Autophagy and autophagy-related proteins in the immune system

Shibutani, Shusaku T ; Saitoh, Tatsuya ; Nowag, Heike ; Münz, Christian ; Yoshimori, Tamotsu

Abstract: Autophagy is an intracellular bulk degradation system that is highly conserved in eukaryotes. The discovery of autophagy-related ('ATG') proteins in the 1990s greatly advanced the mechanistic understanding of autophagy and clarified the fact that autophagy serves important roles in various biological processes. In addition, studies have revealed other roles for the autophagic machinery beyond autophagy. In this Review, we introduce advances in the knowledge of the roles of autophagy and its components in immunity, including innate immunity, inflammatory responses and adaptive immunity.

Abstract

Autophagy is an intracellular bulk degradation system that is highly conserved in eukaryotes. The discovery of Atg proteins in the 1990s has greatly advanced our mechanistic understanding of autophagy, which allowed us to understand that autophagy plays important roles in various biological processes. In addition, recent studies revealed other roles of the autophagic machinery beyond autophagy. In this review, we introduce recent advances in our knowledge of the roles that autophagy and its components play in immunity, including innate immunity, inflammation responses, and adaptive immunity.

Introduction

In macroautophagy (hereafter referred to as “autophagy”), a double-membrane organelle called the autophagosome plays a central role. Autophagosome formation is maintained at relatively low levels under non-stress conditions, and is induced dramatically by various cellular stresses (e.g. amino acid starvation). As shown in [Figure 1](#), autophagosome formation starts with the emergence of a membrane cup called the isolation membrane (also called the phagophore). The isolation membrane elongates and closes, resulting in the formation of a double-membranous autophagosome, which engulfs a portion of the cytoplasm. Then the subsequent autophagosome-lysosome fusion leads to the digestion of its content and inner membrane by lysosomal hydrolases ([Figure 1](#)).

A growing body of evidence suggests that autophagy plays important roles in various biological processes at cellular and physiological levels, and is generally beneficial to cells/organisms(Mizushima and Komatsu, 2011). Furthermore, it became also clear that proteins involved in autophagy have other functions than autophagy. In this review, we will discuss recent advances in our understanding of autophagy and its machinery in relation to innate immunity, inflammatory responses, and adaptive immunity.

Atg proteins

Although autophagic structures were already reported in electron microscopy studies in the 1950s, the molecular mechanism of autophagy remained mostly unknown until the discovery of yeast ATG genes in the 1990s(Clark, 1957; Novikoff, 1959; Ohsumi, 2014). 38 ATG genes have been identified so far, and the 15 core ATG genes in yeast (ATG1-10, 12-14, 16, 18) are conserved in mammals, indicating that autophagy is an evolutionarily conserved process. As in yeast, mammalian core Atg proteins can be classified into several functional units: the ULK complex, Atg9L, the class III PI3K complex, the Atg2-WIPI complex, the Atg12 conjugation system, and the LC3 conjugation system.

Functions of Atg proteins

The ULK complex (a Ser/Thr kinase complex composed of ULK1/2, Atg13, Atg101, and FIP200) and Atg9L (Atg9L1/2) are thought to act most upstream of autophagy(Itakura and Mizushima, 2010). The activity of the ULK complex is regulated negatively by mTORC1 and positively by AMPK. Both the ULK complex and Atg9L1 are required for the recruitment of the autophagy-specific class III PI3 kinase (PI3K) complex(Itakura and Mizushima, 2010; Kageyama et al., 2011).

PI3Ks are lipid kinases that phosphorylate phosphatidylinositol (PI) at the position 3 hydroxyl group of the inositol ring, resulting in the generation of phosphatidylinositol 3-phosphate (PI3P). The autophagy-specific PI3K complex is composed of Atg14L, Vps34 (catalytic subunit), Beclin 1, and Vps15 (hereafter called the Atg14L complex). Atg14L localizes on the endoplasmic reticulum (ER), and its ER localization is required for its autophagy-inducing ability(Matsunaga et al., 2010). The Atg14L complex accumulates at the ER-mitochondria contact sites upon starvation, which requires Syntaxin 17, a SNARE protein that resides on the ER and mitochondria(Hamasaki et al., 2013). It is likely that the Atg14L complex generates PI3P on the ER at the ER-mitochondria contact site to generate the platform for isolation membrane formation. PI3P generation provides the binding site for PI3P-binding proteins, including WIPIs (WIPI1-4: the mammalian orthologues of yeast Atg18). WIPIs form a complex with Atg2 (Atg2A/B). A recent study has shown that WIPI2 directly binds to Atg16L1 and recruits the Atg16L1 complex to the autophagosome formation site(Dooley et al., 2014).

The Atg16L1 complex (composed of Atg16L1, Atg5, and Atg12) specifically localizes to the isolation membrane and dissociates from it upon the completion of autophagosome formation(Mizushima et al., 2001). The ubiquitin-like protein Atg12 is covalently conjugated to Atg5 by Atg7 (E1-like enzyme) and Atg10 (E2-like)(Nakatogawa et al., 2009). Atg16L1 and Atg12-Atg5 form a 2:2:2 complex(Fujita et al., 2009). The Atg16L1 complex functions as the E3-like enzyme for the other ubiquitin-like system: LC3-PE(Nakatogawa et al., 2009). There are seven mammalian orthologues of Atg8 (LC3A/B/C, GABARAP, and GABARAPL1/2/3; represented by LC3 in this review). LC3 is conjugated to the membrane lipid molecule phosphatidylethanolamine (PE) by Atg7 (E1-like) and Atg3 (E2-like)(Nakatogawa et al., 2009). LC3-PE conjugation takes place at the isolation membrane, where the Atg16L1 complex (E3-like) accumulates(Fujita et al., 2008b, 16). LC3 is widely used as a marker for microscopic detection of isolation membranes and autophagosomes. In addition, PE-conjugated LC3 (LC3- II) and unconjugated LC3 (LC3- I) can be separately detected by Western blot, and the amount of LC3- II is also widely used to quantify autophagic activity(Kabeya et al., 2000). It is suggested that LC3 functions in the closure of the isolation membrane(Fujita et al., 2008a, 4; Sou et al., 2008).

