Abstract

This report describes the current status of benchmarks for the 1992 High-Level Synthesis Workshop and suggests guidelines for benchmark submission. The benchmark set currently has 9 designs, where each benchmark includes a VHDL description of the design, documentation of the design's functionality, as well as a set of test vectors and expected outputs for simulation. Documentation of the testing strategy the test vectors are also provided with each benchmark. Although the benchmarks are currently written in VHDL, we have attempted to organize the benchmarks in a language-independent format so that users can easily translate the benchmarks into their favorite HDL; the representative set of test vectors and expected outputs allow a user to ensure, with some level of confidence, that their HDL descriptions preserve the original behavior of the benchmarks. The current benchmark set contains designs that exercise different types of functionality (e.g., DSP, FSM-based, arithmetic, etc.), as well as different types of HDL behavioral constructs (e.g., nested loops and nested conditionals). We conclude with a suggested set of guidelines for benchmark submission.

1 Introduction

The benchmarking effort for High-Level Synthesis (HLS) began during the summer of 1987 when an informal benchmarking discussion was held at the 24th DAC. The urgent need for a set of benchmarks led to the HLSW 1988 Call for Participation stating: *The objective of the workshop is to begin the development of a set of "high-level synthesis benchmarks" that can provide a means of comparing different synthesis systems and guide future work to include a complete range of digital circuits.* This lead to the development of an informal set of benchmarks comprising different types of designs such as simple controllers, microprocessors, digital signal processing algorithms and other applications. These benchmarks were subsequently made available through the SIGDA benchmark repository maintained at mcnc.mcnc.org under the directories *HLSynth89* and *HLSynth91.*

The old benchmark set was not very robust and had several shortcomings. They lacked documentation of design functionality, and more importantly, generally lacked typical simulation vectors that could be used to verify the "correctness" of the input HDL descriptions, as well as of the synthesized designs. [1] However, we have reached a point of maturity in HLS where several researchers use the benchmarks for comparative evaluation of their results. These comparisons are often confusing and sometimes incorrect, due to the inherent ambiguity in the older set of benchmarks.

In this report, we attempt to rectify this situation by providing a set of sample benchmarks that include design documentation, typical design behaviors described as sample test vectors and expected outputs, and documentation of the testing strategy. The benchmarks are written using a common look-and-feel to maintain consistency across different designs. Although the benchmarks described here have been written in VHDL, we have attempted to organize them in a fairly HDL-independent format so as to facilitate greater usability through ease of translation to other HDLs.

This report concludes with some suggested guidelines for benchmark submission.

2 Overview of Benchmarks and Testing Strategy

This section briefly describes the current set of benchmarks, [2] which consists of a set of nine designs as summarized in Table 1. These benchmarks vary in the level of design description (e.g., FSM, functional blocks, algorithms), the style of VHDL used as well as in the VHDL control features and data types exercised. Several benchmarks are derived from "familiar" designs used by HLS researchers in the past (e.g., Fifth-order wave elliptic filter and Diffeq). For each design, we have tried to provide documentation of the functionality and assumptions made in coding the VHDL description. The appendix of this report contains a listing of the VHDL behavioral descriptions.

For each benchmark description, we also provide a brief description of the testing strategy used to obtain the set of test patterns for the benchmark, documentation of the test vectors, as well as the actual test patterns and the expected outputs. While these patterns are certainly not exhaustive, we have attempted to provide tests that exercise typical behaviors of the design, with the hope that it will facilitate ease of translation to other HDLs (and other VHDL modeling styles) that are used by individual synthesis tools.

The test patterns for each benchmark can be viewed as "sanity-checks" that attempt to exercise typical behaviors of the benchmark without performing exhaustive testing. As a general testing strategy, we exercise each function of the benchmark, and try to stimulate these functions under

[1] A notable exception was the set of Hardware-C descriptions that included sample test vectors and expected outputs.

[2] These benchmarks are available by anonymous ftp from *mcnc.mcnc.org* under pub/benchmark/HLSynth92 and from *ics.uci.edu* under pub/HLSynth92.

