ABSTRACT

This paper presents the main approaches used to synthesize talking faces, and provides greater detail on a handful of these approaches. No system is described exhaustively, however, and, for purposes of conciseness, not all existing systems are reviewed. An attempt is made to distinguish between facial synthesis itself (i.e the manner in which facial movements are rendered on a computer screen), and the way these movements may be controlled and predicted using phonetic input.

1 INTRODUCTION

Since the pioneering work of Parke, Plat and Waters, the computer graphics community has maintained a high level of interest in trying to reproduce realistic facial movements for speech, facial expression, and for activities such as chewing or swallowing. A key event in animation was the film "Tony de Peltrie" [4] produced from the University of Montreal where the animation (speech and expression) of the face of the main character (see Figure 1) was the main way of telling the story. This short film popularized the use of shape interpolation between key frames for facial animation.

For nearly 30 years the conventional approach to synthesize a face has been to model it as a 3D object. In these *model-based* approaches, control parameters are identified that deform the 3D structure using geometric, articulatory or muscular models. Nowadays such comprehensive approaches are challenged by *image-based* systems where segments of videos of a speaker are retrieved and minimally processed before concatenation. This evolution, surprisingly, parallels - with a quicker dynamics - the evolution of acoustic synthesis, where corpus-based synthesis tends to wipe out decades of research on parametric (articulatory then formant) synthesis. The more direct link between articulation and facial deformation, compared to acoustics, together with the need for giving the gift of speech to virtual non-human creatures help, in case of facial animation, to maintain a balance between the two approaches.

We will first describe some of the main features of these two approaches, trying to distinguish between control and graphic rendering of the face. Then we will comment on the few evaluation results comparing the performance in terms of intelligibility, ease of comprehension and general acceptability by end users. We will finally argue for *data-driven* comprehensive 3D models of facial deformation that take into account underlying articulatory control of the musculo-skeletal system.

2 MODEL-BASED VISUAL SYNTHESIS

The models that will be presented in this section have in common the aim to reproduce visible 3D facial movements with realistic motions. They differ in the way motion is actually implemented and controlled. Most model-based talking heads used in current text-to-audiovisual speech synthesizers are descendants of Parke's [29, 30] software and his particular 3-D talking head. This line of models should be classified as terminal-analog synthesizers in the sense that do not aim at understanding the underlying physiological mechanisms that produce the speech signals and the facial deformations, but only attempt to reproduce them in geometrical terms. We will first describe briefly such a *geometric* approach and then mention some partial *biomechanical* models of speech articulators that are under development.

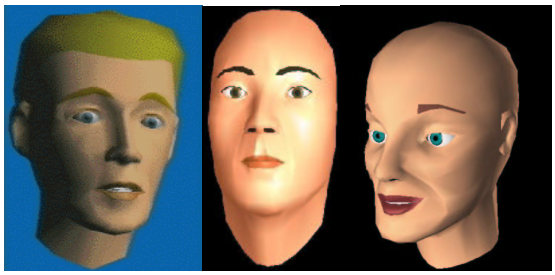

Figure 2: *A gallery of Parke's descendents. From left to right: Sven from KTH, Baldi from PSL, the LCE talking head.*

2.1 Parke's descendants

PSL's Baldi [21], KTH's [5, 6] and LCE's [27] Talking Heads, are all 3D computer graphic objects defined by a set of 3D meshes describing the surface geometry of various organs (skin, teeth, eyes, etc…) involved in the production of speech. These polygonal surfaces typically connect a few hundred 3D vertices (see Figure 2). Such articulated meshes are often used as generic models in model-based movement tracking systems [15, 42] (see Figure 3).