Autophagy and pathogen infection

Autophagy has been studied in relationship to infection by bacteria, viruses, and parasites. As described in [Box 1](#), a number of *in vivo* studies have shown that autophagy serves a protective function against pathogens. Other studies suggest that autophagy suppresses excessive inflammatory responses upon pathogen infection. The relationship between autophagy and inflammation will be discussed later in this review.

Regulation of the autophagy machinery by immune signals

Autophagy is also regulated by a plethora of immune signals, including ligands for pattern-recognition receptors (e.g. Toll-like receptors (TLRs) and Nod-like receptors (NLRs)) and cytokines ([Box 2](#)). In addition, the stimulation of phagocytes by particles coated with TLR ligands also induces LC3 lipidation on phagosomal membranes. This phenomenon is called LC3-associated phagocytosis (LAP) ([Figure 2](#)). It should be noted that LAP phagosomes (single membrane) are different from autophagosomes (double membrane), and that the fluorescence microscopic detection of LC3 should be carefully interpreted because it cannot distinguish these two structures. Although LAP was initially shown to facilitate phagosome-lysosome fusion and accelerates pathogen killing(Sanjuan et al., 2007), further investigation revealed various functions of LAP beyond the acceleration of pathogen killing, including antigen presentation (discussed below in the adaptive immunity section).

Although the examples in [Box 1](#) and [2](#) indicate that the role of autophagy in the protection from pathogen infection *in vivo* is likely to be complex, the most direct way of autophagy-dependent pathogen elimination is the engulfment of pathogen by the autophagosome and the subsequent pathogen killing by lysosome-autophagosome fusion.

Discovery of xenophagy

Autophagy was initially thought to be a non-specific degradation process. However, it is now apparent that autophagy has an ability to selectively target large structures such as intracellular pathogens, damaged organelles, and protein aggregates. This type of autophagy, called selective autophagy, is thought to maintain intracellular homeostasis by eliminating unwanted structures. In particular, selective autophagy against pathogens is called xenophagy.

Anti-bacterial xenophagy both in non-phagocytic and phagocytic cells has been extensively investigated. In the case of phagocytes such as macrophages, dendritic cells, and neutrophils, bacteria are recognized by pattern-recognition receptors on their surface, leading to the activation of intracellular signaling that leads to immune responses. At the same time, bacteria are internalized by phagocytosis, and effectively killed by phagosome-lysosome fusion as well as the exposure to reactive oxygen species and antimicrobial peptides(Flannagan et al., 2009). However, invasive bacteria, such as *Salmonella*, *Listeria*,

and *Shigella*, invade non-phagocytic cells (e.g. intestinal epithelium). They modify endosomes into the niche suitable for their survival and proliferation, and often break into the nutrient-rich cytosol from the vacuole(Cossart and Sansonetti, 2004).

Xenophagy against invasive bacteria in non-phagocytic cells was demonstrated in 2004 by Nakagawa *et al*(Nakagawa et al., 2004). This study showed that Group A *Streptococcus* (GAS) is efficiently targeted by LC3-positive, autophagosome-like double membrane structure and is later subjected to lysosomal degradation. Moreover, the genetic deletion of Atg5 resulted in the absence of the LC3-positive structure and in increased GAS survival. This study clearly showed that autophagy functions as an intracellular innate immune system against bacterial invasion in non-phagocytic cells. Around the same time, it was shown that the survival of *Mycobacterium bovis* BCG and *Mycobacterium tuberculosis* in macrophages is suppressed by autophagy induction(Gutierrez et al., 2004). Follow-up studies have shown that other invasive bacteria, including *Shigella flexneri*(Ogawa et al., 2005), *Salmonella Typhimurium*(Birmingham et al., 2006), and *Listeria monocytogenes*(Py et al., 2007), are also targeted by autophagy.

On the other hand, there are bacterial species that have evolved mechanisms to prevent autophagy in a strain-specific manner, and therefore become more vulnerable to antibacterial xenophagy when these self-defense mechanisms are impaired. These bacteria include *Shigella flexneri*, *Listeria monocytogenes*, and *Legionella pneumophila* as reviewed in detail elsewhere(Huang and Brumell, 2014).

Mechanisms of anti-bacterial xenophagy: ubiquitination of the substrate

The key event that triggers anti-bacterial xenophagy and other selective autophagy is ubiquitination (the covalent conjugation of ubiquitin to the substrate). Ubiquitination is mediated by E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin ligase). E3 ubiquitin ligases recognize substrates and therefore determine substrate specificity. Ubiquitination has been well characterized as a hallmark event in the ubiquitin-proteasome pathway, which degrades individual ubiquitinated proteins by the proteasome(Welchman et al., 2005). However, recent studies have shown its involvement in selective autophagy. Notably, the artificial ubiquitin tagging to monomeric red fluorescent protein (mRFP) or peroxisomes leads to autophagic degradation of mRFP or peroxisomes, respectively(Kim et al., 2008). Moreover, invasive bacteria often colocalize with ubiquitin(Fujita and Yoshimori, 2011). Two E3 ubiquitin ligases have been related to anti-bacterial xenophagy so far: LRSAM1(Ng et al., 2011; Huett et al., 2012) and Parkin(Manzanillo et al., 2013). Parkin is also known as the major E3 ubiquitin ligase responsible for mitophagy (selective autophagy of mitochondria)(Narendra et al., 2008).

