**Abstract:** For effective conservation management, it is very important to provide accurate estimates of animal populations with certain time intervals. So far many studies are performed visually/manually which requires much time and is prone to errors. Besides, only a limited area can be considered for counting because of the effort required. In order to bring a new solution to this problem, herein we propose a novel approach for counting animals from aerial images by using computer vision techniques.

To do so, we apply a probabilistic framework on local features in the image whose spectral reflectance differs from the surrounding region. We use mean shift segmentation and obtain probability density function (pdf) to detect focus of attention regions (FOA). Finally, we benefit from graph theory to detect segments which should represent animals. We test the feasibility of the proposed approach using aerial images of varying quality and angles (including orthogonal time lapse photography) from several different terrestrial ecosystems. Monitored species include birds and mammals. The algorithms successfully detect and count animals and provide a replicable and objective method for estimating animal abundance, however the methodology still requires estimates of error to be incorporated. This approach highlights how technical innovations in remote sensing can provide valuable information for conservation management.

**Keywords:** Aerial imagery, Local Feature Extraction, Probability Density Function, Mean-Shift Segmentation, Graph Theory, Graph-Cut, Animal Detection, Animal Counting.

## 1 INTRODUCTION

Effective conservation management relies on accurate estimates of animal abundance. Many censuses use field survey techniques that manually enumerate the number of individuals from aerial photography. These approaches are very time-consuming and limit the number of censuses that can be conducted in an area. Hence an automatic animal detection and counting method would greatly assist conservation management. By providing fast and consistent information about animal abundance, insights into the causal relationships that determine animal distribution and population dynamics can be rapidly ascertained, especially with respect to land-use change. Moreover, the applicability of space-borne remote

57 sensing data which could be used in future can be evaluated against data from  
58 aerial photography.  
59

60 In related literature, one of the earliest scientific analyses is made by Norton-  
61 Griffiths [1973] by discussing possibilities of collecting accurate animal counts from  
62 aerial images. Laliberte and Ripple [2003] used an image analysis program to  
63 count objects representing animals in aerial images. Groom et al. [2011] used an  
64 image segmentation based method to count flamingos from remotely sensed  
65 images. Descamps et al. [2011] proposed a computer vision approach based on  
66 application of birth-and-death algorithm on aerial images in order to detect and  
67 count large birds. Raybould et al. [2000], proposed an image processing approach  
68 to estimate number of people in outdoor events from aerial images. Lonergan et al.  
69 [2011] used aerial and satellite images to obtain seasonal and yearly count  
70 patterns of British grey seals. Thomas [1996], used aerial images to count yearly  
71 patterns of caribous. McNeil et al. [2011] used a classification based method to  
72 segment background and foreground objects in aerial images to count penguins.  
73 Jachmann [2002] compared the accuracy of aerial counts with ground counts and  
74 discussed the effect of animal sizes, flight and weather conditions on aerial  
75 counting performances. In addition, Tratham [2004] used a further analytical  
76 technique to count macaroni penguins from color aerial photography. The results  
77 showed a strong correlation between the estimates of automated image analysis  
78 and manual ground counts.  
79

80 Sirmacek and Reinartz used aerial images to bring automated solutions to person  
81 detection and counting problem. In their initial study [2011b], they proposed a  
82 dense crowd detection method based on extraction of local features from airborne  
83 images. Local features are used in a probabilistic process to identify locations of  
84 dense crowds. In a following study [2011c], they improved the dense crowd  
85 detection study by adding a feature selection step. By using a background  
86 comparison method, they detected individuals. They applied Kalman filtering on  
87 individual detection results (which are obtained over registered airborne image  
88 sequences) to obtain automatic tracking results. Using several measures they  
89 have extracted over automatically generated probability density functions, they also  
90 estimated the main direction of motion and abnormality level of large crowds  
91 [2011a]. Burkert et al. [2011], used their estimations in order to simulate the human  
92 activity in large areas. All these studied show that, aerial images can be used to  
93 monitor human activities, to detect and track individuals. Availability of high  
94 resolution sensor data, and the software system developments in human  
95 monitoring field lead us to develop algorithms further in order to monitor and count  
96 animals from these images in order to help effective conservation management.  
97

