Abstract

This study characterizes single particle aerosol composition from filters collected during the Observations of Aerosols above Clouds and their Interactions (ORACLES) and Cloud–Aerosol–Radiation Interaction and Forcing: Year 2017 (CLARIFY-2017) campaigns. In particular the study describes aged biomass burning aerosol (BBA), its interaction with the marine boundary layer and the influence of biomass burning (BB) air on marine aerosol. The study finds evidence of BBA influenced by marine boundary layer processing as well as sea salt influenced by BB air. Secondary chloride aerosols were observed in clean marine air as well as in BB-influenced air in the free troposphere. Higher volatility organic aerosol appears to be associated with increased age of biomass burning plumes, and photolysis may be a mechanism for the apparent increased volatility. Aqueous processing and interaction with the marine boundary layer air may be a mechanism for the presence of sodium on many aged potassium salts. By number, biomass burning potassium salts and modified sea salts are the most observed particles on filter samples. These results suggest that atmospheric processing such as photolysis and cloud processing, rather than BB fuel type, has a major role in the elemental composition and morphology of aged BBA.

1. Introduction

45 With Africa producing almost a third of the Earth's biomass burning aerosol (BBA) (Roberts et al., 2009), two aircraft
campaigns, ObseRvations of Aerosols above CLouds and their intEractionS (ORACLES) and CLOUD–Aerosol–
Radiation Interaction and Forcing: Year 2017 (CLARIFY-2017) were focused on understanding African biomass
burning aerosol interaction with clouds and radiation in the southeast Atlantic (Haywood et al., 2021; Redemann et
al., 2021). The CLARIFY campaign was based near Ascension Island in 2017 and ORACLES was based offshore of
Namibia in 2016-2018. CLARIFY findings detail a complex vertical structure which may be due to a temperature
50 inversion which inhibits mixing between layers (Haywood et al. 2021). Over Africa, mixing is inhibited by stable
layers at the top of the continental boundary layer (CBL) (Garstang et al., 1996), and over the southeast Atlantic the
BBA in the residual CBL moves over the marine boundary layer (MBL) as the air is transported west (Haywood et al.
2021). However, BBA aerosol is more often affected by the MBL than previously accounted for, with BBA reaching
the MBL through pathways that are not fully articulated (Zuidema et al., 2018), and entrainment processes through
55 clouds potentially affect aerosol properties. An example of this is the low single scattering albedo in the boundary
layer compared to the free troposphere (Zuidema et al., 2018; Pistone et al., 2019). Both campaigns report that a more
detailed aerosol process-level understanding including the properties of black carbon, organic carbon and inorganic
compounds and how they vary as a function of mixing state and altitude is needed, as is knowledge of properties of
the aerosol as they age from emission to deposition and the degree of mixing of BBA into the MBL (Haywood et al.
60 2021; Redemann et al. 2021).

While in-situ instruments provide data over large temporal and spatial scales, the instruments which analyzed chemical
composition in the ORACLES and CLARIFY campaigns analyzed bulk aerosol; detailed off-line single particle
analysis can offer valuable information to complement these online measurements. The principal in-situ instrument
65 used in these campaigns to determine aerosol chemical composition is the Aerosol Mass Spectrometer (AMS). The
AMS can detect organic and non-refractory inorganic mass at high time resolution. There are limitations on the size
range of aerosols detected depending on the inlet system employed, with no detection above one micron and a
decreasing efficiency above 700 nm. Salts do not vaporize easily and tend to recombine with oppositely charged ions
and make quantification of salts in the mass spectra difficult, if not impossible (Nash et al., 2006). The mixing state
70 of organic and inorganic constituents can only be determined with offline analysis of collected samples rather than in-
situ bulk aerosol measurements. Transmission electron microscopy (TEM) coupled with energy dispersive X-ray
(EDX) is suited to understand physical and chemical properties of individual particles including shape, elemental
composition, mixing state, volatility and viscosity, and it is particularly useful for complex aerosol which have been
processed (Signorell and Reid, 2011; Reid et al., 2018; Li et al., 2003). Therefore TEM-EDX is a useful method for
75 understanding processes affecting aged BB aerosol as well as marine salts which are pervasive over the ocean.

Previous work of African BBA from SAFARI-2000 showed that the aerosols were primarily composed of black
carbon, potassium salts, and organic/sulfur (Liu et al. 2000; Pósfai et al. 2003; Li et al. 2003). The SAFARI campaign

was mostly focused on BBA that were less aged than particles in CLARIFY and ORACLES. SAFARI results showed that KCl particles occur in young smoke more often while K₂SO₄ and KNO₃ particles occur more in aged biomass burning aerosol (Li et al. 2003). This is due to gas phase oxidation of NO_x and SO₂ and the displacement of HCl by the stronger acids HNO₃ and H₂SO₄ during plume transport. The authors theorized that aging caused sulfate to accumulate on organic and soot particles due to the large amount of internally-mixed soot/sulfate and organic/sulfate in haze (Pósfai et al. 2003). Based on the location and composition of the particles, Pósfai et al. (2003) concluded that organic and soot particles were the main CCN constituents of BBA. SAFARI-2000 samples taken in stratus clouds that capped the boundary layer, distinct from the BB haze layer in the FT, and these samples were dominated by sea salt particles (Pósfai et al. 2003). CLARIFY and ORACLES online observations also show an aerosol population dominated by coated black carbon (BC), organic, and sulfates, consistent with the SAFARI TEM findings of BBA. CLARIFY noted a thick inorganic or organic coating around BC (Taylor et al. 2020); while ORACLES noted a less thick coating around BC as well as a decreasing amount of coating with plume age (Sedlacek et al. 2021). ORACLES AMS data also noted a decrease in organic with plume age (Dobracki et al. 2021). As the single particle soot photometer, used to detect coatings on BC, does not differentiate between organic and inorganic material, TEM can help elucidate the type and source of coating on BC.