One possible mechanism underlying the bacteria-ubiquitin colocalization may be the direct ubiquitination of bacteria, and an alternative possibility is the ubiquitination of bacteria-containing endosomes. Several studies support the latter model. The endosomal

membrane is ubiquitinated after *Shigella flexneri* escapes into the cytosol from the endosome(Dupont et al., 2009). *Salmonella* Typhimurium inside endosomes was found to be targeted by autophagosomes(Birmingham et al., 2006; Kageyama et al., 2011). Strikingly, even endocytosed latex beads can induce autophagosome formation after the bead-containing endosomal membrane is ruptured(Kobayashi et al., 2010; Fujita et al., 2013), suggesting that no bacterial factors are required for selective autophagosome formation. Moreover, the rupture in lysosomal membrane induces selective ubiquitination and autophagy of the ruptured lysosome (named lysophagy)(Hung et al., 2013; Maejima et al., 2013). An important insight from these results is that cells may be simply detecting the rupture in pathogen-containing endosomes as an autophagy-inducing signal rather than preparing different autophagy-inducing mechanisms for various kinds of pathogens.

Ubiquitination-dependent and -independent recruitment of LC3 through autophagy adaptor proteins

How can ubiquitination function as the signal for selective autophagy? Autophagy adaptor (receptor) proteins such as p62, NDP52, and optineurin have been suggested to play an important role in xenophagy against intracellular bacteria(Huang and Brumell, 2014). These adaptor proteins contain ubiquitin-binding domains and LC3-interacting regions (LIRs), and therefore it is proposed that the adaptor proteins recruit the LC3 machinery to ubiquitinated substrates ([Figure 2](#)). In addition, NDP52 binds galectin-8, a β -galactose binding lectin. Since β -galactose chains exist in the lumen of endosomes, galectin-8 and its binding partner NDP52 are recruited from the cytoplasm to the endosomal membrane when the endosome is ruptured(Thurston et al., 2012).

Ubiquitination-dependent recruitment of Atg proteins

However, even in the absence of LC3 recruitment to intracellular *Salmonella* (in Atg3, 5, and 7 knockout cells) isolation membrane formation can initiate around *Salmonella*-containing endosomes(Kageyama et al., 2011). In the absence of LC3 recruitment, other Atg proteins such as the ULK1 complex and Atg9L1 are recruited to intracellular *Salmonella*, suggesting that the recruitment of these early Atg proteins is sufficient for the start of isolation membrane formation independently of the adaptor protein-mediated recruitment of LC3(Kageyama et al., 2011), although these isolation membranes cannot mature to complete autophagosome without LC3-PE. A follow-up study revealed that the recruitment of the ULK1 complex, Atg9L1, and the Atg16L1 complex (and the downstream Atg proteins Atg14L, WIPI1, and LC3) to ruptured endosomes is all dependent on ubiquitination(Fujita et al., 2013). The recruitment of the Atg16L1 complex involves the direct Atg16L1-ubiquitin binding through the C-terminal WD domain of Atg16L1 and the direct Atg16L1-FIP200 binding (FIP200 is a subunit of the ULK1 complex)(Fujita et al., 2013). The exact mechanisms for ubiquitination-dependent recruitment of the ULK1 complex and Atg9L1 remain unknown.

Xenophagy against viruses

The role of autophagy in virus infection is complex and dependent on the virus. Although several viruses have autophagy-inhibitory functions, and even exploit autophagy for their replication(Dreux and Chisari, 2010; Yordy et al., 2013), it has been shown that the virulence of several viruses is suppressed by autophagy. For example, capsid proteins of Sindbis virus are degraded by autophagy in a p62-dependent manner, and neuron-specific Atg5-knockout mice exhibit higher susceptibility to the virus infection(Liang et al., 1998; Orvedahl et al., 2010). The following genome-wide siRNA screening identified 141 genes, the knockdown of which affects the colocalization of Sindbis virus capsid protein with GFP-LC3. One of those genes, SMURF1, was shown to be required for cell survival after Sindbis virus and herpes simplex virus type 1 (HSV-1) infection(Orvedahl et al., 2011).

The human immunodeficiency virus type 1 (HIV-1) virulence factor Nef has been shown to suppress autophagy by binding to Beclin 1(Kyei et al., 2009). A recent study showed that the Nef-binding sequence of Beclin 1 (amino acids 267-284) induces autophagy when modified as a cell-permeable peptide (Tat-Beclin 1). Tat-Beclin 1 was shown to suppress Sindbis virus, Chikungunya virus, and West Nile virus, and HIV-1 *in vitro*, and reduced lethality of infection by Chikungunya virus and West Nile virus *in vivo*(Shoji-Kawata et al., 2013).

Autophagy in innate immunity

The innate immune system induces inflammation to protect a host from microbial infection(Kawai and Akira, 2009). Pattern-recognition receptors (PRRs) sense microbial components and induce activation of signal transduction pathways leading to expression of inflammatory mediators such as cytokines and type I interferons (IFNs). Although inflammation is essential for host defense, aberrant induction of inflammation causes the development of inflammatory diseases, such as septic shock, autoimmune diseases and metabolic diseases. Thus, the innate immune system is strictly regulated to avoid either insufficient or excessive inflammatory responses. Accumulating evidence has shown that intracellular degradation system plays an important role in regulation of inflammatory responses. In particular, recent studies have shown the involvement of autophagy in inflammatory responses(Deretic et al., 2013).

Inflammasome

The inflammasome is a cytosolic protein complex consisting of NOD-like receptors (NLRs) or of the absent in melanoma 2 (AIM2) protein together with the adaptor protein apoptosis-associated speck-like protein containing caspase recruitment domain (ASC) and the protease caspase-1(Latz et al., 2013). Inflammasome activation induces proteolytic

maturity of interleukin (IL)-1 β and the related cytokine IL-18 by caspase-1, which in turn induces production of these cytokines. Inflammasomes drive cytokine-dependent host defense against microbes. However, aberrant activation of inflammasomes by an excess of microbial components, host-derived stimulatory factors and environmental irritants often causes massive inflammation, resulting in severe tissue damage. Hence, inflammasomes are strongly associated with the development of infectious and inflammatory diseases.

