gabbro being more than 50% of the outcrop. Above this, abundant sills
6 and irregular intrusions of wehrlite occur within the gabbro.
7
8

9
10 The relationship between dunite and the layered gabbro in the Mixed Unit is not easy to
11 determine, since they rarely occur in contact. Dunite is intruded by wehrlite and
12 pyroxenite close to the base of the Mixed Unit; higher up, bodies of dunite locally appear
13 to enclose gabbro xenoliths. The interlayering of dunite and gabbro that has been
14 described in Oman (e.g. Boudier and Nicolas 1995; Korenaga and Kelemen 1997), is
15 rarely if ever seen in the UAE.
16
17

18 Cross-cutting veins of coarse-grained to pegmatitic gabbro and clinopyroxenite occur
19 throughout the Mixed Unit. These clearly post-date the main rock-types of the MTZ, and
20 provide evidence for a further phase of magmatism. Similar late veins and dykes are seen
21 cutting the mantle section of the ophiolite, and have also been described in Oman (Python
22 and Ceuleneer 2003).

Nicolas and Prinzhofer (1983) and Benn et al. (1988) presented a model for the Oman ophiolite in which the massive dunite unit at the top of the mantle section was considered to be residual, and the gabbro, wehrlite and pyroxenite above were considered to be intrusive. The field relationships in the UAE accord well with the essential facts of this model. However, it is clear from the relationships seen in the Mixed Unit that formation of the layered gabbro pre-dated the intrusion of most, if not all of the wehrlite and pyroxenite bodies. The layered gabbro sheets and lenses seen within the Mixed Unit of the UAE represent xenoliths derived from the base of the crustal section. Although it is entirely possible that the lower units of layered gabbro formed as sills, intruding the upper part of the mantle section (Boudier et al. 1996; Korenaga and Kelemen 1997; Kelemen et al. 1997), evidence for this has been intensely disrupted by later magmatism in the MTZ of the UAE. Similar features have been described from Oman by Juteau et al. (1988), who recognised that a second magmatic event represents an important part of the history of the Oman ophiolite. The UAE blocks were identified as a part of the ophiolite with an unusually thick MTZ, and abundant wehrlite intrusions, by Nicolas and Boudier (2000), and were suggested to represent an area of mantle upwelling. The field

1
2
3
4 relationships described here confirm the presence of abundant wehrlite and a generally
5 thick MTZ, but show that this is indicative of a locus of later magmatism.
6
7

8 **Gabbros of the early crustal section** 9

10 The early crustal section of the ophiolite in the UAE contains good examples of both
11 lower crustal layered gabbro and high-level gabbro. Both units occur along the eastern
12 side of the Khor Fakkan block. The high-level gabbro occurs close to the eastern margin
13 of the Aswad block, whereas the layered gabbro occupies a broad area of outcrop in the
14 central part of the block. These units of the Oman – UAE Ophiolite have previously been
15 described in detail from Oman (e.g. Lippard et al. 1986; Nicolas et al. 2000b).
16
17

18 The layered gabbro comprises coarse-grained olivine gabbro, and mostly preserves a
19 clear rhythmic modal layering, generally on a scale of 1 – 20 cm. The layers are typically
20 sharply bounded. Modally graded layering, which is common in Oman (e.g. Boudier et
21 al. 1996), is very rarely seen in the UAE. Many layered gabbro outcrops also exhibit a
22 mineral foliation, defined by aligned tabular plagioclase and clinopyroxene crystals.
23 Layering is further emphasised by – and in places solely due to – sills of wehrlite and
24 melagabbro which are mainly layer-parallel, although locally cross-cutting. These
25 wehrlitic sills, which vary in thickness from 5 cm to several metres or more, are most
26 common in the lower parts of the crustal section, decreasing in abundance upwards. In
27 some areas, large masses of wehrlite and melagabbro, with some clinopyroxenite and
28 dunite, have been intruded upwards from the Mixed Unit into the layered gabbro, and
29 more rarely into the upper crustal rocks. These large masses can be up to a kilometre
30 across, and their margins grade outwards into more typical layered gabbros with wehrlite
31 sills.
32
33

34 Orientation of layering is variable; in the Khor Fakkan block it is typically moderately to
35 steeply inclined toward the east, but is locally sub-vertical and is clearly not always
36 parallel to the Moho. In the Aswad block, layering is typically shallowly to moderately
37 inclined, giving the impression of an undulose geometry confined by a more or less flat-
38 lying enveloping surface. However it is locally steeply inclined, particularly in the
39 vicinity of fault zones or at the margins of steep sided bodies of younger gabbro.
40
41
42
43
44
45
46
47

1
2
3
4 Over much of the area, contacts between the layered and high-level gabbro are now
5 largely obscured by bodies of younger gabbro (see below), or disrupted by faults. In the
6 few places where the unmodified contact is exposed, the layered gabbro is observed to
7 grade up-sequence, with gradual loss of layering, into the high-level gabbro. Bodies of
8 high-level gabbro are typically medium- to coarse-grained, and very variable in texture,
9 ranging from equigranular to extremely heterogeneous. The most 'varitextured' gabbro
10 (Macleod and Yaouancq 2000) shows patchy gradation from medium-grained through to
11 pegmatitic textures within a single outcrop. In some areas, the gabbro has a poorly
12 penetrative foliation defined by aligned clinopyroxene crystals. However, there is no
13 clear systematic variation in textural types across the outcrop.
14
15
16
17
18
19
20
21
22

23 The upper parts of the high-level gabbro are cut by abundant dykes of microgabbro,
24 generally < 2 m in thickness and preserving sharp, chilled contacts against the host
25 gabbros. In the Aswad block these dykes are most commonly north – south trending,
26 although they cover a range of orientations round to NNW. In the Khor Fakkan block, the
27 dykes typically have a NNW-SSE trend. Dyke density increases upwards in the high-
28 level gabbro, and in the Aswad block this gives a transitional contact into the sheeted
29 dyke complex (the dyke rooting zone), although in some places sharp contacts between
30 sheeted dykes and gabbro indicate the emplacement of multiple pulses of magma. The
31 transition into true sheeted dyke complex is not preserved in the Khor Fakkan block.
32
33
34
35
36
37
38
39
40
41