Sea salt aerosol, generated through a bubble bursting process on the sea surface (Lewis and Schwartz, 2004), have implications for radiative effects (Murphy et al., 1998) and cloud condensation nuclei (CCN) activity (King et al., 2012). Sea salt aerosols are modified when they react with sulfate, nitrate, and organic acids, resulting in a Na-rich and Cl-depleted aerosol and emission of gaseous HCl (Gard et al., 1998). There have been studies on the interaction of urban and anthropogenic sources with marine aerosol (Adachi and Buseck 2015), but single particle studies of sea salt aerosol and variations due to mixing with BB air are scarce. Coastal areas near urban sites show sea salt particles being modified by anthropogenic sources. Adachi and Buseck found that sea salt particles were modified by H₂SO₄ and HNO₃ by acid displacement of Cl (2015) and sea salt particles have also been shown to be Cl-depleted by organic acid displacement (Laskin et al., 2012; Kerminen et al., 1998). Pósfai et al. (1995) performed TEM analysis of marine aerosol as part of the Atlantic Stratocumulus Transition Experiment/ marine Aerosol and Gas Exchange (ASTEX/MAGE) campaign and found that polluted continental air affected sea salt aerosol processing, heterogeneity, and mixing with sulfates and nitrates.

With both biomass burning salts and marine salts being major contributors to aerosol in the southeast Atlantic region, a technique that can detect salts is important to accurately represent the aerosol in the region. Further, the plumes sampled during the CLARIFY and ORACLES campaigns are very aged, which is different from previous campaigns such as SAFARI-2000, which was deployed closer to the burning source, and so TEM results can provide information on processing of very aged BBA. This paper will describe the single particle analysis in context of the ancillary data including AMS measurements, back trajectories, cloud processing, time from source and time in the MBL. Our main questions are as follows: (1) what are the aerosols in the region and do CLARIFY and ORACLES aerosol differ from each other based on differences in BB plume age, (2) what are the are differences observed between MBL and FT

aerosol, (3) what are the mixing states of the aerosol, (4) what are the proposed processes which have acted on the aerosol.

2.0 Method

120

2.1 Filter Sampling

125 Aerosol sampling was performed with the NASA Ames Research Center (ARC) aerosol filter system (AFS), installed on the P3, and the filter system operated on the UK Bae-146 aircraft operated by the Facility of Airborne Atmospheric Measurement (FAAM). Holey carbon TEM grids (Ted Pella, Inc) were attached to 400 nm hole size polycarbonate nucleopore 400 nm hole size (Whatman™) filters. The Bae-146 has been used for filter analysis for single particle analysis (Chou et al., 2008), as well as bulk analysis (Sanchez-Marroquin et al., 2019; Hand et al., 2010; Andreae et al., 2000). The AFS was composed of a filter holder manifold with five separate filters, connected to the aerosol in situ suite inlet during ORACLES 2017 and 2018. A vacuum pump connected to a flow meter to maintain flow of 30
130 liters per minute was used for sampling, with five manually controlled valves that were used to switch the sampling to filter holders. The filter manifold was pre-loaded before each flight with filters. Samples for both campaigns were deposited on TEM grids at the locations, sampling times, and total flow volumes listed in Table 1 of the Supplementary Material.

135 After sampling, the ORACLES 2017 and CLARIFY 2017 filters were sealed in polycarbonate filter holders and wrapped in parafilm paper and aluminum foil and transported together with ice packs in a cooler and placed in a designated freezer immediately at University of Manchester. The ORACLES 2018 filters were sealed in the same manner and transported with ice packs and stored in a designated freezer at Tel Aviv University. A preliminary set of TEM analysis was conducted on the ORACLES and CLARIFY 2017 at the University of Manchester, and then
140 sealed and transported together with ice packs in a cooler for analysis at Tel Aviv University. Care was taken to maintain similar handling, storage, transport, and analysis of all filters in both campaigns. All data included in this study are from the Tel Aviv University analysis.