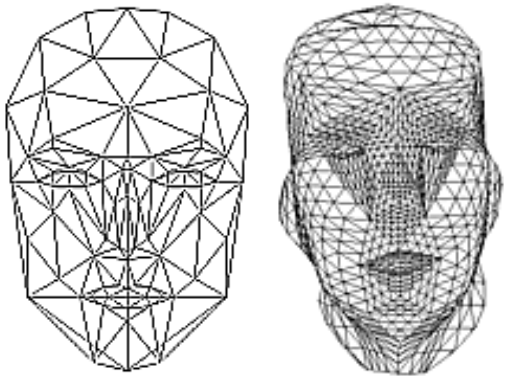

Figure 3: *3D meshes commonly used for tracking head postures and face movements. From left to right: Candide [37] and Eisert's MPEG4 compliant articulated head [42].*

Control parameters move vertices (and the polygons formed from these vertices) on the face by simple geometric functions such as rotation (e.g. jaw) or translation of the vertices in one or more dimensions (e.g., mouth opening or widening). Effects of these basic operations are tapered within specified regions of the face and blended into surrounding regions. Interpolation is also used for most regions of the face that change shape (cheekbones, neck, mouth…) or for generating facial expressions. Each of these areas is independently controlled between extreme shapes and associated with a parameter value. Eyes are often modeled by a specific procedure that typically accepts parameters for eye position, eyeball orientation and size, iris color and size or pupil size.

Note that these control parameters are quite heterogeneous: they can be the 3-D coordinates of a single point such as lip corners, or they can drive complex articulatory gestures such as the tuck for labiodentals, or more complex facial expressions such as smiling or surprise.

Such a synthesis strategy has become a standard in the context of the industrial *ISO/IEC MPEG-4* norm [14, 35]. The 3D coordinates of the 84 Feature Points (FPs) are controlled by a set of 68 FAPs (Facial Action Parameters) that "are responsible for describing the movements of the face, both at low level (*i.e.* displacement of a specific single point of the face) or at high level (*i.e.* reproduction of a facial expression)" [35, p. 33].

2.2 Articulatory degrees-of-freedom

In the previous models, *geometric* degrees-of-freedom of some characteristic *FPs* of the 3D meshes were considered. Three main problems arise when piloting mesh deformations from such FPs:

1. FAPs are at the same time *geometric* and *articulatory* degrees-of-freedom. The jaw feature point (taken as the mean position of the two lower incisors) acts also as the mean carrier of the lip movements. There is thus a contradiction between an extrinsic geometric control of the lip aperture and the intrinsic *articulatory* control between lips and jaw. This antagonism is solved in MEPG4 by the laconic instruction associated with FAP3 *open_jaw* "does not affect mouth opening" [40, p.412]
2. Most FAPs are low level, and do not take into account speech-specific gestures, which led Vignoli & Braccini [43] to add another layer of control parameters, called APs (Articulatory Parameters), corresponding to mouth height, mouth width, protrusion and jaw rotation, that control the FAPs.
3. Although these APs constitute a more comprehensive set of *articulatory* degrees-of-freedom, they do not solve the problem of extrapolating the movement of tens of

vertices starting from the displacement of a single feature point.

Instead of ad hoc tapering or shape interpolation, we have proposed elsewhere [1, 18, 36] to define APs as *articulatory* degrees-of-freedom delivered by a guided statistical analysis of 3D coordinates of hundreds of facial fleshpoints (see §6).

2.3 Skin and muscle-based facial animation

Vertices of the previous 3D meshes can in fact be considered as fleshpoints. A more comprehensive way of addressing the problem of modeling facial deformation due to underlying movements of the speech organs is to simulate the biomechanical properties of skin tissues and of the musculo-skeletal systems.

Instead of geometric control parameters, facial movements are here directly controlled by muscular activations that are supposed to be more directly connected to communicative intentions. Ekman and Friesen [16, 17] thus established the Facial Action Coding System (FACS) that describes facial expressions by means of 66 muscle actions.