42 **Sheeted dyke complex and pillow lavas**

43
44 In the UAE, these upper parts of the early crustal section are only exposed on the eastern
45 side of the Aswad block, south of Fujairah. The sheeted dyke complex is defined as being
46 composed of more than 90% dykes, with up to 10% inter-dyke screens of gabbro or
47 basalt. Individual dykes are up to 2 m wide, with 30 to 50 cm more typical. Some dykes
48 preserve chilled margins on both sides, others have chills on only one side. The dyke
49 trend varies from north to NNW, and the dykes are steeply dipping to vertical. Some
50 distinct, later dykes cut across earlier chilled margins.
51
52
53
54
55
56

57
58 A transitional contact occurs between the sheeted dyke complex and the overlying pillow
59 lavas. The pillow basalts occur as small, discontinuous outcrops, some of which have
60
61
62
63
64
65

1
2
3
4 been heavily quarried in recent years. They are fine-grained, highly shattered
5 (microjointed), and weathered to patchy green and purple colours. A few outcrops are
6 vesicular, and pillow structures are present at some localities, although these are not
7 always clearly recognisable due to the shattered nature of the outcrops. Small areas of
8 basaltic microbreccia are also seen. Sedimentary layers are absent and interpillow
9 sediment is rare. Only the lower part of the lava sequence (Lippard et al. 1986) is present
10 in the UAE.

13
14
15
16
17
18
19

20 **The later magmatic sequence in the UAE**

21
22 One of the most distinctive features of the ophiolite in the UAE is the presence of
23 abundant, cross-cutting, bodies of younger gabbro that intrude all levels of the crust, from
24 the Mixed Unit up to the pillow lava, and locally also intrude down into the mantle
25 harzburgite and dunite. These younger gabbros in the UAE have been fully described for
26 the first time during the BGS mapping project, which has identified a number of different
27 facies, and mapped out the extent and morphology of the gabbroic bodies in detail (Styles
28 et al. 2006).
29
30
31
32
33
34

35
36 The younger gabbros are most abundant in the Aswad block, where they form an
37 extensive network that makes up around half of all crustal exposure (Fig. 2). In the Khor
38 Fakkan and Fizh blocks only small areas have been identified, the most extensive of
39 which occurs in the southern part of the Khor Fakkan block. These younger gabbros are
40 clearly similar to the late intrusive complexes that have been identified in Oman
41 (Smewing 1980; Lippard et al. 1986; Adachi and Miyashita 2003), but they appear to be
42 considerably more voluminous in the UAE.
43
44
45
46
47
48

49
50 The younger gabbros are highly heterogeneous, and it has proved possible to map out a
51 number of different facies in the field. However, they have certain characteristic features
52 that distinguish them from the gabbros of the main ophiolite succession: 1) although
53 markedly heterogeneous they are, in general, finer-grained than the layered and high-
54 level gabbros, and contain areas of microgabbro; 2) they are commonly associated with
55 more-evolved, dioritic and tonalitic intrusions; 3) they are typically associated with
56 ductile shear zones and faults; 4) evidence of polyphase intrusions is common.
57
58
59
60
61
62
63
64
65

1
2
3
4 The younger gabbros form a network of intrusions with a very complex geometry (Fig.
5 5). Large areas of younger gabbro (up to several km across) typically contain abundant
6 xenoliths of the host rocks up to a kilometre in size. The margins of the intrusive bodies
7 are intricate, with many sheets and veins of younger gabbro cutting the host rocks (Fig.
8 6). In the Khor Fakkan block most of the younger gabbro occurs as a relatively coherent,
9 inclined sheet-like body with an elongate north-trending outcrop. Along much of its
10 length this body intervenes between the Mixed Unit and the base of the layered gabbro,
11 but toward the south and north, it transgresses the layered gabbro and intrudes the base of
12 the high-level gabbro. In the Aswad block the younger gabbros preserve a complex
13 morphology that includes flat-lying sheet-like elements, particularly in the western and
14 southern parts of the block (Fig. 6a). Broad, composite dyke-like bodies and sheets (Fig.
15 6b) characterise the central part of the block, confined within or associated with north- to
16 NW-trending zones of ductile shearing and brittle faulting. The former are characterised
17 by intense zones of mylonitisation with small-scale isoclinal shear folds. In the east of the
18 block, contacts with layered gabbro are generally steep and strongly discordant to the
19 layering (Fig. 6c), and monoclinial drag-like folds tens of metres in amplitude have been
20 recognised at some of these contacts. In the Aswad block, the younger gabbros most
21 commonly occupy a structural position between the layered gabbro and higher units, but
22 with many offshoots extending both upwards and downwards and transgressing the
23 earlier ophiolite sequence (Fig. 5).

37
38
39
40

41 Although the younger gabbros are texturally heterogeneous, their most distinctive feature
42 is the presence of large amounts of microgabbro. In some areas, particularly in the eastern
43 part of the Aswad block, the younger gabbros are characterised by a groundmass of
44 microgabbro, with irregular patches and veins of coarser-grained gabbroic and dioritic
45 material. Locally, intense foliation can be seen. This type of younger gabbro has been
46 mapped out as the 'Fujairah facies'. In the western part of the Aswad block, a more
47 varitextured groundmass is shot through with dyke-like intrusions of a brown-weathering,
48 fine- to medium-grained microgabbro with a distinctive 'splintery' appearance, and has
49 been mapped as the 'Bithnah facies'.
50
51
52
53
54
55
56
57

58 The younger gabbros are commonly associated with intrusions of more-evolved magma;
59 this is particularly clear in the Fujairah facies of the eastern part of the Aswad block,
60
61
62
63
64
65

1
2
3
4 which is intimately associated with veins, sheets and larger irregular bodies of white-
5 weathering tonalite up to 1 km² in outcrop area. The tonalites most commonly form sub-
6 vertical sheets a few metres across, but also occur as larger bodies and as vein networks
7 throughout the younger gabbros. Some tonalitic intrusions have a characteristic texture
8 known as ‘vinaigrette’ (Styles et al. 2006), with blebs of microgabbro within the tonalite
9 groundmass indicating mingling of two immiscible magmas (Fig. 6b).