Design name	Design description	Design level	VHDL description style	Control feature	Data types	Test vectors
Traffic light controller	FSM	FSM beh.	1 Process	Nested Case, nested Ifs	Bit Vectors	23
Diffeq	Differential equation Solver	Algorithmic Beh.	1 Process	Embedded Loop, straight line code	Integers	12
Kalman filter	Digital FIlter	Algorithmic Beh.	1 Process	Nested Loops, nested Ifs	Signed Integers, Arrays	8
Armstrong counter	Controlled Counter	Functional & Algorithmic Beh.	4 Process	Nested Ifs	Bit Vectors	24

Figure 1: Status of HLSW92 Benchmarks

different combinations of inputs. For designs that are partitioned into components, we attempt to test each component in different modes with test vectors designed to detect "stuck-at-0" and "stuck-at-1" faults at various points in the hardware. The paths are also tested for "stuck-at-0" and "stuck-at-1" faults at any point on the path. In addition, we try to test some specified ports in both their complimentary forms (1 and 0) which is analogous to testing for "stuck-at" faults in the synthesized hardware.

3 Traffic Light Controller

Description

This benchmark describes a traffic light controller that regulates traffic at the intersection of a highway and a sideroad. The model is written such that the highway has priority over the side road. It uses a short timeout and a long timeout along with the traffic data on the side road to determine the length of time the traffic lights are in a particular state. The detailed functioning is described in [MeCo80].

Assumptions

The model assumes that some clocking signal is available to generate the timeout signals.

Testing Strategy

The tests consists of exercising paths to encompass all sequence of events. These tests ensure that all sequences of events behave in the predicted manner.

4 Armstrong Counter

Description

The Armstrong counter counts up or down till a prespecified external limit is reached. It operates with the Clock and Strobe signals acting as triggers.

The counting is done on the positive edge of clock. The decoding is performed on the positive edge of the strobe signal and the limit is loaded on a negative edge of Strobe signal.

If the counter reaches the limit, further counting is disabled till a new limit is loaded or the counter is cleared.

The benchmark was derived from the controlled counter description in [Arms89]

Caveats

The model does not support the behavior of the counter under these conditions:

- While the counter is counting towards the limit, the counting direction is changed. This means the counting should stop since the value now has crossed the limit in the direction of count;

however, the model does not support this behavior.

For example, let the counter's state be at 1 and counting-up, with the limit set at 7. If the count direction is now changed to downward count, the counter has already crossed the limit 7 during count down, so it should stop counting.

- While the counter is counting towards the limit, the limit is changed so that the counter now exceeds the limit. This means the counting should stop since the value now has crossed the limit in the direction of count; however, the model does not support this behavior.

  For example, let the counter's state be at 7 and counting-up with the limit set at 14. If the limit is now changed to 5, the counter has already crossed the limit 5 during count down, so it should stop counting.

Testing Strategy

The testing strategy consists of running a clock process and a counter testing process. The types of tests include performing a complete count-up and count-down sequence and also testing whether the limit function works while performing the count-up and count-down.

5 Differential Equations

Description

This benchmark provides the hardware description for a small fixed-point calculation loop. The algorithm tries to numerically solve the equation

y" + 3xy' + 3y = 0

Here, u is assumed to represent dy/dx or y'. dx is approximated as x1 - x. Similarly, dy = y1 - y and du = u1 - u. The value 'a' provides the number of times the numerical loop is executed. u1, x1 and y1 represent the new values of u, x and y. Thus, x1 = x + dx, y1 = udx + y, u1 = u - 3xudx - 3ydx. The behavior executes by loading the initial values of x, y, u, dx, and a.

This benchmark was derived from [BrGa87].

Testing Strategy

For this benchmark, the tests include checking the execution of the loop a desired number of times and checking for overflow on the outputs. We also check for correct operation under different conditions such as when the inputs are zeroes or negative numbers.

6 Elliptic Filter

Descriptions

The elliptic filter belongs to the class of Infinite Impulse Response (IIR) filters, where the filter's response to an impulse input remains non-zero till infinite time in a theoretical sense. The particular

filter we deal with here is a low pass filter, meaning that it filters off frequencies higher than a certain limit, called the cut-off frequency.

This filter design description is composed of a basic block of several arithmetic operations, and has long been a popular benchmark for comparing the results of scheduling. The benchmark derived from descriptions in [KuWK85] and [Orch90].

Testing Strategy

The functional testing of the elliptic filter is usually done with a 'delta' function, the rough approximation of which in the digital domain is a vector that is '1' in the first instance, and is '0' for all other states. The corresponding output has to be tested by substituting the vector in the z-transform of the state equation.

The vectors were derived heuristically, according to standard practices used in such cases. We consider vectors that are all similar (say all 0's and all 1's), vectors that have different combinations of even and odd numbers as current state vectors, and vectors that are powers of 2.

7 Kalman Filter

Description

The purpose of the Kalman filter is to predict the state vector of a system from a set of observed quantities. The dimensionality of the state vector is larger than that of the measurements. The imbalance is remedied by using many successive data observations in the prediction process.