2.2 Transmission Electron Microscopy – Energy Dispersive X-Ray Analysis (TEM-EDX)

145 A JEOL™ JEM-2010F FEG-TEM with a ThermoNoran™ energy dispersive X-ray detector (EDX) was used at Tel Aviv University's Exact Sciences' electron microscopy laboratory to analyze 14 filters from CLARIFY (2017) and 16 filters from the ORACLES (2017, 2018) campaigns. TEM analysis was performed at 200 KeV accelerating voltage, a take-off angle of 15.9 degrees for X-ray emission from the sample, with an electron beam dwell time of no more than 30 seconds and spot size 3. The filter was scanned visually and representative particles near the center of
150 the TEM grid were analyzed. EDX spectra was collected for each particle and elemental weight percentage and atomic percentage were found per particle and normalized to 100% using NSS software with Cliff-Lorimer Absorbance correction method. C and O are considered semiquantitative due to the contribution from the Formvar film of C and

O from the TEM grid. Ratios of elements such as Na/S and Na/Cl were found by obtaining the either the weight or atomic values for individual particles, finding the ratio of interest, and averaging the ratio per filter.

155

2.3 Back-trajectory analysis

Back trajectories of each sample were generated using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPPLIT) model (Stein et al., 2015), with the time step set to one hour. Filter sampling lasted up to approximately ten minutes per filter, and back trajectories were calculated as an ensemble of each minute of filter sampling time. To improve the accuracy of the trajectory, we used the hourly high-resolution ERA5 reanalysis data (fifth-generation atmospheric reanalysis data) to drive the calculation. The ERA5 data is on $0.25^\circ \times 0.25^\circ$ horizontal resolution and includes 37 pressure levels. We collocated the cloud liquid water content of ERA5 to the coordinates of trajectories, with a threshold of 0.001 g/kg to detect clouds on the trajectory. Two collocations were performed: one with the 4-D coordinates of the trajectory (time, longitude, latitude, altitude) and another one with 3-D coordinates (time, longitude, latitude). Thus, the cloud liquid content points and profiles at the trajectory are provided, and the mean time of trajectory inside the cloud (cloud liquid water content >0.001 g/Kg), and under clear sky (no cloud liquid water above the trajectory) are calculated accordingly. For each sample, we calculated the back trajectories for 1, 2, 3, 5, 7 and 10 days, and the in-cloud and clear sky time correspondingly.

170

To determine fire locations, fire radiative power (FRP) data was measured by the spinning enhanced visible and infrared imager (SEVIRI) from the geostationary satellite Meteosat-8. The FRP is produced with a 15-min repeat cycle for pixels which contain active burning (Roberts et al., 2005); hourly data was used to match the time step of the trajectory. The age of the BB aerosol is then estimated as the time in days when the trajectory first intercepts the FRP points, similar to the method used by Vakkari et al. (Vakkari et al., 2018). The BBA 7-day backtrajectory overlaid with MODIS landcover classifications is included in the Supplementary Material.

175

2.4 Aerosol Mass Spectrometer and Single Particle Soot Photometer

The non-refractive chemical composition for submicron particles was measured using two Aerodyne Time-of-Flight Aerosol Mass Spectrometer (ToF-AMS, Aerodyne Research Inc.), a compact version (C-ToF-AMS) used in CLARIFY (Wu et al., 2020) and a high-resolution (HR-ToF-AMS) used during ORACLES (Dobracki et al. in prep; Redemann et al. 2021). The mass concentrations of organic, sulfate, nitrate, and ammonium were provided. Organic aerosol fractions including f43, f44 and f60 were also derived from the mass spectra obtained during both campaigns. f43 is the fraction of the measured organic mass at m/z 43 relative to the total organic aerosol (OA) mass concentration and is indicative of aliphatic carbon chains ($C_3H_7^+$) and oxygenated fragments ($C_2H_3O^+$) (Ng et al., 2011) common of fragments of aldehydes, ketones, and acid functionalities. Likewise f44 is the fraction of the measured organic mass present at m/z44 relative to the total OA mass concentration. The m/z44 mass is particularly useful in AMS analysis since it is a result of thermal decomposition of the diacid and organic peroxides on the heater to form CO_2^+ .

185

190 Since these compound classes are commonly associated with low volatility organic fractions, a high f44 has been associated with low volatility aerosol (Aiken et al., 2008).

The mass concentration of the refractory black carbon (rBC) of particles ranging from 80 – 650 nm was obtained by the single-particle soot photometer (SP2, Droplet Measurement Technologies, Boulder, CO) using laser-induced
195 incandescence. Detailed information on SP2 measurements can be found in Taylor et al. (2020).

3.0 Results

3.1 Overview of observations

200

Table 1 shows the conditions in which the filters were collected along with ancillary indicators including latitude and longitude, collection above or below cloud, and AMS data including organic, SO₄ NO₃, NH₄ and BC mass and fraction of PM₁. Time in-cloud in the 24 hours prior to filter collection and time from fire provide additional context for the sampled aerosols. The gaps in the AMS values are due to quality assurance checks which determined that the data
205 for specific filters are unreliable. In the “time from fire” column, if back trajectory analysis did not show interception with fire but rather a marine source, “marine” is noted in the column. There are more samples taken above cloud, and generally, BC mass values are higher in above cloud samples. 6/14 CLARIFY filters and 3/16 ORACLES filters were sampled in the MBL, with the remainder sampled in the FT. The ORACLES 2017 and CLARIFY 2017 filters were sampled from mid-August to early September, while the ORACLES 2018 filters were collected late September
210 through October. The ORACLES samples, in general, represents aged BBA and CLARIFY samples represent extremely aged BBA.