Muscles apply forces to sets of geometric structures representing soft objects, in particular skin tissue. The simplest approach to skin tissue emulation is a collection of strings connected in a network [34] then organized in layers [41, 44]. Instead of the infinitesimally thin surface with no underlying structure considered in geometric models and the simplest muscle-based models (see Figure 4), the facial mesh is organized in layers - typically three: epidermal, dermal and subcutaneous (muscular) layers as in Waters & Terzopoulos models (see Figure 6) - where transverse deformation modes, volume conservation or more complex deformation models such as finite-element modeling (see Figure 5) are considered.

Although such models can potentially separate out the active contribution of muscular activation from the passive contribution of the skin tissues and of the musculo-skeletal structure to the resulting skin deformation, the dimensionality of the control space is very high compare to the degrees-of-freedom (DOF) of the facial geometry effectively used in the task. The muscular system is highly redundant and movements typically recruit a few dozen individual muscles whose actions need to be coordinated, sometimes in a very precise way (see §4.2).

3 IMAGE-BASED VISUAL SYNTHESIS

In the past decade, a series of new systems based on more simple image processing techniques has emerged. These systems consider how the color of each pixel in an image of the face changes according to the sound produced. These image-based systems have the potentiality to generate hyper-realistic images since minimal image processing is performed on large sets of natural videos. We

will distinguish here between two "families" of systems: (a) systems consisting in selecting appropriate segments of a large database and patching selected regions of the face on a background image; (b) systems that consider facial or head movements as displacements of pixels.

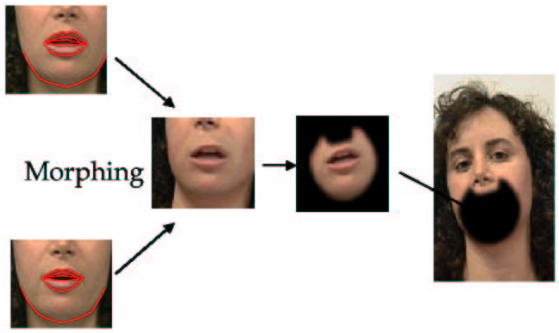

Figure 7: *VideoRewrite consists in patching at the right position of the background image the mouth shape obtained by blending appropriate regions of images of the database.*

Figure 8: *VideoRewrite estimates the best insertion planes for each head posture***.**

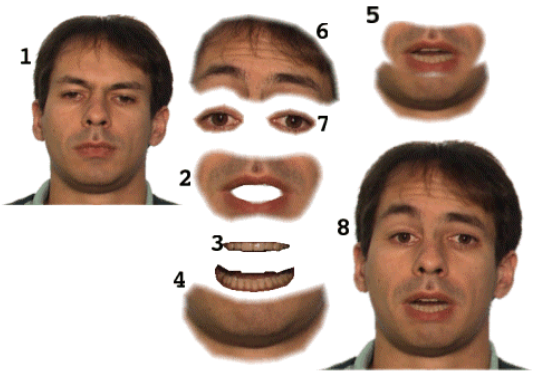

Figure 9: *In the sample-based ATT Talking Face, the head is decomposed into several facial parts. To generate a novel appearance, base head (1) is combined with mouth (5), eyes (7) and brows (6). The mouth area is generated by overlaying lips (2) on upper teeth (3) and lower teeth + jaw (4). This allows animating a jaw rotation independent of the lip shape***.**

3.1 Overlaying facial regions

The most illustrative system involving the overlapping of facial regions is VideoRewrite [8]: as seen in Figure 7, sequences of mouth shapes are morphed, roto-translated and overlaid with a background video. The morphing smooths out concatenation artifacts. Then the mouth patch is morphed onto an insertion plane approximating the head orientation (see Figure 8). This step is essential (a) for collecting coherent mouth shapes at the training stage, especially when the blending between morphed mouth shapes will be computed and (b) for the perceptual fusion between head and facial movements at synthesis time.

Although this technique seems to be completely data-driven, VideoRewrite also uses an underlying parameterization of mouth shapes in the selection process: the selection of visual triphones uses dynamic programming where a distance term involves these underlying parameters while *jaw lines* should be determined to obtain a realistic blending between the background video and mouth shapes.