98 Here we propose a novel system which is based on applying image processing  
99 and computer vision techniques to aerial photography in order to automate the  
100 detection, identification, and enumeration of animals. Our approach depends on  
101 local feature extraction from input aerial images. Extracted features are used as  
102 observation points to generate a probability density function (pdf). Using pdf and  
103 segmentation result of the input image we detect focus of attention regions (FOA)  
104 which help us to simplify our animal detection problem. Inside of FOA regions, we  
105 apply a graph theory based on the animal detection algorithm and to finally obtain  
106 the number of animals in the input image. The results from our aerial images which  
107 are from various test environments show that remote sensing and computer vision  
108 approaches can be a valuable information source for animal conservation  
109 management. In the following section we start with introducing local feature  
110 extraction from input aerial images.  
111

## 112 **2 LOCAL FEATURE EXTRACTION**

113  
114 For local feature extraction, we use features from accelerated segment test  
115 (FAST). FAST feature extraction method is especially developed for corner  
116 detection purposes by Rosten et al. [2010], however it also gives responses on  
117 small regions which are significantly different than its surrounding pixels. Sirmacek

118 and Unsalan experimented to use this feature extraction method for detecting  
119 object characteristics in satellite images [2011]. Their test results prove that FAST  
120 features can be used to extract important interest locations in remotely sensed  
121 images.

122  
123 In this study, we use the intensity band of the input image for FAST feature  
124 extraction. We assume  $(x_i, y_i) i \in [1, 2, \dots, K_i]$  as extracted FAST local features.  
125 Here, the  $K_i$  indicate the maximum number of features. In Figure 1 (a) and (b), we  
126 represent our  $Test_1$  image from our database and the extracted local features  
127 respectively. In the next step we use extracted local features to estimate pdf.

### 3 PROBABILITY DENSITY ANALYSIS

141 Since we have no pre-information about animal locations in the image, we  
142 formulate the animal detection method using a probabilistic framework. We  
143 assume each FAST feature as an observation of a probability density function to  
144 be estimated. For the locations where an animal exists, we assume that more local  
145 features should come together. Therefore, knowing the pdf will lead to detection of  
146 animal locations. For pdf estimation, we benefit from a kernel based density  
147 estimation method. Using Gaussian symmetric kernel functions, the pdf is formed  
148 as below;

150

151

152

(1)

$$p(x, y) = \frac{1}{R} \sum_{i=1}^{K_i} \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x - x_i)^2 + (y - y_i)^2}{2\sigma}\right)$$

153 where  $\sigma$  is the bandwidth (smoothing parameter) of the Gaussian kernel, and  $R$  is  
154 the normalizing constant to normalize  $p(x,y)$  values between  $[0,1]$ . In kernel based  
155 density estimation the main problem is how to choose the bandwidth of the  
156 Gaussian kernel, since the estimated pdf directly depends on this value. For  
157 instance, if the resolution of the camera increases or if the altitude of the plane  
158 decreases, the pixel distance between two local features will increase. That  
159 means, Gaussian kernels with larger bandwidths will make these two features  
160 connected and will lead to detect them as a group. Therefore, the bandwidth of the  
161 Gaussian kernel should be adapted for any given input image. In probability theory,  
162 there are several methods to estimate the bandwidth of kernel functions for given  
163 observations such as statistical classification based methods, and balloon  
164 estimators. Unfortunately, those approaches require very high computation time  
165 especially when many observation points exist. For time efficiency, we follow an  
166 approach which is slightly different from balloon estimators. First, we pick  $K/2$   
167 number of random observations to reduce the computation time. For each  
168 observation location, we compute the distance to the nearest neighbour  
169 observation point. Then, the mean of all distances gives us a number  $l$ . We  
170 assume that the variance of the Gaussian kernel ( $\sigma^2$ ) should be equal or greater  
171 than  $l$ . In order to guarantee the intersection of kernels of two close observations,  
172 we assume the variance of Gaussian kernel as  $5l$  in our study. If there is an aerial  
173 image sequence, this value is computed only for one time over one image. Then,  
174 the same  $\sigma$  value is used for all images of the same sequence. Our automatic  
175 kernel bandwidth estimation method makes the algorithm robust to scale and  
176 resolution changes. In Figure 2 (a), we represent the pdf detected with extracted  
177 FAST local features.  
178

(b)

**Figure 2.** (a) Obtained pdf for Test<sub>1</sub> aerial image, (b) extracted FOA regions

#### 4 DETECTING FOCUS OF ATTENTION (FOA)

182 After calculating  $p(x,y)$ , we use Otsu's automatic thresholding method on this pdf to  
183 detect regions having high probability values which indicates focus of attention  
184 (FOA) regions. This FOA is stored in a binary image  $B(x,y)$  [Otsu, 2009]. After  
185 thresholding, depending on the resolution of the input data, binary regions smaller  
186  
187  
188  
189  
190  
191  
192

193 than  $X$  pixels are eliminated since they cannot indicate FOA regions suitable for  
194 animals. In Figure 2 (b), we represent detected FOA regions (in this case  $X=1000$ )  
195 for  $Test_1$  image.