Figure 1 indicates the location of filter sampling as well as back-trajectories including altitude per filter. As shown by the back trajectories, the filter samples covered different BB sources such as savanna, forest and grasses. CLARIFY
215 sampling was more centered around Ascension Island whereas ORACLES sampling was closer to the African coast with most filters, except for two, sampled during October 2018.

3.2 Aerosol classifications

220 The TEM filters showed a heterogeneous aerosol population with variations in mixing for organic, NaCl salts, potassium salts, and black carbon. ~30-70 particles on each filter were analyzed to determine composition and particle type. The main particle types including potassium salts, sea salt, black carbon and organic aerosol will be described along with the main findings in the following sections.

225

3.2.1 Organic Aerosol

The AMS data corresponding to filter collection times show that 35% to 70% of CLARIFY and 18% to 68% of ORACLES PM1 is organic, by mass; therefore in-situ data indicates that a substantial amount of PM1 aerosol is organic in both campaigns. While TEM results show organic aerosol for both CLARIFY and ORACLES filters, there is significantly more organic aerosol present on the ORACLES filters. We hypothesize that this is due to differences in the volatility and viscosity of the organic material. Figure 2, left panel, shows a comparison of the fraction of particles, by number, with organic on each filter and the AMS organic fraction, by mass, for the corresponding filter. The majority of CLARIFY filters do not have any particles with organic material, while the majority of ORACLES filters have some particles which contain organic material. As AMS data shows a significant amount of organic aerosol present in both campaigns (Wu et al. 2020; Redemann et al. 2021), the differences in visible organic material on filters can be attributed to loss of volatile organics in the TEM chamber. It is known that volatile species will be lost from particles in a TEM chamber (Pósfai et al. 2003; Hudson et al. 2004) and preferential loss of organic would indicate a comparatively volatile material.

For context, Figure 2, right panel, shows the f_{43} vs f_{44} space for the entire ORACLES and CLARIFY campaigns, with filter data overlaid and marked by filter collection below cloud as well as the CO values marked in the colorbar to denote whether the sample is from a BB plume. Both campaigns show a high f_{44} typical of highly aged organic aerosol, and the ORACLES data show a slightly lower f_{43} which is associated with low volatility oxygenated organic aerosol (LV-OOA), although the difference is quite small. Low volatility oxygenated organic aerosol will typically have a lower f_{43} and higher f_{44} than semi volatile oxygenated organic aerosol (SV-OOA) (Ng et al., 2010, 2011).

TEM has been used to differentiate groups into high contact angle and low contact angle groups where viscosity and volatility of each particle can be qualitatively determined from the particle image. While factors such as surface tension and adhesion forces influence particle shape, viscosity and volatility can still be qualitatively measured on a comparative basis by using electron microscopy images (Reid et al. 2018). Figure 3, top panel, shows a progression from left to right of increasingly volatile organic as imaged by the TEM. The presence of more rounded, viscous organic (Figure 3, top panel, left image) in ORACLES compared to CLARIFY's low contact angle organic (Figure 3, top panel, right image) on the filters is also indicative of relatively higher volatility of organic in CLARIFY filters.

Figure 3, bottom panel, shows the reduction in Org/BC and Org44/BC mass ratios, based on AMS measurements, for both CLARIFY and ORACLES filters as age from biomass burning source is increased. Filters where backtrajectories did not indicate a BB source are included in the "marine" category. It appears that increased age reduces the organic to BC fraction, similar to the findings of Dobracki et al. (submitted) which found organic aerosol to black carbon mass ratios decreasing from 14 to 10 as the aerosol aged over the Atlantic, indicating a loss in organic aerosol in the BB plumes with age. UV exposure can work to break down oligomers and low-volatility components in organic (Wong

et al., 2015; Lignell et al., 2014) and may account for lower amounts and/or higher volatility of organic present on CLARIFY filters.

265

Tar balls are a type of round organic aerosol unique to biomass aerosol and as of now, the only way to identify tar balls has been through microscopy. Tar balls are estimated to contribute up to ~30% of BB aerosol mass (Sedlacek III et al., 2018). They are highly spherical, high viscosity, and largely resistant to electron beam damage. SAFARI found a considerable number of tar balls (Pósfai et al., 2003) as well as the Biomass Burning Observation Project (BBOP) (Sedlacek III et al., 2018). Adachi et al. (2019) observed tarball formation, likely from primary organic particles, within three hours of emission, with the processing of tar balls possible related to oligomerization of OA. We did not find many tar balls in the CLARIFY and ORACLES campaigns, with the exception of filters corresponding to RF10 and RF11, which were aged for 1 and 2 days, respectively. RF10 had very viscous aerosol but was mixed with considerable amounts of nitrogen and sulfur. This suggests a removal process for tar balls in very aged BB plumes as they are advected west over the ocean.