The VideoRewrite principle can also be applied to a more complete decomposition of the face. In the sample-based ATT Talking Face [12, 13], Cosatto & Graf decompose the face into 6 regions comprising the eyes, the mouth, the teeth and the chin. Such a further decomposition reduces the number of parameters needed to describe each region which in turn could be controlled in an independent manner. It is therefore the responsibility of the control model to capture and restore the coordination between the control parameters of the different regions, while bigger regions have the advantage of maintaining coherence despite possible inaccurate estimation of optimal control parameters.

3.2 Moving pixels

Instead of considering the deformation/ movement of whole regions of the face, MikeTalk [19] tries to reproduce speech movements by computing displacements of pixels on the screen. MikeTalk computes an optical flow to find where each pixel of a source image projects/moves in a target image. Interpolation between two images A and B – visemes in the case of MikeTalk - is performed by blending results of the optical flow computation from A to B and B to A. Any remaining "holes" in the interpolated images

are patched using neighboring pixels. Inter-viseme optical flows can be cumulated and a further model of optical flow deformation can also be evaluated using Principal Components Analysis (PCA). First components have a clear articulatory interpretation in terms of jaw and lip movements. Moreover fine details such as lip raising movements as required for the production of labiodentals emerge clearly from the data, showing the excellent and precise job made by the computation of the optical flow.

Figure 10: *MikeTalk computes and blends two optical flows in order to symmetrically morph between two visemes*

4 CONTROL MODELS

We will consider here the problem of how coordinative structures of control parameters can be implemented in practical terms given actual trajectories to be reproduced. We will not address the problem of how muscular activations actually drive the articulators (please refer to the discussion of the equilibrium hypothesis for speech in [32]).

4.1 Visemes

The basic control model for speech articulation consists in interpolating between a finite set of visual targets that can be mapped with the center of realizations of phonemes in context. Visemes can thus be defined as allophonic visual realizations of phonemes. Benoit and colleagues [3] identified 21 visemes that constitute the "labial space" of the French speaker they analyzed. Although such a control strategy, maintaining the facial coherence in the vicinity of targets, is still used in quite a number of systems (especially in image-based synthesis - for example in MikeTalk), it does not take into account asynchronies between movement transitions of different articulators observed in natural speech. Consequently it is sometimes difficult to identify a unique target for each viseme in each parametric trajectories. One solution is to increase the number of such allophonic variations and increase the complexity of the rule-based control system or to use a more speech-specific coarticulation model.

4.2 Coarticulation models

Instead of a nomenclature of all possible (visual) realizations of phonemes in context, coarticulation models specify algorithmically how context-independent targets are combined. The most popular system for driving parametric facial models is Cohen & Massaro's coproduction model [11]: control parameters for each context-independent target are blended spatially and temporally according to weighting factors for each phoneme considered.

Ohman's model [25], originally applied to lingual coarticulation in occlusives, has also been applied successfully to facial data [18]. This model first identifies two groups of gestures on which the coarticulation will operate: a slowly varying vocalic gesture and rapid consonantal gestures that aim at producing certain constrictions given the underlying vocalic gestures. Consonants and vowels thus play asymmetrical roles in the coarticulation model: the vocalic gesture is computed first, then context-sensitive consonantal targets are computed as modulated deviations from the underlying vocalic gesture.

Note that most control models used for more general motor planning identify two or more different representation spaces for motor planning and control [2]. They distinguish between the control space for movement planning, called the *distal* space, and the control parameters of the plant itself, the *proximal* space. Muscular activations are such proximal commands while lip geometry or coronal contact can be considered as distal targets. Such control models [9] require an inversion process able to deal with incomplete distal specification and some movement optimization such as minimum force, torque or jerk requirements.

4.3 Triphone models

In the previous approaches, parametric trajectories are essentially controlled by target interpolation using predefined transition functions. As video-based movement tracking and motion capture systems become more and more accessible, and video storage for post-processing can be envisaged, it is no longer necessary to use coarticulation models for extrapolating from a limited range of data.