Autophagy in production of IL-1 β and IL-18

Genome-wide association studies have identified ATG16L1 as a genetic factor responsible for susceptibility to Crohn's disease, a chronic inflammatory disease of the intestine(Hampe et al., 2007; Rioux et al., 2007). The importance of ATG16L1 in maintenance of intestinal homeostasis has been confirmed in mouse models. Hematopoietic cell-specific ATG16L1-deficient mice and mice expressing Crohn's disease-associated ATG16L1 variant (ATG16L1 T300A) were susceptible to colitis induced by dextran sulfate sodium and pathogenic bacteria, respectively(Saitoh et al., 2008; Murthy et al., 2014, 16; Lassen et al., 2014). ATG16L1-deficient macrophages produce high amount of IL-1 β and IL-18 in response to lipopolysaccharide (LPS), ATP and monosodium urate (MSU) crystals ([Figure 3](#)). Expression of Crohn's disease-associated ATG16L1 variant in peripheral blood mononuclear cells from Crohn's disease patients and in macrophages from genetically engineered mice results in elevated production of IL-1 β (Murthy et al., 2014; Lassen et al., 2014; Plantinga et al., 2011). Caspase-3 and caspase-7, apoptotic proteases, enhance production of IL-1 β by inducing proteolytic cleavage of the Crohn's disease-associated ATG16L1 variant(Murthy et al., 2014; Lassen et al., 2014). ATG7-deficient macrophages also produce high amount of IL-1 β and IL-18 in response to various inflammasome inducers(Saitoh et al., 2008). Hence, loss of autophagy in macrophages greatly augments production of IL-1 β and IL-18.

Autophagy in inflammasome activation

NLR family, pyrin domain containing 3 (NLRP3) protein is a well characterized PRR that induces production of IL-1 β and IL-18(Latz et al., 2013). Various NLRP3-inflammasome inducers such as ATP, palmitic acid, MSU crystals, silica nanoparticles, cholesterol crystals and influenza A virus cause mitochondrial damage leading to release of reactive oxygen species (ROS). NLRP3 forms the inflammasome complex with ASC and caspase-1, and induces production of IL-1 β and IL-18 in response to mitochondrial ROS. Because autophagy maintains cellular homeostasis by promoting turnover of organelles, autophagy-deficiency causes accumulation of old and dysfunctional mitochondria. Accumulated old and dysfunctional mitochondria produce an excess of ROS upon stimulation, thereby potently activating the NLRP3-inflammasome(Zhou et al., 2011; Nakahira et al., 2011, 3) ([Figure 3](#)). In addition, lysophagy may also be important for suppression of inflammasome activation, since extracellular irritative particles such as MSU and Silica internalize into cells via the endocytic

pathway and break lysosomes, which could damage mitochondria. Lysophagy sequesters lysosomes damaged by MSU or Silica *in vitro* and *in vivo*(Maejima et al., 2013). Upon influenza A virus infection, nucleotide-binding oligomerization domain containing 2 and its downstream regulator receptor-interacting serine-threonine kinase 2 induce mitophagy by inducing ULK1 phosphorylation to prevent excessive NLRP3-inflammasome activation(Lupfer et al., 2013). Autophagy-deficiency worsens the symptoms of various inflammatory diseases such as colitis, sepsis, pneumonia, diabetes, atherosclerosis, and urinary tract infections by enhancing NLRP3-inflammasome-dependent production of IL-1 β and IL-18(Nakahira et al., 2011; Lupfer et al., 2013; Wen et al., 2011; Razani et al., 2012; Wang et al., 2012). On the other hand, inducers of autophagy can suppress inflammasome-dependent production of IL-1 β and IL-18, and ameliorate symptoms of inflammation-associated tissue damage(Shaw et al., 2013; Guo et al., 2014; Abderrazak et al., 2015). Hence, autophagy would be an attractive therapeutic target for treatment of inflammasome-related inflammatory diseases.

Autophagy inhibits not only the NLRP3-inflammasome but also other inflammasomes such as the AIM2-inflammasome. Lysine 63-linked ubiquitination of ASC, an essential adaptor molecule of inflammasomes, is induced upon activation of the NLRP3- and AIM2-inflammasomes(Shi et al., 2012). Autophagy recognizes ubiquitinated ASC by the ubiquitin sensor sequestosome 1 (SQSTM1)/p62 and induces selective degradation of inflammasomes thereby suppressing production of IL-1 β and IL-18 ([Figure 3](#)). Furthermore, the autophagy system delivers IL-1 β into lysosomal compartments to induce its degradation(Harris et al., 2011) ([Figure 3](#)). Hence, autophagy can target multiple steps of inflammasome activation and thus potently inhibit production of IL-1 β and IL-18.

Autophagy limits inflammasome activation under normal and nutrient-rich conditions. However, a recent study has shown that autophagy often mediates the unconventional secretion of IL-1 β under nutrient starvation(Dupont et al., 2011). Golgi reassembly stacking protein and RAB8A, membrane traffic regulators, are involved in autophagy-dependent unconventional secretion of IL-1 β . On the other hand, other studies have shown that autophagy suppresses IL-1 β production under nutrient starvation(Wang et al., 2012; Shi et al., 2012). Hence, a role of autophagy in IL-1 β production under nutrient starvation is still unclear and needs to be further investigated.

Autophagy in non-canonical inflammasome activation

Recent studies have shown that the non-canonical inflammasome consisting of caspase-11 in mouse and caspase-4 and caspase-5 in human induces IL-1 α/β and IL-18 production in response to cytosolic LPS(Lamkanfi and Dixit, 2014). During infections with gram-negative bacteria, a cluster of guanylate-binding proteins, small interferon-inducible GTPases, moves to the surface of the bacteria-containing vacuoles (BCVs) and induces the membrane rupture(Meunier et al., 2014). Destabilization of BCVs releases bacterial components into the cytosol thereby facilitating the recognition of their LPS by the non-canonical inflammasome.

Autophagy-deficiency causes accumulation of the destabilized BCVs, resulting in an enhanced activation of the non-canonical inflammasome (Figure 3). Autophagy targets damaged BCVs via ubiquitin and galectin-8, and induces their autophagic degradation as described above. Hence, autophagy-mediated clearance of BCVs prevents excessive induction of the inflammatory response mediated by the non-canonical inflammasome.