## 196 197 **5 DETECTING ANIMALS BASED ON SEGMENTATION AND GRAPH THEORY**

198  
199 We apply segmentation to FOA regions in order to detect locations of animals  
200 inside those regions. For segmentation, we benefit from the mean shift  
201 segmentation approach which was proposed by Comanicu and Meer [2002].  
202 Within the mean shift segmentation process, we choose the spatial bandwidth ( $h_s$ )  
203 and the spectral bandwidth ( $h_c$ ) parameters as 7 and 6.5 respectively after  
204 extensive tests, and we use the same parameters for all input images. The  
205 segmentation result is a new image called  $S(x,y)$  which holds each segment  
206 labelled by a single color. We represent the mean shift segmentation result for our  
207  $Test_1$  image in Figure 3 (a). As can be seen in this result, mean shift segmentation  
208 reduces the complexity of the problem however the segments still do not indicate  
209 animal locations directly. Therefore, we continue our further analysis by using  
210 graph theory.

211  
212 A graph  $G$  is formed as  $G = (N, E)$ , where  $N$  holds the nodes of this graph,  
213 and  $E$  is the edge matrix showing the relations between these nodes. In our study,  
214  $N$  holds the mass centers of the segments which are detected by mean shift  
215 segmentation algorithm. To reconstruct graph edges, we benefit from Delaunay  
216 triangulation, since only neighbouring segments can correspond to parts of an  
217 animal. Using Delaunay triangulation, we connect only neighbouring segments  
218 which also reduce the graph complexity. Therefore,  $E$  is a  $M \times M$  matrix, where  $M$   
219 represents the total number of segments in  $S(x,y)$  matrix.  $E$  is defined as  $E(i,j)=1$   
220 where  $i, j \in [1, 2, 3, \dots, M]$ , if  $i$  and  $j$  nodes are connected by Delaunay triangulation.  
221 Otherwise,  $E(i,j) = 0$  which means there is no edge between  $i$ th and  $j$ th nodes.  
222 Besides, we also assign a weight value to each graph edge. For  $i$ th and  $j$ th graph  
223 nodes if  $E(i,j) = 1$ , we assign the weight to this graph edge as  $w_{ij}$ . Here  $w_{ij}$  is the  
224 color distance between two segments, which is computed by using Euclidean  
225 distances of RGB components of  $i$ th and  $j$ th segments. The constructed graph for  
226  $Test_1$  image is represented in Figure 3 (b).

227  
228 Finally, we apply graph cut to the constructed graph to obtain animal  
229 segments. We cut some graph edges of  $G$  by considering edge weights. From  $G$ ,  
230 we obtain new sub-graphs as  $G^s = (N^s, E^s)$ , where  $E^s$  is defines as below;  
231

$$E^s(i, j) = \begin{cases} 1 & \text{if } (E(i, j) = 1) \wedge (w_{ij} < \epsilon_1) \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

232  
233 Here,  $\epsilon_1$  is the color distance threshold to decide to cut a graph edge. To calculate  
234  $\epsilon_1$  threshold value we list histogram of all  $w_{ij}$  distances and apply Otsu's  
235 thresholding. We assume the threshold value obtained by Otsu's thresholding  
236 method as  $\epsilon_1$  threshold value to cut graph edges. After applying graph cut, we  
237 assume connected segments which are represented with  $G_s$  sub-graphs as  
238 detected animals. In Figure 3 (c), we represent detected animals in  $Test_1$  aerial  
239 image.

We tested the proposed animal detection algorithm on 70 different aerial images having different animal species. We provide some of the experimental results in Figure 4. True detection and false alarm numbers are obtained as 306 and 131 respectively in 340 total numbers of animals. That corresponds to 90% true detection and 38.52% false alarm performances respectively.

## 7 CONCLUSION

274  
275  
276

Herein we propose a novel approach which is based on applying image processing and computer vision techniques to aerial photography in order to automatically detect and count animals. The proposed approach depends on local feature extraction, probabilistic detection of focus of attention regions, and graph theory based identification of animal regions. Obtained test results on our aerial images from various test environments show promising results and prove that remote sensing and computer vision approaches can be a valuable information source for animal conservation management. In the future studies, we would like to benefit from hyperspectral and thermal images in order to improve results in the regions where the animals have similar colors to the earth texture. If higher resolution images are available, we also would like to focus on detecting animal species from aerial images.