270

275

3.2.2 Potassium salts and black carbon

More than 60% of particles, by number, from the two campaigns were potassium salts, either externally or internally mixed. This is consistent with findings from (Li et al., 2003) where organic particles and potassium salts were the predominant particle types in the smoke. The salts were often mixed with black carbon, organic, or sulfates. One very common particle type was potassium salt internally mixed with BC, where the K-salt encapsulates the black carbon in a core-shell configuration. EDX analysis can ablate the salt and leave the refractory black carbon core intact. Another common particle type was organic aerosol with interstitial salts. These two common K-salt mixtures are shown in Figure 4. The coating of BC gives rise to absorption enhancements as discussed by Taylor et al. (2020), where they found universally thickly coated BC, and almost no externally mixed BC. The source of the coating is not described in that paper, and TEM results show that a common coating type is a hygroscopic salt, with implications for both absorption enhancement and enhanced CCN capability of the particles. The three common black carbon mixing states, BC with salt, BC with organic, and externally mixed BC are shown as a fractional amount that exists in each campaign and BL/FT in Table 2. Internal mixing refers to a particle which has two or more separate components, whereas externally mixed particles contain one component per particle. The predominant mixing state is BC internally mixed with salt, however, BC mixing with organic is likely underestimated due to volatilization of organic in the chamber.

280

285

290

295 3.2.3 Marine aerosol

The predominant aerosol on CLARIFY filters are either marine salts or BBA which have been influenced in some manner by the marine atmosphere. The analysis here will focus on CLARIFY aerosol as they show more marine influence than ORACLES. Most CLARIFY filters have sea salt aerosols (SSAs) with Na and/or Cl present in varying

300 ratios in the particles, as presented in Table 3. There are also minor amounts of Ca, Mg, K, as would be present in
seawater. However, Na and Cl in the sea salt aerosol rarely exist in a 1:1 atomic ratio, as would be expected from
freshly emitted SSA, indicating that the particles have been processed. A schematic of the SSA lifecycle, with
representative particles from several CLARIFY filters and example mechanisms for Cl depletion, is provided in Figure
5. Briefly, freshly emitted sea salt, generated from ocean bubbles bursting, has Na and Cl present in a 1:1 atomic
305 ratio. The aerosols are quickly processed in the atmosphere, within the span of hours, with nitrates and sulfates
replacing Cl. S is removed from the atmosphere through oxidation of SO₂ in water associated with sea salt particles,
and N species like HNO₃ and NO₂ are also available for reactions with sea salt. Volatized Cl can then form new
aerosol which does not have Na present. Variations of Na:Cl, then, can help determine whether SSA is freshly formed,
aged, or very aged based on the degree to which nitrates and sulfates have Cl present.

310 Table 3 details CLARIFY filters which have SSA with varying levels of aging, while Table 4 details three filters
consisting of Cl-rich aerosol. Both Table 3 and Table 4 list altitude, CO, and time from fire source to provide context
as to whether the air mass is BB influenced. As a measure of aging and sea salt conversion, Table 3 lists Na:Cl and
Na:S weight percent ratios for particles which have those elements present, averaged per filter. Table 4, as it is based
315 on Cl aerosol without Na present, does not list these ratios. Table 3 also lists the percent of particles per filter which
contain Na or Cl, as well as average weight percent of Na or Cl in the particles, averaged per filter. For context, Na
and SO₄ weight percent in sea salt, based on the composition of sea water, are 60.31 and 7.68, respectively (Seinfeld
and Pandis, 2012). Using the atomic weights of sulfur and oxygen, this leaves an expected Na:S ratio of approximately
16:1 in sea salt. A lower than 16:1 ratio indicates Cl displacement by S and is an indicator of aerosol aging, therefore
320 based on the ratios in Table 3, our samples are, on average, very aged sea salt.

All SSA in the filters collected in the MBL have NaCl with varying levels of Cl depletion. The presence of Na
collocated with Cl on all below-cloud filters and in only 2/7 of the above-cloud filters suggests the particles are less
aged in the BL samples compared to the FT samples. Gold 23, a filter sampled in the FT, has a high Na:Cl ratio for
325 particles with both Na and Cl, and this suggests that these salts are aged due to the Cl depletion. The other filter
sampled above-cloud with Cl, Gold8, has mostly Cl-only particles and a few crystals of Na:Cl which appear freshly
emitted with a cubic NaCl structure. Cl-only particles in the FT suggests mixing of the MBL and FT, as it shows that
Cl from the ocean has reached the FT through convection or turbulent mixing at the top of the MBL. Unprocessed
NaCl particles in the FT implies a rapid mixing (within hours as this is the average processing time of NaCl) of MBL
330 and FT air associated with the Gold 8 samples. Both Gold8 and Gold23 filters have backtrajectories which show
airmasses from the continent which are entirely within the FT, therefore supporting the top-of-BL mixing with FT
hypothesis rather than sea salt being present due to airmass transport through the MBL.

In the above-cloud CLARIFY samples, all particles were subject to BB influenced air based on CO values, where we
335 choose 120 ppbv as a CO level indicating BB influenced air above background levels. In the FT, Cl was mostly not

present or depleted. There was BC often mixed with sodium sulfates, Cl, and nitrate, as well as K-salts mixed with NaSO₄.