Autophagy in calpain-dependent production of IL-1 α

Maturation and production of IL-1 α involve caspase 1-dependent and caspase 1-independent processes(Netea et al., 2014). In caspase-1-independent process, maturation of IL-1 α by calpain is triggered by ROS released from damaged mitochondria. Autophagy-deficiency in phagocytes causes elevated T helper 17 (TH17) cell response, resulting in severe lung tissue damage in a mouse model of tuberculosis(Castillo et al., 2012). Autophagy-deficient macrophages produce high amount of IL-1 α in response to *Mycobacterium tuberculosis* due to elevated mitochondrial ROS. Hence, mitochondrial ROS play a critical role in activation of the inflammasome and calpain in autophagy-deficient macrophages.

Nucleic acid sensors

The innate immune system senses viral nucleic acids by PRRs such as Toll-like receptors (TLRs), retinoic acid-inducible gene (RIG)-I-like receptors (RLRs) and cyclic guanosine monophosphate–adenosine monophosphate (cGAMP) synthase (cGAS), and induces production of IFN- α and IFN- β , type I IFNs(Kawai and Akira, 2010; Yoneyama et al., 2015; Cai et al., 2014). Type I IFNs induce the expression of a series of antiviral factors to establish an antiviral state and play a crucial role in host defense against viruses.

Autophagy in TLR-mediated type I IFN production

TLR7 and TLR9 sense viral single-stranded RNA (ssRNA) and unmethylated CpG DNA, respectively, in endo-lysosomes and mediate robust production of type I IFNs by plasmacytoid dendritic cells (pDCs)(Kawai and Akira, 2010). Autophagy-deficiency severely impairs TLR7-dependent production of type I IFNs by pDC infected with vesicular stomatitis virus (VSV) and Sendai virus (SeV)(Lee et al., 2007). Autophagy-deficiency also severely impairs TLR9-dependent production of type I IFNs by pDC stimulated with A/D-type unmethylated CpG oligonucleotides (a ligand for TLR9). Furthermore, LAP-deficiency severely impairs DNA-immune complex-induced TLR9-dependent type I IFN production by pDCs(Henault et al., 2012). Hence, autophagy and LAP are required for nucleic acid sensing and TLR-mediated type I IFN production by pDCs.

Autophagy in RLR-mediated type I IFN production

RIG-I and the melanoma differentiation-associated gene 5 (MDA5), called RLRs, are caspase-recruited domain (CARD)-containing RNA helicases and sense viral

double-stranded RNA (dsRNA) in the cytosol(Yoneyama et al., 2015). After sensing viral dsRNA, RLRs induce production of type I IFNs through activation of the mitochondrial CARD-containing adaptor protein interferon- β promoter stimulator-1 (IPS-1), also called MAVS/VISA/CARDIF. ATG5-deficiency enhances the production of type I IFNs by RNA viruses such as vesicular stomatitis virus (VSV), and inhibits viral replication. ATG5-deficiency causes accumulation of old and dysfunctional mitochondria, which in turn induces elevated expression of IPS-1 protein and generation of mitochondrial ROS, resulting in enhanced production of type I IFNs by dsRNA(Tal et al., 2009). The ATG12-ATG5 conjugates and its binding partner Tu translation elongation factor suppress dsRNA-induced production of type I IFNs by disrupting signals from RLRs and IPS-1(Jounai et al., 2007; Lei et al., 2012). Hence, autophagy and a unique function of autophagy-related proteins are involved in negative regulation of RLR-mediated type I IFN production.

Autophagy in cGAS-mediated type I IFN production

Recent studies have identified that cGAS senses microbial dsDNA in the cytosol(Cai et al., 2014). After dsDNA recognition, cGAS generates cGAMP to activate the stimulator of interferon genes (STING), a downstream regulator, which in turn induces production of type I IFNs, resulting in the establishment of an antiviral state. Loss of ATG9A causes hyper aggregation of STING on Golgi-derived compartments and enhances STING-dependent production of type I IFNs(Saitoh et al., 2009). ATG9A controls subcellular localization of STING via unknown mechanisms. ULK1 inhibition also enhances STING-dependent production of type I IFNs(Konno et al., 2013). ULK1 induces phosphorylation of STING to prevent sustained type I IFN production. Inhibition of Beclin1 enhances cGAS-dependent production of type I IFNs. Beclin1 binds with cGAS to inhibit cGAMP synthesis(Liang et al., 2014). Hence, unique functions of autophagy-related proteins limit production of type I IFNs induced by cytosolic dsDNA.

Endogenous antigen processing for MHC class II presentation

In contrast to innate immune sensing via PRRs, the adaptive immune system relies on the recognition of peptides processed from pathogen- or tumor-associated proteins and their presentation on major histocompatibility complex (MHC) molecules. For this purpose, MHC class I molecules get primarily loaded with proteasomal products for CD8 $^{+}$ T cell recognition, while MHC class II molecules receive fragments of lysosomal degradation for CD4 $^{+}$ T cell recognition(Blum et al., 2013). Autophagy delivers cytoplasmic constituents for lysosomal hydrolysis, thereby contributing to endogenous antigen processing for MHC class II presentation ([Figure 4](#))(Romao et al., 2013a). This was first noted for a prominent CD4 $^{+}$ T cell antigen of the Epstein Barr virus (EBV)(Paludan et al., 2005; Leung et al., 2010). Further studies demonstrated that rapamycin-induced autophagy or targeting model antigens to

autophagosomes by fusion to LC3 augments intracellular antigen presentation on MHC class II molecules(Jagannath et al., 2009; Schmid et al., 2007; Jin et al., 2014). However, the best characterized physiological process that requires intracellular antigen loading is T cell education in the thymus(Nedjic et al., 2008). Thymic epithelial cells (TECs) present self-antigens on MHC molecules for the induction of central T cell tolerance. Indeed, TECs display high constitutively active levels of autophagy(Nedjic et al., 2008; Kasai et al., 2009), resulting in compromised CD4⁺ T cell education without it(Nedjic et al., 2008). Antigen targeting to the autophagy machinery depletes specific T cells during negative selection, which eliminates autoreactive T cells(Aichinger et al., 2013). Therefore, endogenous MHC class II antigen processing via autophagy contributes to the induction of T cell tolerance and promotes the presentation of intracellular antigens to CD4⁺ T cells.