Whole control trajectories can be stored into segment dictionaries, selected, retrieved and further processed before concatenation. So a new class of visual speech synthesis systems [8] exploit the same popular data-driven techniques as used for acoustic synthesis… and face the same problems of determining the optimal selection criteria and smoothing algorithms.

Note the kinematic triphone model proposed by Okadome et al [26], where the kinematics of actual triphone articulatory tongue movements are characterized by the position and the first derivative of each parameter at each acoustic target of the triphone. Reconstruction is done using a minimum-acceleration constraint. Such a stylization simplifies the inter-triphone smoothing process while demonstrating good reconstruction of velocity profiles and parameter asynchronies [38].

4.4 Audiovisual synchrony

Most audiovisual synthesis systems (post)synchronize an acoustic synthesizer with the visual synthesizer via a minimal common input: a phonemic string with phoneme durations. This approach has some clear advantages such as the ability to easily couple two heterogeneous synthesis systems, or to feed visual synthesis with pure acoustic speech recognition results for "lip-sync" [7, 8].

Such phoneme-driven control does not, however, guaranty a complete coherence of audiovisual signals, even when synthetic trajectories are obtained by stretching natural ones as mentioned in the preceding section. The lengthening of an allophone can be due to a decrease in speech rate, pre-boundary lengthening, lexical stress or emphatic accentuation: these multiple causes result in very different velocity profiles and thus in different kinematics.

The most evident solution for ensuring coherent audiovisual kinematics is to record synchronously the acoustic signal and visual parameters. Then concatenative synthesis can be performed using selection of audiovisual segments [23], using both segmental and suprasegmental criteria. An interesting approach is to train a Hidden Markov Model (HMM) with audiovisual stimuli [7, 39]. Viterbi decoding of the resulting bimodal HMM will give the most probable set of visual parameters given the acoustic trace [45].

5 EVALUATION

Given that these systems and models have been presented to different scientific communities, its is very difficult to compare the achievements and evaluations of each technique. Most of the time, informal evaluation is performed, and very few evaluations involve direct comparison with "ground-truth" natural motion or video. Brant [7] for example presented synthesized (via trained audiovisual HMM) versus real facial motion driving the same 3D model to seven observers and found no significant preference rates. However it is very difficult to sort out the relative influences of the quality of the control parameters and the unrealistic synthetic face with which observers were presented in Brant's study.

A more systematic evaluation was performed at ATT [28] on 190 subjects to show the benefit of audiovisual communication. The third experiment of this study aimed at comparing the *appeal* ratings for three different synthetic faces driven by the sample synthetic audiovisual control parameters: (a) a standard flat 3D talking head, (b) a texture mapped 3D talking head and (c) a sample-based talking face. Subjects were not particularly seduced by synthetic faces: the best score was obtained by (a) while (c) obtained the worst rating. Surprisingly attempting to increase naturalness resulted in inverse satisfaction. These results seem to contradict the results of the first experiment evaluating the intelligibility of digits in noise where (a) and (c) performed equally well. However actual and estimated times to complete the task were both significantly

higher for (c): sample-based faces seem thus to require more cognitive effort and more mental resources. This is also illustrated by the fact that, despite their long-standing experience of audiovisual perception and successful implementation of Baldi, Massaro recognizes that they "failed to replicate the prototypical McGurk[1] fusion effect" [20, p.22], whereas they observed quite a number of combination /bga/ and /gba/ responses. Perceivers thus take into account the two channels of information, as evidenced in the reported performance of *coherent* audiovisual stimuli in noise, but the fusion of this information should be more difficult in the case of synthetic stimuli because of the incoherent or impoverished information provided by the two channels.