10
11
12
13
14
15
16 The younger gabbros typically occupy rather different structural levels to the wehrlitic
17 and pyroxenitic rocks of the Mixed Unit, and so the relationships of these units are not
18 clear, although younger gabbros can be seen to cut across the Mixed Unit rocks in many
19 places. At some localities it is clear that more than one phase of wehrlite intrusion is
20 present, with phases pre- and post-dating younger gabbro. Both the younger gabbros and
21 the wehrlite and pyroxenite, together with some microgabbro dykes as described below,
22 clearly cross-cut the early crustal section of the ophiolite. Therefore, all these units can be
23 grouped together as a later magmatic sequence.
24
25
26
27
28
29
30
31
32

33 **Younger microgabbro dykes**

34
35
36 Dykes of microgabbro occur throughout the ophiolite crustal section, and much less
37 commonly in the mantle. They are typically 10 cm to 1 m in width, rarely up to a few
38 metres, and most examples are chilled against the host rocks. A number of different dyke
39 types can be identified on the basis of field relationships, although the relative age of an
40 individual dyke may not always be clear in the field. Many of the dykes in the upper parts
41 of the high-level gabbro are related to the sheeted dyke complex, and represent an
42 integral part of the early crustal section. However, a number of younger dykes are also
43 present; some of these are considered to be related to the younger gabbros, whilst others
44 are clearly later still. In particular, some very young dykes cut across rocks of the mantle
45 section.
46
47
48
49
50
51
52
53

54
55 Most of the microgabbro dykes are vertical to steeply dipping and have a WNW-ESE to
56 NW-SE trend, although there are variations. They typically weather to a pale greenish-
57 grey colour, and break into angular blocks that stand out against the more rounded
58
59
60
61
62
63
64
65

1
2
3
4 weathering of the surrounding coarse-grained gabbro. Some dykes contain small
5 phenocrysts of black clinopyroxene or white plagioclase.
6
7
8
9

10 **PETROGRAPHY**

11
12
13 The petrography of the main units of the Oman – UAE Ophiolite has been described in
14 detail elsewhere (e.g. Lippard et al. 1986). In this section, therefore, we focus on those
15 units that have been recognised as parts of the later phase of magmatism in the UAE, in
16 particular the rocks of the Mixed Unit and the younger gabbros.
17
18
19

20
21 The Mixed Unit wehrlites are coarse-grained rocks, consisting of ~ 70 % forsteritic
22 olivine (partially serpentinised), 20-30 % clinopyroxene (diopside – diopsidic augite),
23 and up to 10 % plagioclase. These grade into olivine-clinopyroxenites, largely consisting
24 of clinopyroxene with up to 20 % olivine. Textures are equigranular to poikilitic, with
25 clinopyroxene forming large, poikilitic plates up to several centimetres across with
26 rounded inclusions of olivine. Plagioclase, where present, is typically interstitial. Similar
27 textures have been described in Oman wehrlite by Juteau et al. (1988) and Boudier and
28 Nicolas (1995). These textures indicate a crystallisation sequence of olivine –
29 clinopyroxene – plagioclase, which contrasts with the typical MORB crystallisation
30 sequence of olivine – plagioclase – clinopyroxene (Koga et al. 2001; Koepke et al. 2009),
31 and suggests that the wehrlites were derived from a non-MORB hydrous parental magma.
32 The impregnated dunites also have poikilitic textures, being largely composed of
33 equigranular olivine crystals (often highly serpentinised) with rare, large poikilitic
34 clinopyroxene plates. Up to 5 % spinel is typically present in these rocks.
35
36
37
38
39
40
41
42
43
44
45
46

47 Wehrlite sills intrusive into the layered gabbro tend to be more feldspathic than Mixed
48 Unit wehrlite, and grade into melagabbro. Overall, the wehrlite consists of 60 – 80 %
49 olivine and 10 – 40 % clinopyroxene, with up to 15 % interstitial, highly altered
50 plagioclase. Some samples contain large poikilitic clinopyroxenes enclosing smaller
51 olivine crystals; other samples are fairly equigranular and are possibly recrystallised. The
52 olivine is commonly serpentinised, although the amount of alteration varies from a few
53 thin veins in olivine crystals to complete serpentinisation with no relict olivine.
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 The layered gabbro consists of 20 – 50 % clinopyroxene (diopside to diopsidic augite)
5 and up to 15 % olivine, with the remainder of the rock being composed of plagioclase
6 (bytownite). A few samples contain primary amphibole or orthopyroxene. Small amounts
7 (< 1%) of spinel are present in most samples. In many layered gabbros, there is
8 significant evidence of late alteration: the clinopyroxene has been replaced by amphibole
9 and chlorite, the olivine is partly serpentinised, and the plagioclase is saussuritised.
10 Texture is quite variable; some samples are granular, whereas others have a distinct
11 lamination defined by the parallel alignment of elongate plagioclase laths. Clinopyroxene
12 crystals are commonly poikilitic, enclosing grains of plagioclase and/or olivine, and
13 indicating the typical MORB crystallisation sequence of olivine – plagioclase –
14 clinopyroxene. Although layering can be seen in some thin sections, it is generally of a
15 larger scale than can be easily studied in thin section. No systematic textural difference
16 has been observed between the layered gabbro within the Mixed Unit and those within
17 the main layered gabbro unit. The high-level gabbro has similar mineralogy to the layered
18 gabbro, and poikilitic textures are common, with large clinopyroxene crystals enclosing
19 plagioclase laths and olivine grains. Many of the high-level gabbros are finer-grained
20 than the layered gabbro.
21
22
23
24
25
26
27
28
29
30
31
32
33
34

35
36 The younger gabbros show a wider variation in mineralogy and texture. They vary from
37 medium- to coarse-grained, and from equigranular to sub-ophitic or moderately foliated.
38 Many samples are essentially biminerally, being composed of around 30-50 %
39 clinopyroxene and 50-70 % plagioclase. The clinopyroxenes, which vary in composition
40 from diopside to augite, typically have a dusky appearance due to fine exsolution
41 textures. They are commonly partly altered to brown hornblende at the grain margins by
42 late magmatic processes, and a few examples have large plates of poikilitic brown
43 amphibole with little or no pyroxene present. Pervasive post-crystallisation hydrothermal
44 alteration to pale green to colourless, fibrous (actinolitic) clinoamphibole is widespread.
45 Plagioclase shows variable amounts of saussuritic and/or sericitic alteration.
46
47
48
49
50
51
52
53