Exogenous antigen processing for MHC class // presentation

In addition to this function of classical autophagy in antigen processing, the LC3 lipidation machinery also regulates exogenous antigen processing via phagocytosis. During this LC3-associated phagocytosis (LAP), LC3 is found coupled to a subset of phagosomal membranes that surround TLR2, T cell immunoglobulin mucin protein 4 (TIM4), Fc receptor and Dectin-1 binding cargo(Sanjuan et al., 2007; Martinez et al., 2011; Florey et al., 2011; Romao et al., 2013b; Ma et al., 2012). Production of reactive oxygen species seems to be required to maintain LC3 conjugation to LAP phagosomes(Romao et al., 2013b)(Martinez et al., 2015). The fate of these LAP phagosomes depends on the cellular background, in which they form. Mouse macrophages were found to rapidly degrade LAP phagosome content in lysosomes, possibly by LC3B dependent recruitment of the FYVE and coiled-coil domain containing protein 1 (FYCO1), which might accelerate microtubule transport of LAP phagosomes(Sanjuan et al., 2007; Martinez et al., 2011; Ma et al., 2014, 1)(Ma et al., 2014; Martinez et al., 2011; Sanjuan et al., 2007). In contrast, plasmacytoid dendritic cells (DCs), human macrophages as well as monocyte-derived DCs seem to stabilize these vesicles for the fusion with TLR containing endosomes and prolonged antigen processing for MHC class II presentation, respectively(Romao et al., 2013b; Henault et al., 2012)(Henault et al., 2012; Romao et al., 2013). Both, Dectin-1 and TLR2 engaging cargo seem to be efficiently processed via LAP for MHC class II presentation ([Figure 4](#))(Romao et al., 2013b; Ma et al., 2012)(Ma et al., 2012; Romao et al., 2013). Similarly, the LC3 lipidation machinery appears to be required for efficient MHC class II presentation *in vivo*(Lee et al., 2010). Moreover, hydrolases that facilitate antigen processing can be transported into lysosomes via autophagy, as shown for peptidylarginine deiminases (PADs) that generate citrullinated peptides, which constitute CD4⁺ T cell epitopes in rheumatoid arthritis(Ireland and Unanue, 2011). LAP, however, does not seem to affect all phagocytosed cargo similarly. While the autophagy machinery has been reported to assist the transport of B cell receptor recognized antigens to TLR containing endosomes(Chaturvedi et al., 2008), this does not seem to be significantly

required to establish antigen presentation to helper T cells during germinal center reactions(Pengo et al., 2013). Thus, the autophagy machinery that mediates LC3 lipidation can modify phagosome fate and content, facilitating exogenous antigen presentation onto MHC class II molecules.

Antigen processing for MHC class I presentation

The classical function of the LC3 lipidation machinery, delivering substrates for lysosomal degradation, might limit antigen access to proteasomal turn-over(Wenger et al., 2012). In addition, proteasomes can be targeted by the autophagy machinery(Kristensen et al., 2008)(Cuervo et al., 1995), but this might mainly affect dysfunctional proteasomes(Marshall et al., 2015) and contribute little to further constrain proteasomal antigen processing for MHC class I presentation(Wenger et al., 2012). However, viral infections can block this proteasomal degradation and transporter associated with antigen processing (TAP) mediated import of antigenic peptides into the endoplasmic reticulum (ER) for MHC class I loading. Under these conditions, autophagy and possibly even LAP might contribute to MHC class I loading ([Figure 4](#)). Indeed, involvement of autophagy in MHC class I antigen presentation during herpesvirus infection in vitro was shown for herpes simplex virus (HSV) and human cytomegalovirus (HCMV), both encoding TAP blocking proteins(English et al., 2009; Tey and Khanna, 2012)(English et al., 2009; Tey and Khanna, 2012). Notably, autophagy was reported to assist in interferon- γ (IFN- γ) mediated MHC class I up-regulation(Li et al., 2010). Autophagy therefore might contribute to the delivery of intracellular antigens to vesicular MHC class I loading compartments, and to extracellular antigen processing for MHC class I presentation, so called cross-presentation. Cross-presentation of respiratory syncytial virus (RSV), HIV, Chlamydia and Aspergillus antigens were reported to benefit from the LC3 lipidation machinery(Johnstone et al., 2012; Blanchet et al., 2010; Fiegl et al., 2013; De Luca et al., 2012), presumably via LAP phagosome fusion with vesicular MHC class I loading compartments. Hence, vesicular MHC class I loading might benefit from autophagy and LAP, especially when TAP is blocked.

Antigen packaging for cross-presentation

In addition to the catabolic functions of the LC3 lipidation machinery, alterations affecting the completion of the autophagosome maturation process might promote exocytosis. This has been demonstrated in yeast for signal peptide independent secretion(Duran et al., 2010; Manjithaya et al., 2010)(Duran et al., 2010; Manjithaya et al., 2010) and suggested among others for high mobility group protein B1 (HMGB1), IL-1 β , ATP and secretory lysosome release by mammalian cells(Thorburn et al., 2009; Dupont et al., 2011; Martins et al., 2014; DeSelme et al., 2011). Moreover, some viruses like HIV, polio and EBV might utilize exocytosis involving autophagic membranes to exit infected cells(Kyei et al., 2009; Jackson et al., 2005; Nowag et al., 2014). This autophagic exocytosis could also benefit antigen processing and

has been shown to facilitate tumor and influenza A virus antigen cross-presentation ([Figure 4](#))(Uhl et al., 2009; Li et al., 2008)(Li et al., 2008; Uhl et al., 2009). Accordingly, vesicular fractions generated from antigen donor cells under autophagy stimulating and lysosome inhibiting conditions, some of them called defective ribosomal products in blebs (dribbles), are now being explored as antigen formulations for better cross-presentation(Ye et al., 2014). Thus, autophagic membranes might contribute to antigen release for efficient cross-presentation.