340 Filter Gold 24, interestingly, shows sodium nitrate mixed with black carbon. N can be difficult to detect in EDX spectra as it is between the C and O peaks and can be difficult to deconvolute; therefore the presence of N in the EDX spectra indicates that there is a substantial amount in the particles. Gold 24 was collected above-cloud and in highly BB-influenced air (331 ppbv of CO; 1.9 μg/cm³ NO₃). Gold 9, also collected above-cloud in BB influenced air (329 ppbv of CO; 3.1 μg/cm³ NO₃), also has sodium nitrate but to a lesser extent than Gold 24. As these are the two above-cloud CLARIFY filters with the highest CO levels, and are also the two filters which show some presence of sodium nitrate, this suggests that BB air may influence the sea salt conversion from NaCl to NaNO₃. This is likely due to the significant amount of NO_x in the initial BB plume to form HNO₃ and drive Cl out of the sea salt aerosol. There is also an influence of marine air on BC. For example, the bottom center image in Figure 6 shows a black carbon particle mixed with sodium nitrate from the Gold 24 filter, collected in the FT. The presence of the Na in the FT suggests BB entrainment into the MBL and subsequent mixing of marine air into the FT.

350 There were different morphologies and compositions of the marine salts due to different salt conversion processes: some large rounded NaCl over 1.5 micron in diameter and Ca, Mg, and Na sulfates and chlorides. Figure 6 shows a few examples of the many different morphologies of marine salts found on the filters. Figure 6 image F is from Gold 1 which was collected in the MBL, and the particle is BC encapsulated in sodium sulfate; this may be due to aqueous processing where sodium sulfate forms around a BC core. This suggests that while in the FT there is BC and K-salts mixed with sodium, BC, if entrained in the MBL, can also be significantly affected by sea salts and mixed with sodium nitrates and sulfates.

360 Three filters from CLARIFY, Gold 14, 15 and 18 were dominated by Cl particles which do not have Na present. Table 4 shows the three Cl dominant filters along with altitude at filter exposure, CO levels, and time from fire, and Figure 7 provides flight tracks including altitude and particle counts during the filter exposure time. The Cl-rich filters are interesting because of the high spatial density as well as the uniformity of the particles on the filter. The uniform particle composition and morphology of the particles suggests that, per filter, the particles have been subject to similar atmospheric processing. Gold 14 was collected in the FT and backtrajectories show interception with biomass burning six days prior to filter collection. Backtrajectories for filters Gold 15 and 18, both collected in the MBL, show that they do not intercept with the fires and are not as influenced by BB air as Gold 14.

370 Gold 14 was collected above-cloud, with 47/47 of the particles having strong Cl and N peaks, and some of the particles show very minor amounts of Si. Wu et al. (2020) noted an increase in nitrate mass concentration with increasing altitude, and found that the nitrate aerosol mostly existed as ammonium nitrate in the FT. They suggest that the increased levels of nitrate in the FT may be due to colder temperatures at high altitudes which would help partition the HNO₃-NH₃-NH₄NO₃ system into the aerosol phase (Wu et al. 2020). Particle counts from the condensation particle

counter (CPC) show a large increase in particle numbers when the flight C042 increased in altitude from 2250m to 2800 m, which may signify an area of newly formed ammonium nitrate as the nitrate partitions into the aerosol phase.

375 As ammonium nitrate is a semi-volatile hygroscopic inorganic salt which can dissolve into the aqueous aerosol phase, we hypothesize that the Cl aerosols are from HCl in the gas phase which partitions into the aerosol water and ammonium nitrate aerosol. Relative humidity at filter collection times according to backtrajectories is in the 60-70% range, which would also help the aerosol become aqueous and the subsequent uptake of HCl. Hydrochloric acid partitioning into aerosol water has also been inferred in urban atmospheres, where the highly water absorbing and

380 soluble chloride in the aqueous phase enhances aerosol water uptake through co-condensation and particle growth, causing haze to form (Gunthe et al., 2021).

Gold 15 was collected below cloud at 329 meters and 21/21 of the analyzed particles were composed predominantly of carbon and chlorine with small amounts of silicon and potassium; the particles appeared very similar across the

385 filter so EDX on additional particles was not performed. These may be HCl gas uptake onto sea spray aerosol. Gold 18 was collected below cloud at 332 meters. 32/32 particles sampled on the TEM filter were either CaCl_2 or MgCl_2 with silicon and may have formed through chlorine reacting with Ca and Mg in aerosolized sea water.

The high density of the chloride particles on the filters, compared to the other TEM filters, along with the uniform

390 composition and morphology of these particles, suggests either condensation onto new particles formed in the FT or condensation onto marine particles formed from spray in the MBL. While the prevailing view is that new particle formation rarely occurs over open oceans, work by Zheng et al. (2021) shows new particle formation in the remote MBL occurs frequently after the passage of a cold front, with factors such as removal of existing particles by precipitation, vertical transport of reactive gases from the ocean and cold temperatures facilitating new particle

395 formation. Iodine species can also form new particles in pristine regions (He et al., 2021). These conditions do not characterize our sample, however, these studies are part of a growing area of work which supports new particles formation in the remote MBL; if the newly formed particles are aqueous, they can support HCl uptake and may explain the Cl-dominant aerosol observed.

400 The filters were collected in both above and below cloud conditions, which suggests a mixing of the MBL and FT, as Cl, either in the gas or aerosol phase, reached the FT after having being emitted from the ocean; air exchange at the top of the BL due to turbulent mixing may be for the cause of this, particularly as there is a transition from stratocumulus to cumulus near Ascension Island, and a corresponding increase in convection (Gordon et al., 2018). We hypothesize that Cl in the FT may be from HCl in the BL which gets taken up into cloud droplets, and on their

405 evaporation at cloud top is re-released onto more neutral aerosol such as ammonium nitrate.