54
55 Some 5 – 10 % interstitial quartz, commonly with feldspar in symplectic intergrowth, is a
56 fairly common constituent of the younger gabbros, particularly in the north-eastern part
57 of the Aswad block. Olivine is a very rare constituent of the younger gabbros, but a few
58
59
60
61
62
63
64
65

1
2
3
4 samples contain up to 5 %. Most rocks contain very minor amounts of opaque mineral
5 and apatite as accessory phases.
6

7
8 In the south of the Aswad block, a distinct orthopyroxene-bearing facies of the younger
9 gabbros has been identified, and has a very characteristic appearance in thin section. The
10 major component of the outcrops is a sub-ophitic to granular, reasonably fresh, two-
11 pyroxene microgabbro. The mineralogy includes 40 – 60 % plagioclase, 20 – 40 %
12 clinopyroxene, and 5 – 20 % orthopyroxene. Some samples also have poikilitic plates of
13 brown-green amphibole. Both pyroxenes tend to occur as subhedral to euhedral crystals,
14 and some examples have long bladed orthopyroxenes which formed early in the
15 crystallisation process. Similar rocks have been described from the Fizh-South Complex
16 in Oman, which is also considered to represent a younger intrusion (Adachi and
17 Miyashito, 2003).
18
19
20
21
22
23
24
25
26

27 The tonalitic rocks associated with the younger gabbros are medium- to coarse-grained
28 and generally consist of 30 – 50% quartz and 40 – 60% plagioclase, with smaller amounts
29 of hornblende and biotite. Some samples contain concentrically zoned plagioclase
30 phenocrysts. Zircon, apatite and titanite are relatively common accessories in these more
31 evolved intrusions.
32
33
34
35
36

37 Most microgabbro dykes comprised ~ 30-70 % clinopyroxene and 30-70 % plagioclase
38 when fresh, but in the majority of samples the clinopyroxene has been replaced by a
39 green amphibole ± chlorite. A few dykes contain up to 15% quartz or orthopyroxene, and
40 opaque oxides are common accessories. Textures are most commonly ophitic to sub-
41 ophitic, typically with pyroxene crystal shapes preserved by the amphiboles that have
42 replaced them.

50

51 **GEOCHRONOLOGY OF THE OPHIOLITE UNITS**

52 **Sampling and analytical methods**

53
54
55
56 Dating of ophiolites has always proved difficult because zircon is generally most
57 abundant in evolved, felsic rock types and least abundant in primitive, mafic, MORB-like
58 rock-types with low Zr contents. Previous U-Pb dates have thus only been obtained from
59
60
61
62
63
64
65

1
2
3
4 trondhjemitic intrusions (Tilton et al. 1981; Warren et al. 2005). However, the likelihood
5 of successfully finding zircon in mafic igneous rocks may increase with the degree of
6 chemical evolution and grain size, and so we sampled both tonalites and a number of
7 coarse-grained and pegmatitic gabbros. Large samples (15-20 kg) were taken to further
8 improve chances of success and where possible duplicate samples were taken from the
9 same area. Dating was carried out at the NERC Isotope Geoscience Laboratory, UK.
10 Zircons were separated and hand picked to obtain the best quality grains. Carefully
11 selected zircon grains were then abraded using the air abrasion technique of Krogh
12 (1982) or a modified chemical abrasion technique based on that developed by Mattinson
13 (2005). U-Pb chemistry used either a $^{233}\text{U}/^{235}\text{U}/^{205}\text{Pb}/^{230}\text{Th}$ or $^{235}\text{U}/^{205}\text{Pb}$ mixed spike
14 solution and followed the procedures of Krogh (1973), Parrish (1987) and Parrish and
15 Noble (2003). Analyses were conducted on a VG 354 multi-collector Thermal Ionisation
16 Mass Spectrometer (TIMS) equipped with a WARP filter, axial Daly photomultiplier and
17 Ortec ion counting detection system, or using a Thermo-Electron Triton multi-collector
18 TIMS instrument fitted with an axial secondary electron multiplier and multiple-ion
19 counters. Data were processed using error propagation and data reduction methods of
20 Parrish et al. (1987) and Roddick (1987). Concordia diagrams were plotted using the
21 Isoplot 3 macro of Ludwig (2003).

39 **Results**

40
41 Several samples were collected from the early crustal section, but unfortunately none
42 yielded sufficient zircon for analysis. However, dates were successfully obtained from
43 three samples from the later magmatic sequence. Images of the zircons from these
44 samples are shown in Fig. 7, and the data are shown in Table 1.
45
46
47

48 Sample UAE167 was taken from a sheet of pegmatitic gabbro intruding dunite and
49 wehrlite of the Mixed Unit in the Khor Fakkan Block at grid reference [431488
50 2803498]. Four separate zircon fractions from this sample were analysed and give a
51 concordia age of 96.40 ± 0.29 Ma (Fig. 8a). This date provides a younger limit for the
52 age of the early crustal section.
53
54
55
56

57 Sample UAE163 was taken from a pegmatitic gabbro associated with the Bithnah facies
58 of the younger gabbros at grid reference [413816 2786470]. Four separate zircon
59
60
61
62
63
64
65

1
2
3
4 fractions from this sample gave concordant analyses with a Concordia age of $95.74 \pm$
5
6 0.32 Ma (Fig. 8b).

7
8 Sample UAE180 was taken from the felsic part of a mingled-magma ('vinaigrette')
9
10 intrusion within the Fujairah facies of the younger gabbros at grid reference [423702
11
12 2781090]. This sample contained very low-U zircons and out of twelve separate multi-
13
14 grain fractions, three gave reliable analyses, producing a Concordia age of 95.26 ± 0.31
15
16 Ma (Fig. 8c).