Autophagy in T cell development

Beside its role in antigen processing, autophagy shapes adaptive immunity throughout lymphocyte development and effector functions. While myeloid cells seem to differentiate in the absence of autophagy and can even cause severe myeloproliferation, autophagy deficiency in hematopoietic progenitor cells of mice severely compromises the lymphoid lineage(Mortensen et al., 2011, 7). Accordingly, thymocyte development up-regulates and is dependent on functional autophagy(Pua et al., 2007; Arsov et al., 2011)(Arsov et al., 2011; Pua et al., 2007). In the absence of autophagic clearance of damaged mitochondria (so called mitophagy) naïve T cell numbers are severely reduced(Pua et al., 2009; Farfariello et al., 2012)(Farfariello et al., 2012; Pua et al., 2009). Thus, mitophagy seems to be a prerequisite for T cell development.

Autophagy in T cell function

Proliferative T cell responses up-regulated autophagy(Pua et al., 2007), on which T cell survival during proliferation depends(Pua et al., 2007; Willinger and Flavell, 2012). Lack of autophagy leads to terminally differentiated CD8⁺ T cells in senescence with dysfunctional mitochondria, increased ROS production and elevated p38 MAPK levels(Henson et al., 2014). Indeed, p38 MAPK suppresses autophagy in these cells, and its inhibition restores proliferative function. Furthermore, the altered cell organelle homeostasis with increased ER structures compromises Ca²⁺ mobilization after T cell stimulation(Jia et al., 2011). This seems not only to affect effector, but also regulatory T cells(Parekh et al., 2013). Moreover, CD4⁺ T cells defective in autophagy are susceptible to apoptosis upon activation(Kovacs et al., 2012). In addition, autophagy deficiency caused impaired memory CD8⁺ T cell survival during lymphocytic choriomeningitis virus (LCMV), influenza virus and mouse cytomegalovirus (MCMV) infection(Puleston et al., 2014; Xu et al., 2014). T cell memory responses could be partially restored with the autophagy stimulator spermidine(Puleston et al., 2014). Therefore, autophagy might be required for lymphocyte expansion and memory maintenance.

Autophagy in B cell development

The loss of autophagy in developing B cells results in marginally decreased total numbers (Arsov et al., 2011; Miller et al., 2008)(Arsov et al., 2011; Miller et al., 2008). However, murine

B1a cells are compromised after essential autophagy gene deficiency(Miller et al., 2008; Pengo et al., 2013)(Miller et al., 2008; Pengo et al., 2013). This decrease seems to originate from autophagy dependent pre- to pro-B cell transition. Therefore, a subset of B cells is dependent on autophagy during their differentiation.

Autophagy in plasma cell and memory B cell maintenance

In line with the dependency of functional autophagy for B cell development, effector functions of the humoral immune response are also affected by autophagy deficiency. The terminal effector function resides in plasma cells that continuously generate antibodies. In addition, memory B cells can be reactivated for antibody production upon cognate antigen encounter. Both, T cell dependent and independent antibody responses that lead to plasma cell differentiation require autophagy(Pengo et al., 2013; Conway et al., 2013a)(Conway et al., 2013; Pengo et al., 2013). Moreover, long-term survival of plasma cells in the bone marrow of mice is reduced by autophagy deficiency(Pengo et al., 2013). The absence of autophagy in plasma cells results in a massive enlargement of the ER, which triggers unfolded protein responses during the production of immunoglobulins. This uncontrolled stress response is thought to induce cell death(Pengo et al., 2013). However, a direct effect of autophagy on antibody production by plasma and multiple myeloma cells could not been shown(Milan et al., 2015; Pengo et al., 2013). In addition to this role in plasma cell maintenance, autophagy is also required in memory B cell survival. Mice with autophagy-deficient B cells were severely impaired in their specific secondary antibody responses towards influenza A virus due to compromised memory B cell maintenance(Chen et al., 2014). Consequently, humoral immune responses, particularly the protection due to sustained antibody production and secondary responses, necessitate autophagy.

Concluding remarks

Since the discovery of Atg proteins, the molecular mechanism of autophagy and its relationship with immunity has been extensively investigated. As described in this review, it is now indisputable that autophagy and its machinery play various and critical roles in immunity, including the elimination of pathogens, the regulation of inflammation responses, antigen processing/presentation, and development of immune cells. However, we are still in the process of understanding the exact functions of Atg proteins and mechanism of autophagosome formation. Future investigation will clarify the fundamental mechanism of autophagy in more detail and will reveal unidentified roles of autophagy in immunity.

Box 1: *In vivo* roles of autophagy in pathogen infection

In mice, the conditional knockout of Atg genes was employed for these studies since the systemic knockout of Atg genes results in lethality shortly after birth(Mizushima and Komatsu, 2011). For example, Atg5 knockout in myeloid cells resulted in decreased resistance to *Listeria monocytogenes* and *Toxoplasma gondii*(Zhao et al., 2008, 5) and *Mycobacterium tuberculosis*(Watson et al., 2012; Castillo et al., 2012). Atg5 or Atg16L1 knockout in intestinal epithelial cells also resulted in decreased resistance to *Salmonella enterica* serotype Typhimurium (*S. Typhimurium*)(Benjamin et al., 2013; Conway et al., 2013b). Survival of neonatal mice after Sindbis virus infection was decreased by neuron-specific knockout of Atg5(Orvedahl et al., 2010). Atg5 knockout in dendritic cells in mice decreased survival after herpes simplex virus type 2 (HSV-2)(Lee et al., 2010). In *Drosophila*, the knockdown of Atg proteins decreased host survival after *Listeria monocytogenes* infection(Yano et al., 2008). Autophagy suppresses vesicular stomatitis virus (VSV) replication in *Drosophila*(Shelly et al., 2009). *Caenorhabditis elegans* treated with feeding RNAi for atg genes as well as *Dictyostelium* mutants of atg genes showed reduced survival after *Salmonella* Typhimurium infection(Jia et al., 2009).