410 3.3 Marine boundary layer and aqueous phase processing

The MBL had a large effect on BB aerosols and as well as processing of sea salt aerosols. A comparison of cloud processing and time in the FT and MBL for the aerosol collected during the filter sampling time is provided in Figure 8. The filters are segregated by collection in the MBL and FT and the fractional time spent in each environment is shown in Panels B (collected in BL) and D (collected in FT). Panel D shows that aerosols collected in the FT, irrespective of campaign, have spent nearly all their time in the FT. Panel B shows that of filters sampled in the BL, CLARIFY aerosols have spent more than 80% of the fractional time spent in the BL in the day before filter sampling compared to ORACLES' 45%.

415
420 The cloud processing intensity, which is the mean cloud liquid water content multiplied by the mean in-cloud time, in the days prior to the air mass reaching the downwind filter collection location is provided in Figure 8 Panel A. Aerosols collected in the MBL were subject to more cloud processing than those collected in the FT, as the aerosols would need to be entrained into BL. ORACLES aerosol, on average, spent slightly more time in-cloud and with clouds with a higher liquid water content than CLARIFY aerosol, particularly apparent for those filters collected in the MBL.

425
430 In sea salt, K weight percent is 1.1, assuming sea salt has the composition of seawater and ignoring atmospheric processing (Seinfeld and Pandis, 2012). The K-salt from BB has a significantly higher weight percent than the minor amounts of K found in seawater and sea salt. The fraction of K-salt mixed with sodium increases with age, as shown in Figure 8 Panel C. This implies that the K-salt from biomass burning is processed in a way which allows Na incorporation into the particle. As Na is not volatile at atmospheric pressures, we hypothesize that the mechanism is processing by particle mixing, either by cloud drop coalescence or drizzle wash out of aerosol and evaporation.

435
440 The interaction of the MBL with BBA and the effect of BB air on marine aerosol has been shown in previous sections, and we hypothesize the mixing of Na salts with BBA to be due to aqueous processing and particle mixing through, for example, cloud drop coalescence. An aqueous K-salt particle from CLARIFY's Gold 9 filter is presented in Figure 9. It has varying Na:K ratios by weight percent, designated in the red circles, and there is no Cl in the particle. We assume that the Na present is from marine sources because the area with an 11:1 ratio has 13 wt% Na but only 1.2 wt% K; this is a higher Na wt% than would typically be expected from BBA. However, it should be noted that Na may also be from biomass burning, as sodium has been noted in BB fuel, with the type influencing the amount of Na in particles (Hudson et al., 2004). The image shows that Na mixes with K-salts, organic and sulfur in varying degrees throughout a single aqueous particle and therefore this is a potential mechanism for Na incorporation into existing K-salts.

445 Single particle structure and morphology is important as it affects aerosol optical properties and ability to act as cloud condensation nuclei. Figure 10 shows BC + K-salt (top panel) and BC + (organic/sulfur) mixtures as a function of

time in cloud encountered one day before sampling. The spherical nodules are black carbon and the more reflective white areas in the bottom panel are the sulfur/organic mixture. Each particle ID shows the TEM image and associated time in cloud (hours) in the day before sampling, the mean liquid water content of the clouds (g/kg) in the day before sampling, and the weight percent of elements in the particle. From left to right, the time in-cloud increases. If the electron beam visibly altered the particle, an “after” image is shown along with an “before” image to indicate the particle’s response to the electron beam. In each particle, the black carbon is insoluble and appears unaffected by increased cloud processing; however, both the K-salts and the sulfur/organic appear affected by increased time in cloud. In the left most panel for Figure 10, top panel, the K-salt is completely unaffected by exposure to the electron beam. The other images in Figure 10 show electron beam damage, indicating that these K-salt structures are more susceptible to volatilization and degradation due to the electron beam; this may be due to degradation of the K-salt during cloud processing. The K-salt particles on the right, which were subject to the most time in cloud, have a less distinct morphology which may indicate periods of water uptake and loss. In Figure 10, bottom panel, the sulfur-organic constituent of the aerosol which was subject to the least about of time in-cloud appears to have high viscosity, and was unaffected by the electron beam. After more time in cloud, the sulfur/organic on these particles appear to have a lower viscosity, to be more flat, and also to be more affected by the electron beam. Although these are only a few particles, the images imply that cloud processing can affect certain constituents of mixed aerosols more than others; the structure of the K-salt and the viscosity of the sulfur/organic mixture appear to be more affected by aqueous processing compared to BC.

465

3.4 Elemental mixing in individual particles

EDX of individual aerosol particles can provide information on elemental mixing across the entire ORACLES and CLARIFY sample sets. Figure 11 shows the elemental mixing of CLARIFY and ORACLES samples collected in the free troposphere and boundary layer, designated in separate columns, with each row of pie charts indicating whether a set of two elements are collocated on individual particles for all particles of the specified particle set. All percentages are based on particle numbers rather than mass. The elements S, Na, Cl and K were chosen for elemental mixing analysis as they are the elements which most commonly appear in the EDX spectra. C and O are found in the spectra of almost all particles, and so these elements are not included in this analysis.