The operation of the Kalman filter chip is as follows: First a set of coefficient matrices is downloaded into the chip. Once this is completed, the chip enters its control loop. Within this loop, four steps are repeated indefinitely. First, 13 measurements "y" are read into the chip. Second, the state vector "x" (of dimension 16) is estimated. This involves multiplication by a 16x16 matrix, multiplication by a 16x13 matrix, and numerical integration using the previous state estimate. Third, the control output vector "v" (of dimension 4) is computed from the state estimate. This involves multiplication by a 4x16 matrix. Fourth, the control vector "v" is output from the chip.

The Kalman filter model was derived from [Newt92].

Assumptions

The Kalman filter requires negative numbers to control its feedback. The highest negative number is two to the fifteen. Also, coefficients below unity are required to ensure that feedback does not cause the numbers to blow up. Hence, all inputs numbers have been multiplied by 1024, that is pitched 10 binary places above unity.

Testing Strategy

We start off the testing process by loading the constant matrices A, G and K. There exists 2 types of test sequences. Four different run of test vectors was followed by a run of four identical inputs. This is done to demonstrate the convergence of the state vector estimation process. We have also included some sanity check vectors.

Complete details of the testing strategy can be obtained in [Newt92].

8 Greatest Common Divisor

Description

The gcd model described in this example consists of two 8-bit input ports, one 8-bit output port, and a one-bit input port that enables the gcd model when the value is low.

The gcd model can be enabled by setting rst='0'. The output ou will be evaluated as gcd(xi, yi) based on the input values of xi and yi. If rst='1', then the output will be evaluated to be "00000000".

This algorithm is derived from [BrBr].

Testing Strategy

All possible paths in this benchmark are tested. The test types include checking when the input numbers are multiples, and when the numbers are not multiples of each other. The other sets of tests include the case when the input numbers are large.

9 Am 2901

Description

Am2901 is a four-bit microprocessor slice (from Advanced Micro Devices Inc.) It can be described either using functional blocks or by its behavior.

Its main functional blocks are as follows :

- 16-word by four bit two port RAM, with an up/down shifter at the input.
- A register (called Q) with an up/down shifter at the input
- An ALU source selector which select two inputs out of, Port A of RAM, Port B of RAM, Q register output, External data input and Logical 0
- A 4-bit ALU, capable of performing arithmetic and logical functions on the selected source words.
- A destination selector which decides whether to load the ALU output (with or without shifting) into the RAM, whether to load the ALU output (with or without shifting) or the Q register contents (with shifting) into the Q register OR whether the ALU output or the Port A contents should be forwarded to the External data output.

The behavior description of 2901 consists of a VHDL process that has three case statements corresponding to ALU operand selection, ALU function selection and ALU destination and data-output selection.

In the model, data is first read into "A" and "B" from the RAM words addressed by Aadd and Badd. Then the ALU operands are selected. The ALU does computation on these operands. After

that, the destination selector decides whether and how to write the ALU results to the RAM and Q register.

The complete details of the function of this design can be found in [AMDe82]. Further details of the model can be found in [Ghos92].

Testing Strategy

There are two types of paths in this design. One path starts at some register (or external data input), goes through the ALU and ends at a register. The other path starts at a register, goes via the ALU and ends at a RAM. Each of these paths tests a different ALU source line.

Further details of the test patterns can be found in [Ghos92].

10 Am 2910

Description

The Am2910 is a microprogram address sequencer intended for use in high-speed microprocessor applications [AMDe89].

The Am2910 has a four-input multiplexor that is used to select either the register/counter (R), direct data input (D), microprogram counter (uPC) or the top of stack (TOS) as the source of the next microinstruction address.

The register/counter performs the operations of load or decrement. The microprogram counter is used when incrementing needs to be performed, to execute sequential microinstructions. The third source for the multiplexor is the direct (D) input. This source is used for branching. The fourth source available at the multiplexor input is the top of the stack which is used to provide return address linkage when executing microsubroutines or loops.

The device provides three-state Y outputs. These can be particularly useful in designs requiring automatic checkout of the processor. The microprogram sequencer outputs can be forced into high-impedance state, and pre-programmed sequences of microinstructions can be executed via external access to the address lines.

The detailed model is described in [Ghos92].

Testing Strategy

In testing the Am2910 models, the overall strategy adopted is to test each "hardware" component (e.g. stack, register/counter etc.) using sequences of test vectors.

Because the components are not being tested in isolation, we need to set up input values at input ports of the chip and propagate them to the input of that component. Also, the output of a component has to be propagated to the output ports of the chip.