17 18 19 20 **MINERAL CHEMISTRY OF THE OPHIOLITE UNITS**

21
22 Major-element chemistry of minerals from a small subset of ophiolite rocks was obtained
23
24 by electron microprobe analysis (EPMA) of carbon-coated polished thin sections, carried
25
26 out at the British Geological Survey, Keyworth, UK. The EPMA analyses were obtained
27
28 using a Cameca SX50 wavelength dispersive electron microprobe. The rocks were
29
30 analysed using an accelerating potential of 15kV and a 20nA beam current. Elements
31
32 were analysed using the PET, LiF and TAP diffracting crystals, calibrated using internal
33
34 mineral and pure metal standards. All Fe was measured as FeO and mineral formulae
35
36 were calculated by the Cameca software. For every sample clinopyroxene and plagioclase
37
38 were analysed by selecting ~10 examples and analysing the core and rim of each crystal.
39
40 Using these data, averages were calculated to characterise the mineral chemistry of the
41
42 rocks; a summary of the data is presented in Table 2. Magnesium numbers (Mg#) were
43
44 calculated as $Mg\# = \text{atomic Mg} / (\text{Mg} + \text{Fe}^{2+}) \times 100$.

45
46 A total of 50 samples of the gabbroic rocks were analysed, as well as eight samples of
47
48 wehrlite. The clinopyroxenes in all the different gabbros were found to have
49
50 clinopyroxene Mg# between 70 and 95, whilst all analysed plagioclases have anorthite
51
52 contents above 50%, and more commonly above 70%. The wehrlite samples have high
53
54 clinopyroxene Mg#s, > 85, and anorthite contents > 80%, but they clearly fall within the
55
56 same range as the layered gabbro. Closer study shows that, at any given feldspar An%,
57
58 many of the younger gabbros have lower clinopyroxene Mg#s than the gabbros of the
59
60 early crustal section, though complete separation of the two suites is not possible (Fig. 9).
61
62 Mineral compositions of the wehrlites plot with those of the layered gabbro rather than

1
2
3
4 the younger gabbros. This difference between the gabbros accords with the work of
5 Yamasaki et al. (2006), who used major element chemistry to recognize two gabbroic
6 suites (GB1 and GB2) in the Wadi Haymiliyah section of the ophiolite in Oman. The
7 dividing line between their two suites does not fully discriminate the two gabbroic suites
8 in the UAE (Fig. 9), but in general the UAE younger gabbros are more similar to the GB2
9 suite. Similar mineral chemistry features have been recognized in the Fizh-South
10 intrusions (Adachi and Miyashito 2003). The clinopyroxenes of the UAE younger
11 gabbros are also characterized by lower Al₂O₃ contents than those of the main crustal
12 section (0.7 – 2.5% in the younger gabbros; 2.0 – 3.3% in the layered and high-level
13 gabbros and in the wehrlites). The TiO₂ contents of clinopyroxene from all the gabbros
14 and wehrlites overlap, lying between 0.1 and 0.7%; the orthopyroxene-bearing younger
15 gabbros have TiO₂ contents < 0.3%, whereas those of the Bithnah facies gabbros range
16 between 0.3 and 0.7%. In general, the clinopyroxenes of the younger gabbros have a
17 lower Mg# at any given TiO₂ content than those in the gabbros of the early crustal section
18 and the wehrlites.

31
32
33

34 **GEOCHEMISTRY OF THE OPHIOLITE UNITS**

35
36
37 Whole-rock samples representing all the rock-types of the ophiolite have been analysed
38 for major, trace and rare-earth elements by ICP-OES and ICP-MS at Cardiff University,
39 UK. Over 150 of these samples were from rocks of the crustal section and the intruding
40 younger gabbros and wehrlites, and these data are presented in Table 3. Full analytical
41 procedures are documented by Lilly (2006).
42
43
44
45

46
47 In Oman, most detailed geochemical studies have been carried out on the volcanic rocks,
48 which provide the most direct way of studying the chemistry of the magmas (e.g
49 Alabaster et al. 1982; Einaudi et al. 2000). However, in the UAE, outcrops of the
50 volcanic section are limited, and so magmatic variations have to be deduced from dykes
51 and from the plutonic rocks. Analysis shows that most of the gabbros are cumulate, as
52 indicated by geochemical features such as positive Eu anomalies and depletion in
53 incompatible elements and the LREE (Fig. 10). Their whole-rock geochemistry thus does
54 not represent the original magma compositions, although ratios of elements that are
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 similarly compatible may provide information about the magmas. Despite careful sample
5 selection, the chemical compositions of the rocks may also have been affected by
6 hydrothermal alteration. This alteration has chiefly affected some major elements and the
7 Large Ion Lithophile Elements; other trace elements have remained relatively immobile
8 (Lilly, 2006).
9

10
11
12
13
14 All the gabbros (layered, high-level and younger gabbros) have SiO₂ contents between 40
15 and 53 wt%, MgO between 5 and 15 wt%, and TiO₂ commonly <0.4 wt%. In general, the
16 gabbros are difficult to distinguish on the basis of their whole-rock chemistry: an
17 example is given by the TiO₂ – Mafic Index gabbro discrimination plot of Serri (1981), in
18 which all the gabbro types overlap, the majority lying within the low Ti field which is
19 considered to represent supra-subduction zone ophiolites (Fig. 11). Similar features are
20 seen on a plot of Nb/Yb vs La/Nb (Fig. 12); the younger gabbros perhaps tend towards
21 lower Nb/Yb ratios and higher La/Nb ratios than the layered and high-level gabbros, but
22 there is much overlap. An interesting exception to the typical variation is the
23 orthopyroxene-bearing younger gabbros, which can be easily distinguished on this plot
24 by their high Nb/Yb and low La/Yb ratios. They are most clearly characterised as having
25 a La/Nb ratio < 1, whereas all the other gabbros have La/Nb > 1. The association of high
26 Nb contents with orthopyroxene in the gabbros might be interpreted to suggest that Nb is
27 concentrated in the orthopyroxene, but in fact Nb is incompatible in orthopyroxene
28 (Kelemen and Dunn 1992). The unusually high Nb contents thus appear to be a feature of
29 the original magmas, but the origin of these magmas would require further study.
30
31

32
33
34 In contrast to the gabbros, the whole-rock chemistry of the microgabbro dykes typically
35 represents magma compositions that have been unaffected by cumulus processes, and
36 these provide a clearer picture of magma evolution with time in the UAE part of the
37 ophiolite. All samples show wide variation in the mobile elements Rb, Sr, Ba and Th
38 (Fig. 13), but the other trace elements are relatively immobile (Lilly, 2006).