6 MODELS AND DATA

As demonstrated by perception experiments on segmental [33] and suprasegmental [24] aspects of acoustic synthetic speech, listeners are very sensitive to subtle details of the acoustic structure of speech signals. No doubt, observers also anchor their comprehension of visible speech on the coherence and subtlety of facial deformations induced by the underlying articulatory movements. We believe that this coherence could only be obtained by a careful and precise collection, comprehension and modeling of these articulatory movements and of the global interaction between movements and skin deformation. In fact, movements like lip protrusion or jaw oscillation produce deformation all over the face, while most model-based and image-based systems described above circumscribe influence of control parameters to a limited region using tapering or patching procedures on meshes or

images. For example, very few models take into account that the nose wings move clearly during speech production (see Figure 12) and that some lingual and laryngeal movements have visible consequences.

Whatever the strategy adopted to render articulatory movements, there is a clear need for precise data on articulatory and geometric DOFs of the facial movements – at least for characterizing or labeling a database.

Motion capture devices (e.g. Qualisys, Vicon) offer greater and greater spatial and temporal resolution to recover, in real-time, the 3D positions of more and more pellets or beads glued on the subject's face. Although the animation industry now makes intensive use of these tracking systems for animating more and more realistic virtual creatures (see Figure 14), research institutes still rely on the quality and efficiency of controlled experiments. Using a very simple photogrammetric method – previously used by Parke to build his initial model [31] - and up-to-date calibration procedures, we recorded 40 prototypical configurations of a French speaker whose face was marked with 168 glued colored beads (on the cheek, mouth, nose, chin and front neck areas), as depicted in Figure 11. In a coordinate system linked with the bite plane, every viseme is characterized by a set of 197 3D points including positions of the lower teeth and of 30 points characterizing the lip shape (for further details see [18, 36]). Although these shapes have potentially 3*197 = 591 geometric DOFs, we show that 6 DOFs already explain 97% of the variance of the data. Of course jaw opening, lip protrusion and lip opening are part of these DOFs, but more subtle parameters such as lip raising, jaw advance or independent vertical movements of the throat clearly emerge. These control parameters emerge from statistical analysis and their influence on facial deformation is additive. These parameters clearly influence independently the movements of the whole lower face. This influence is sometimes subtle and is sometimes not continuous in geometry, but should not be neglected. Although its crude linear assumptions do not take into account, for now, saturation due to tissue compression, this multilinear technique renders nicely the subtle interaction between speech organs and facial parts (such as formation of wrinkles or movements of the nose wings mentioned above).

7 CONCLUSIONS

Whatever potential vocations this paper may have generated in the audience during the workshop or among its readers, the animation industry clearly drives the progress in facial animation and we should draw some lessons from its history. The panel session on facial animation at Siggraph'97, which involved the participation of such notable researchers as D. Terzopoulos, M. Cohen, F. Parke, D. Sweetland and K. Waters, discussed almost exclusively model-based approaches. Most of the speakers expressed a need for more data acquisition facilities, and a reliance on the progress of models incorporating true biomechanics and aerodynamics. Is this call still true? We may draw a (pessimistic?) parallel with results in speech research, where data-driven techniques tend to question the need for more comprehensive models of speech production or intonation.

Terzopoulos concluded his discussion: "An intriguing avenue for future work is to develop brain and perception models that can imbue artificial faces with some level of intelligent behavior", while Waters added: "As the realism of the face increases, we become much less forgiving of imperfections in the modeling and animation: If it looks like a person we expect it to behave like a person… Evidence suggests that our brains are even "hard-wired" to interpret facial images. If cartoons can use characters that have non-human charateristics, such as dogs, cats, ants or monsters, to speak, we are compelled to address these perception issues and revise –for pure audio stimuli also?- our evaluation criteria.

ACKNOWLEDGMENTS

This review benefited from input from my colleagues P. Badin, F. Elisei and M. Odisio. I thank A. Breen, T. Ezzat, Y. Payan, and M. Slaney for providing information about their systems. M. Tabain did not proofread this last paragraph but I learned quite a lot from her correction of the previous ones.