Further details of the test patterns can be obtained in [Ghos92].

11 Intel 8251

Description

The Intel 8251 Universal Synchronous/Asynchronous Receiver/Transmitter (USART), designed for data communication with Intel's microprocessor families described in [Inte81]. It is used as a peripheral device and is programmed by the CPU to operate using many serial data transmission techniques.

The USART accepts data characters from the CPU in parallel format and then converts them into a continuous serial data stream. It accepts serial data streams and converts them into parallel data characters for the CPU. The USART will signal the CPU whenever it can accept a new character for transmission or whenever it has received a character for the CPU. The CPU can read the status of the USART at any time.

The complete functional definition of the 8251 is programmed by the system's software. A set of control words must be sent out by the CPU to initialize the 8251 to support the desired communication format. These words must immediately follow a reset (internal/external).

The VHDL model consists of three major processes "main", "receiver" and "transmitter". The model describes how each of the above process handle the various mode words namely, Synchronous mode word, Asynchronous mode word Command word, and Status Word.

It also describes the operation in the following modes, Asynchronous Mode (Transmission), Synchronous Mode (Transmission), Asynchronous Mode (Receive) and the Synchronous Mode (Receive).

Further details regarding the model can be obtained from [Ghos92].

Testing Strategy

In testing the functionality of the 8251, we mainly concentrate on testing its main operational modes, Synchronous transmission, Asynchronous transmission Synchronous receive (External Synchronization), Synchronous receive (Internal Synchronization) and Asynchronous receive.

Further details regarding the test patterns can be obtained from [Ghos92].

12 Benchmark Guidelines

In this section, we suggest some guidelines for the submission of new benchmarks. This is a first step towards introducing more rigor in the benchmarking process, and towards the creation of a robust set of benchmark examples for testing High-Level Synthesis tools and systems.

12.1 "Well-Known" HDL Description

The design must be described using a "well-known" HDL which has a publicly available LRM, and which has a publicly available simulator. Sample HDLs that fit this criterion include VHDL, Verilog and Hardware-C.

The HDL description must be liberally commented to allow readability.

12.2 Design Documentation, Assumptions, Simplifications

The source of the design information should be specified (e.g., data sheet, initial design spec., etc.).

A description of the design's functionality (using English, flowcharts, block diagrams, etc.) must accompany the HDL description.

All assumptions and simplifications made in writing the HDL model must be clearly stated.

12.3 Simulation Vectors

A set of input and expected output functional test vectors must accompany the HDL description for simulating typical operational behaviors of the design. These test vectors are not designed to exhaustively test the design. Instead, they give some level of confidence in the behavioral HDL model, and allow translation and validation of the model into another HDL or description style.

The test vectors must also be accompanied by a (English) description of what functionality is being tested.

The input and expected output vectors should be described in a generic format that allows ease of use in different simulation environments. A brief description of the test vector format must accompany the test vector set.

12.4 Simulator Details

Each benchmark design must indicate the name, version, and availability (where appropriate) of the simulator used to test the design.

12.5 Synthesis Outputs

The outputs of synthesis tools must be simulated using the same simulator and test vectors used to check the behavior of the input description.

13 Summary

This report presented the status of, and briefly described the benchmark set developed for the Sixth International Workshop on High-Level Synthesis. Several researchers are in the process of contributing more benchmarks; these will be placed in the HLSW92 benchmark repositories both at MCNC and at U.C. Irvine, as soon as they are complete. We will periodically provide updates on the status of benchmarks through the High-Level Synthesis Workshop electronic mailing list.

We are actively soliciting (new or old) benchmarks that follow the suggested guidelines, and ask that you help us create a more comprehensive set of benchmarks by providing design examples.

In conclusion, it should be noted that this is still a preliminary effort in standardizing the benchmarks for High-Level Synthesis. We have yet to resolve several difficult issues, including a standard mechanism for specifying timing and other constraints in the test data sets. We look forward to receiving feedback, comments, suggestions and criticisms.

14 Acknowledgments

We would to thank the following people for their help in benchmark preparation: Indraneel Ghosh (Am2901, Am2910, I8251), Ted Lee (Greatest Common Divisor), D. Sreenivasa Rao (Elliptic Filter) and Joe Lis (Differential Equations, Armstrong Counter). We are grateful to Prof. Daniel Gajski for

his constant encouragement, support and suggestions in this effort. We would also like to thank Prof. Fadi Kurdahi for his support of this activity. This work was supported in part by NSF grants MIP 9009239 and MIP 8922851.