1
2
3
4 few outcrops that occur in the UAE, have similar patterns. These compositions essentially
5 match those of the Geotimes unit identified in the Oman volcanic rocks by Alabaster et
6 al. (1982) and are the most similar in chemistry to MORB.
7
8
9

10 Many of the dykes found in both the Khor Fakkan and Aswad blocks represent part of the
11 later magmatic suite. Many can be identified as later intrusions in the field because they
12 cut, or are associated with, younger gabbro bodies; others are characterised by distinctive
13 chemical features that differ from those of the sheeted dyke complex. These dykes are
14 typically basalt or basaltic andesite in composition. Many of them have clear negative
15 Nb, Ta, Zr and Hf anomalies on MORB-normalised spider diagrams (Fig. 13). The
16 majority of these dykes are characterised by LREE depletion, although some samples
17 have more 'u-shaped' boninitic patterns with depletion of the MREE (Fig. 13). They are
18 geochemically similar to the Clinopyroxene-phyric and Lasail units identified by
19 Alabaster et al. (1982) in Oman.
20
21
22
23
24
25
26
27
28

29 The youngest dykes found in the UAE are a group of basaltic dykes, chiefly occurring in
30 the Khor Fakkan block, some of which cut rocks of the mantle section. These dykes have
31 strongly LREE-enriched compositions (Fig. 13), and compare to the lavas of the Salahi
32 Unit of Oman (Alabaster et al. 1982).
33
34
35
36

37 The three different groups of dykes found in the UAE can be clearly identified by a
38 number of common discrimination plots (Fig. 14). On a plot of Ti versus V (Fig. 14a), the
39 pillow lavas and sheeted dykes can be seen to have Ti/V ratios > 20 , which is a feature of
40 MORB (Shervais 1982). Most of the later dykes have Ti/V ratios < 20 (and many < 10),
41 placing them in the field of island arc basalts. The youngest, enriched dykes have higher
42 Ti/V ratios, approaching the values expected for alkaline rocks. On a Zr versus Zr/Y
43 diagram (Fig. 14b; Alabaster et al. 1982), the pillow lavas and sheeted dykes plot within
44 the MORB field, whereas the younger dykes plot in or below the field of island-arc
45 basalts. Again, the later, enriched, Salahi-type dykes are distinguished by this plot. On a
46 Cr/Y plot (Fig. 14c; Pearce 1982) the sheeted dykes and pillow lavas, and the late
47 enriched dykes plot in or close to the MORB field, whereas the other dykes plot in the
48 island arc basalt field. On the Th/Yb – Nb/Yb plot of Pearce (2008) (Fig. 14d), most of
49 the pillow lavas and sheeted dykes fall in the MORB end of the oceanic basalt array,

2
3
4 although some are displaced towards the volcanic arc field; the majority of the dykes
5 associated with the later magmatic sequence fall above the oceanic basalt array,
6 indicating an arc component. The later enriched dykes are displaced to the higher Nb/Yb
7 area that is typically associated with alkaline, OIB-like volcanics.
8
9

10 11 12 13 14 **DISCUSSION**

15
16 Detailed field data from the BGS mapping project in the UAE have clearly indicated the
17 presence of voluminous younger magmatism within the Oman – UAE Ophiolite. This
18 later magmatic sequence includes wehrlite and pyroxenite that intrude the Moho
19 Transition Zone and the lower part of the early crustal section, as well as larger gabbro
20 bodies with dioritic and tonalitic to trondhjemitic components, and microgabbro dykes,
21 all of which intrude the higher parts of the early crustal section. Although components of
22 a similar younger magmatic sequence have been identified in Oman (Ernewein et al.
23 1988; Juteau et al. 1988; Shervais 2001; Dilek and Flower 2003; Adachi and Miyashita
24 2003; Yamasaki et al. 2006), they have typically been described as distinct intrusive
25 complexes. This contrasts with the pervasive later magmatic sequence that has been
26 mapped out in detail across much of the ophiolite outcrop in the UAE.
27
28

29
30 New geochronological data indicate that the later magmatic sequence in the UAE formed
31 over a period of around 1.2 million years, between c. 96.40 and 95.26 Ma. The
32 magmatism in the early crustal section is constrained to before 96.40 ± 0.29 Ma, but its
33 exact age and duration are not known; it is likely to have formed during the preceding 1-2
34 million years (Rollinson 2009). The date of 95.26 ± 0.31 Ma obtained in this study for a
35 tonalitic sample is essentially identical to the age given by Warren et al. (2005) for a
36 trondhjemite intrusion from the ophiolite in Oman, indicating that emplacement of the
37 later magmatic sequence was occurring along the length of the ophiolite at broadly the
38 same time. Obduction of the ophiolite began around 94.5 Ma (Warren et al. 2005), less
39 than one million years after the later sequence of magmatism had ceased, indicating that
40 it is likely to have formed in a marginal, supra-subduction zone environment rather than
41 at a mid-ocean ridge (Warren et al. 2005; Styles et al. 2006).

1
2
3
4 The early crustal section of the Oman – UAE Ophiolite has commonly been considered to
5 have formed from MORB-like magmas at a constructive plate margin (Lippard et al.
6 1986; Boudier and Juteau 2000), although some authors have suggested formation in a
7 back-arc basin environment (Pearce et al. 1981) or a zone of spreading above a nascent
8 subduction zone (Shervais 2001). In the UAE, the crystallisation sequences of early
9 crustal gabbros are those that would be expected from MORB magmas. The
10 geochemistry of pillow lavas and sheeted dykes is broadly similar to that of MORB, but
11 some aspects appear transitional towards island arc-type magmas. Similarly, some gabbro
12 samples from the early crustal section show geochemical features more characteristic of
13 island arc settings. In general, then, evidence from the UAE fits with the theory that the
14 early crustal section was formed from MORB-like magmas at a spreading centre that was
15 in close proximity to a zone of subduction initiation (Dilek and Furnes, 2009).
16
17

18 The origin and internal relationships of the later magmatic sequence in the UAE are
19 rather more complicated, due to the presence of a number of different components. These
20 are discussed in turn below.
21
22