In contrast, however, systemic Atg16L1 hypomorphic mice, which show abnormality in the packaging and secretion of antimicrobial granules in Paneth cells(Cadwell et al., 2008, 2010), exhibit enhanced resistance to urinary tract infection of uropathogenic *Escherichia coli* (UPEC) and intestinal infection by *Citrobacter rodentium* with increased inflammatory cytokine response and the increased recruitment of monocytes and neutrophils to infected sites(Wang et al., 2012; Marchiando et al., 2013). The enhanced clearance of bacteria in systemic Atg16L1 hypomorphic mice may be partly explained by the enhanced inflammatory responses seen in autophagy-deficient macrophages(Saitoh et al., 2008).

Box 2: Immune signals that regulate autophagy

TLR4 stimulation by lipopolysaccharides (LPS) induces autophagosomes in macrophages(Xu et al., 2007). Other TLR ligands also induce GFP-LC3 dots and autolysosomes in macrophages(Delgado et al., 2008). Nod1 and 2, which are cytosolic receptors for bacterial peptidoglycan, interact with Atg16L1 and mediate the recruitment of Atg16L1 to the bacterial entry site in non-phagocytic cells, macrophages, and lymphocytes(Travassos et al., 2010). Nod2 stimulation also induces autophagosomes in dendritic cells(Cooney et al., 2010). NLRX1 is required for VSV-induced autophagy by interacting with Atg16L1 complex through TUFM(Lei et al., 2012). In contrast, other Nod-like receptors, including NLRC4, NLRP3, NLRP4, and NLRP10 suppress autophagy by sequestering Beclin 1(Jounai et al., 2011). HMGB1, which is released into the extracellular space and activates TLRs, is required for autophagy and suppression of endotoxin-induced cell death of macrophages(Yanai et al., 2013). HMGB1 has also been shown to bind to Beclin 1 and induces autophagy by releasing

Beclin 1 from Bcl-2(Tang et al., 2010). HIV-1 envelope glycoproteins (Env) expressed at the cell surface activate autophagy and causes apoptosis in bystander CD4⁺ T cells through the chemokine receptor CXCR4(Espert et al., 2006). IFN- γ has been shown to induce autophagy in macrophages in an Irgm1-dependent manner(Gutierrez et al., 2004; Singh et al., 2006). TNF- α induces autophagy in myoblasts in an NF- κ B-independent manner(Keller et al., 2011), and enhances NDP52 recruitment to *Shigella* in HeLa cells(Mostowy et al., 2011). IL-1 β also induces autophagy in macrophages in a TBK-1-dependent manner (Pilli et al., 2012). In contrast, T Helper 2 cytokines IL-4 and IL-13 suppress autophagy(Harris et al., 2007). The transcription factor STAT3, which is activated by various cytokines, has been shown to suppress autophagy through inhibition of protein kinase R(Shen et al., 2012).

Figure legends

Figure 1: A schematic diagram of autophagy

Autophagy-inducing signals (e.g. amino acid starvation and pathogen infection) initiate the formation of the isolation membrane (also called the phagophore). The closure of the isolation membrane results in the formation of the autophagosome. The following lysosome-autophagosome fusion leads to the degradation of the contents inside the autophagosome by lysosomal hydrolases in the autolysosome.

Figure 2: Xenophagy and LC3-associated phagocytosis (LAP)

(left) In ubiquitin-dependent xenophagy, the recruitment of Atg proteins occurs after the pathogen-containing endosome is ruptured. Endosomal membrane proteins are ubiquitinated immediately after the membrane rupture. In addition, adaptor proteins such as p62, NDP52, and optineurin mediate recruitment of LC3 to ubiquitinated substrate. NDP52 can be recruited to the ruptured endosomal membrane through the binding to galectin-8, which recognizes β -galactose chains in the lumen of endosomes (not depicted here). Isolation membrane formation takes place in the proximity of the pathogen-containing endosome, and finally the autophagosome engulfs the pathogen-containing endosome. The following lysosome-autophagosome fusion eliminates the pathogen.

(right) In contrast to xenophagy, the double membrane autophagosome is not formed in LAP. Instead, the phagosomal membrane is directly decorated by LC3 lipidation. LAP facilitates lysosome-phagosome fusion or prolonged antigen processing for MHC class II presentation in a cell type specific manner as discussed in the adaptive immunity section.

Figure 3: Autophagy suppresses inflammasome-mediated production of IL-1 β

NLRP3 forms an inflammasome with its adaptor ASC, and its excessive activation causes inflammatory diseases such as gout. Activators of the NLRP3 inflammasome cause mitochondrial damage, which in turn causes production of reactive oxygen species (ROS), resulting in activation of the NLRP3-inflammasome. Autophagy induces elimination of old and dysfunctional mitochondria to suppress ROS generation and subsequent activation of the NLRP3-inflammasome. Autophagy also induces elimination of damaged phagosomes, ubiquitinated ASC and IL-1 β to suppress IL-1 β production mediated by other inflammasomes.

Figure 4: Autophagy proteins in MHC restricted antigen presentation

Autophagy proteins contribute at least by three pathways to vesicular antigen loading onto MHC molecules. Autophagosomes can fuse with endosomal MHC loading compartments and deliver cytoplasmic constituents for MHC class II loading. MHC class I loading might also occur in these vesicular compartments, especially under conditions, in which the classical MHC class I antigen processing, for example TAP, is inhibited. LC3 associated

phagocytosis (LAP) can deliver extracellular antigens to this loading compartment. LC3 might need to be deconjugated from the outer autophagosomal and the LAP phagosome membrane by Atg4 for efficient fusion with the endosomal MHC loading compartment. Finally, signal peptide independent, but autophagy dependent exocytosis seems to efficiently transfer antigens from donor cells to antigen presenting cells (APCs), primarily for cross-presentation onto MHC class I molecules.