23 The Moho Transition Zone in the UAE can be divided into a massive dunite unit and the
24 upper Mixed Unit, as described above. The massive dunite unit is considered to be
25 residual, as described by Nicolas and Prinzhofer (1983), but the overlying Mixed Unit
26 clearly represents multiple phases of intrusion. During the earliest of these, layered
27 gabbros were formed at the base of the early crustal section. The mode of formation of
28 these layered gabbros has been the source of some considerable debate, as summarised by
29 Macleod and Yaouancq (2000). They may, at least in part, have been injected as sills as
30 suggested by Kelemen et al. (1997); but in the UAE, the lower layered gabbros have been
31 so much disrupted by later magmatism that it is difficult to draw definitive conclusions.
32
33

34 Following formation of the early crustal section, the Mixed Unit developed through the
35 intrusion of large volumes of ultramafic, chiefly pyroxenitic and wehrlitic, magmas.
36 These ponded close to the base of the crust, with offshoots rising up through the crust and
37 spreading out to form wehrlite and melagabbro sills within the layered gabbro sequence.
38 At the base of the crust, blocks and sheets of layered gabbro were stoped, surrounded and
39 disrupted by intrusive ultramafic material, forming xenoliths. Locally, the margins of

63
64
65

1
2
3
4 these xenoliths were partially assimilated by the intruding magmas, producing
5 gradational contacts with 'ghost' layering.
6

7
8 Petrographical analysis shows that the wehrlites have a different mineral crystallisation
9 sequence to that expected for MORB, with early crystallisation of pyroxenes which
10 indicates more hydrous melts (Yamasaki et al. 2006; Koepke et al. 2009), typical of
11 magmas formed above subduction zones. Some previous workers (e.g. Juteau et al. 1988)
12 have interpreted this crystallisation sequence as indicating that the wehrlites were formed
13 from a different parental magma to the layered gabbros. However, others have questioned
14 this, suggesting that the majority of wehrlites record equilibration with parent melts that
15 were similar to MORB (Koga et al. 2001). Adachi and Miyashiro (2003) were able to
16 recognise two groups of wehrlites in Oman, one of which was chemically similar to the
17 layered gabbros, whilst the other (the Fizeh-South complex) was distinctly different and
18 considered to be later.
19
20
21
22
23
24
25
26
27
28

29 In the UAE, the mineral chemistry of the analysed wehrlites appears to overlap with that
30 of the layered gabbro and to be distinct from that of the younger gabbros. However, field
31 relationships clearly show that the large wehrlite bodies were intruded following
32 crystallisation of the early crustal gabbros; and the crystallisation sequence indicates that
33 there must have been some change in the parental magma, probably due to the addition of
34 fluids. This in itself is enough to identify the wehrlites as part of a second magmatic
35 phase, although the origin of the parental magma is not clear.
36
37
38
39
40
41

42 As with the wehrlitic intrusions, field relationships show that the younger gabbros clearly
43 cross-cut the gabbros of the early crustal section. Relationships between the younger
44 gabbros and wehrlites are less clear, although at the few localities where they are seen
45 together, the younger gabbros appear to intrude the wehrlites.
46
47
48
49

50 Petrographical analysis shows that a phase of the younger gabbros crystallised
51 orthopyroxene at an early stage. Earlier crystallisation of pyroxenes is considered to
52 indicate more hydrous melts (Yamasaki et al. 2006), and thus is linked to magmas formed
53 above subduction zones. Mineral analysis indicates generally lower Mg# in
54 clinopyroxene (at given feldspar An contents) in the younger gabbros than in the gabbros
55 of the early crustal section. This has also been recognised in Oman as a diagnostic feature

3
4 for younger gabbros, which have been proposed to have formed in a supra-subduction
5 zone setting (Yamasaki et al. 2006).
6
7

8 The whole-rock chemistry of the younger gabbros shows characteristics related to
9 cumulate processes, so that it can be difficult to interpret these data in terms of magma
10 compositions. However, in general, the younger gabbros have some geochemical features
11 that are commonly ascribed to supra-subduction zone magmas, such as lower TiO₂ and
12 lower Nb contents. An exception to this is the orthopyroxene-bearing facies, which shows
13 unusually high whole-rock Nb contents; the origin of these unusual magmas is uncertain.
14
15
16
17
18
19

20 Associated with the later magmatic sequence are a number of microgabbro and basalt
21 dykes. As discussed above, the dykes can be divided into three clear groups on the basis
22 of their geochemistry. The first group, which has a MORB-like geochemistry, occurs as
23 dykes in the sheeted dyke complex or in the high-level gabbros; these dykes are always
24 <2 m thick and north- to NNW-trending. The second group has more variable field
25 relationships, but includes dykes that are found within the rocks of the later magmatic
26 sequence, and thus can clearly be shown to be part of this later set of intrusions. This
27 group of dykes has many of the geochemical features that are associated with island arc
28 magmatism. They include some dykes with boninitic chemistry, which is generally
29 considered to be a good indicator of the onset of subduction (Pearce et al. 1984). The
30 third group is a volumetrically minor phase of enriched magmatism; these dykes are
31 found at a variety of structural levels, including the mantle section, and so are considered
32 to be among the youngest intrusions in the UAE part of the Oman – UAE ophiolite.
33
34
35
36
37
38
39
40
41
42
43

44 This division into three magmatic phases, based on dyke geochemistry, fits with divisions
45 recognised in the volcanic pile of the Oman section of the ophiolite (e.g. Alabaster et al.
46 1982, Lippard et al. 1986). The MORB-like intrusions belonging to the early crustal
47 section correspond to the Geotimes unit of Alabaster et al. (1982); the dykes associated
48 with the later magmatic sequence show more similarity to the Lasail unit; and the
49 youngest, enriched dykes correspond to the Salahi unit. Many workers in Oman have
50 similarly identified later phases of magmatism within the intrusive rocks, although these
51 have typically been volumetrically restricted (examples include the Lasail Complex of
52 Lippard et al. 1986; the Fizh-South Complex of Adachi and Miyashiro, 2003; and the
53

1
2
3
4 DWGB2 suite of Yamasaki et al. 2006). Two stages of melt production have also been
5
6 recognised from study of chromites in the mantle section (Python et al. 2008; Dare et al.
7
8 2008; Rollinson 2008). The newly mapped later magmatic sequence of the UAE
9
10 represents the first time that these younger intrusions have been recognised on such a
11
12 large scale.

13
14 The origin of the younger intrusions within the Oman – UAE Ophiolite has long been a
15
16 matter for debate. Many authors have attributed them to the onset of subduction, citing
17
18 their chemical resemblance to arc-type basalts (e.g. Alabaster et al. 1982; Umino et al.
19
20 1990; Searle and Cox 1999; Shervais 2001; Ishikawa et al. 2002; Dilek and Flower 2003;
21
22 Arai et al. 2006; Yamasaki et al. 2006; Lilly 2006). However, others have suggested
23
24 different mechanisms, such as melt/rock interaction between the shallow upper mantle
25
26 and melts produced by high degrees of melting of previously depleted mantle (Godard et
27
28 al. 2006).

29
30 Our work in the UAE provides several separate strands of evidence that indicate a supra-
31
32 subduction zone setting for the later magmatic sequence: 1) widespread, heterogeneous
33
34 intrusions that do not show the physical features expected of MORB magmatism, but
35
36 instead cut across the early mantle and crustal ophiolite sections; 2) emplacement of the
37
38 later magmatic sequence less than 1 Ma before the start of obduction; 3) petrological data
39
40 consistent with the involvement of hydrous magmas; 4) mineral and whole-rock
41
42 geochemical data that show features, such as low Ti and Nb, and high Th, associated with
43
44 SSZ settings. A trend of increasing influence of SSZ processes towards the north-west of
45
46 the ophiolite has been suggested on the basis of work in Oman (Python et al. 2008) and
47
48 the later magmatic sequence of the UAE could represent the culmination of this trend.
49
50 We suggest that subduction initiation may have occurred at an earlier stage in the north-
51
52 west, thus allowing the generation of the voluminous later magmatic sequence of the
53
54 UAE.

55 56 57 58 59 60 61 62 63 64 65

1. The northern end of the Oman – UAE Ophiolite, exposed in the UAE, is
characterised by early, ‘classic’ ophiolite mantle and crustal sections cross-cut by

1
2
3
4 a voluminous later magmatic sequence which can constitute up to 50% of the total
5 exposure.
6

- 7
8 2. The magmas of the early crustal section were formed before c. 96.4 Ma, at a
9 spreading centre, either on a mid-ocean ridge or in a marginal basin.
10
11 3. The magmas of the later magmatic sequence were formed between c. 96.4 and c.
12 95.2 Ma, above a newly initiated subduction zone. They show many features of
13 SSZ-type magmas, including petrological evidence for hydrous magmas and
14 geochemical evidence for depletion in Ti, Nb and LREE relative to MORB.
15
16 4. Emplacement of the later magmatic sequence ended with obduction of the
17 ophiolite around two million years after the onset of subduction.

In: Malpas, J, Moores E M, Panayiotou A, Xenophontos C (eds) Ophiolites: Oceanic
Crustal Analogues. Proceedings of the Symposium "Troodos 1987" Geological Survey
Department, Cyprus, Nicosia. pp 375-395

Warren, C J, Parrish, R R, Waters, D J, Searle, M P (2005) Dating the geologic history of
Oman's Semail ophiolite: insights from U-Pb geochronology. Contributions to
Mineralogy and Petrology 150: 403-422

Yamasaki, T, Maeda, J, Mizuta, T (2006) Geochemical evidence in clinopyroxenes from
gabbroic sequence for two distinct magmatisms in the Oman ophiolite. Earth and
Planetary Science Letters 251: 52-65

5 **Figure list**
6

7 Figure 1: Overview map showing the location of the main blocks of the Oman-UAE
8 ophiolite (ophiolite blocks shown in grey), after Lippard et al. (1986).
9

10
11 Figure 2: Simplified geological map showing the main features of the ophiolite in the
12 UAE, after British Geological Survey (2006).
13
14

15 Figure 3: Cartoon of a hypothetical vertical section illustrating the main features of the
16 Moho Transition Zone in the UAE. The vertical extent from the top of the harzburgite to
17 the base of the layered gabbro varies from a few tens of metres to more than a kilometre.
18
19

20
21 Figure 4: Photographs of Mixed Unit outcrops, showing paler-coloured gabbro enclaves
22 isolated within darker-coloured, intrusive wehrlites. Tabular shape of enclaves is
23 controlled by layering. Hammer for scale, c. 30 cm long. Photographs © Ministry of
24 Energy, UAE.
25
26
27

28
29 Figure 5: Cartoon illustrating the pervasively sheeted and cross-cutting nature of the
30 younger gabbros.
31
32

33 Figure 6: Photographs showing the relationships of the later magmatic sequence: a)
34 sheets of pale-coloured younger gabbro cut darker Mixed Unit lithologies across a
35 hillside (view about 1 km across); b) “Vinaigrette” sheet associated with the later
36 magmatic sequence truncates layering in layered gabbro in a new road cutting, figure for
37 scale; c) Irregular sheet of younger gabbro cuts across layering in layered gabbro, figure
38 for scale; d) Close-up of margin of younger gabbro dyke cutting layered gabbro. Pen c.

4 Figure 10: N-MORB normalized trace element patterns for representative samples of
5 layered gabbro (black), high-level gabbro (white) and younger gabbro (grey).
6 Normalising factors from Sun and McDonough (1989).
7
8
9

10 Figure 11: TiO_2 versus Mafic Index plot for whole-rock gabbroic samples, after Serri
11 (1981).
12
13

14 Figure 12: Nb/Yb vs La/Nb plot for whole-rock gabbroic samples.
15
16

17 Figure 13: N-MORB normalized trace element patterns for representative samples of
18 pillow basalt and sheeted dyke complex (white), dykes associated with the later
19 magmatic sequence (grey) and late, enriched dykes (asterisk). Normalising factors from
20 Sun and McDonough (1989).
21
22
23

24 Figure 14: a) Ti versus V plot for lavas and dykes. Lines indicate constant Ti-V ratios; b)
25 Zr versus Zr/Y plot for lavas and dykes. Fields after Alabaster et al. (1982): MORB –
26 Mid-ocean Ridge Basalt, IAT – Island Arc Tholeiite; c) Cr vs Y plot for lavas and dykes.
27 Fields after Pearce (1982), names as in c); Nb/Yb versus Th/Yb plot for lavas and dykes.
28 MORB-OIB array after Pearce (2008).