475

A higher fraction of ORACLES aerosol contains S, 80%, compared to CLARIFY’s 40%. Three quarters of CLARIFY particles which contain S also contain Na, while most ORACLES particles contain S without Na present. S is mixed with K in 34% of CLARIFY and 73% of ORACLES aerosols. This suggests that ORACLES S is predominantly from biomass burning as it is collocated with K, and potassium is frequently used as a marker for BBA, consistent with the high amounts of K-salts observed in TEM samples. 76% of ORACLES FT aerosol contain collocated S + K, compared with 59% of ORACLES BL aerosol. In comparison, 35% and 33% of CLARIFY FT and BL aerosols have collocated S+ K, respectively, implying a dilution of BBA in the CLARIFY aerosol population collected on filters, in comparison to ORACLES.

480

485 70% of CLARIFY aerosols and 33% of ORACLES aerosol contain some combination of Cl and/or Na. Of
ORACLES aerosols containing Na, only a minor fraction is mixed with Cl, compared with 20% of CLARIFY particles
containing both Na and Cl. Cl can be found in fluids of some vegetation and so can be present in BBA (Liu et al.
2000), thus while ORACLES Cl may be due to either biomass burning or a marine influence, it is likely that the high
fraction of CLARIFY particles with Cl present, relative to the ORACLES population, is indicative of a marine
490 influence. This is also supported by the difference in CLARIFY Cl in the BL (75% of particles) versus the FT (31%
of particles), as well as CLARIFY filters Gold 14, 15 and 18 which were dominated entirely by Cl particles.
81% of ORACLES and 54% of CLARIFY aerosols have K present. 22% of CLARIFY aerosol contain collocated K
and Cl, while Cl is present, with or without K, in only 3% of ORACLES aerosol. S mixed with Cl is present in 15%
of CLARIFY and 3% of ORACLES aerosol. ORACLES aerosols contain a much lower fraction of Cl-containing
495 particles than CLARIFY.

44% of CLARIFY aerosol contains Na compared to 30% of ORACLES aerosol. 38% of CLARIFY aerosols have Na
collocated with K, versus 26% of ORACLES particles. 56% and 17% of ORACLES and CLARIFY aerosols contain
K but no Na, respectively. Following trends pointed out earlier, Na is present in relatively more CLARIFY aerosol
500 than ORACLES.

The higher number of particles with S present in ORACLES samples, particularly the FT, may indicate a higher
fraction of BBA (because it is collocated with K) compared to CLARIFY, or more sulfate aerosol formation via cloud
processing. Studies have shown formation of sulfate to be related to cloud processing (Ervens et al., 2018), and
505 ORACLES samples were subject to higher amounts of cloud processing than CLARIFY samples.

The high amounts of Na and Cl, both separate and collocated in CLARIFY samples, particularly the BL, suggests a
high amount of marine boundary layer influence and marine salts. While the majority of particles in both CLARIFY
and ORACLES contain K, K largely exists independently of Cl in the ORACLES samples, while it is mixed with Cl
510 for a substantial fraction of CLARIFY particles particularly in the BL where 42% of particles contain collocated K +
Cl. Similarly, S exists largely without Cl in ORACLES particles but is collocated with Cl in 27% of CLARIFY
particles. This implies gas phase Cl condensation onto BBA, particularly K-salts, in CLARIFY aerosol. There is also
a substantial difference in the amount of Na collocated with K in the FT and BL for both ORACLES and CLARIFY
campaigns: CLARIFY FT 35%, BL 43%; ORACLES FT 22%, BL 50%. The majority (59%) of ORACLES FT
515 particles contain S independent of Na; however, of the ORACLES samples collected in the BL, 46% of the particles
contain S collocated with Na. This implies, again, a marine boundary layer influence in the increased Na-containing
particles in the BL for both campaigns. Assuming that BBA is in the FT and then becomes entrained in the BL, this
transition could help facilitate aqueous processing and particle mixing through droplet coalescence in cloud and
evaporation, which would incorporate Na onto the BBA.

520

4.0 Conclusions

This work combines online field measurements and TEM analysis of two campaigns with disparate aging of BBA aerosol. Detailed single particle analysis revealed considerable heterogeneity in the aerosol population of CLARIFY and ORACLES filters in terms of mixing of elements and processing of individual particles. We find similarities to the previous major campaign which analyzed African BBA, SAFARI-2000, in that we find an abundance of potassium salts, black carbon, and organic carbon with interstitial potassium salts (Pósfai et al., 2003; Li et al., 2003). While SAFARI noted an abundance of potassium salts, our TEM analysis shows for the first time in the region that a large fraction of BC is internally mixed with potassium salts. This has implications for radiative effects due to lensing as well as CCN capability due to the hygroscopicity of the salt. While SAFARI analysis found abundant KCl near source, both the CLARIFY and ORACLES campaign are in areas measuring much more aged aerosol, and our results show that KCl was not widely found. This is presumably because replacement of Cl by nitrates and sulfates has occurred. Near Ascension Island, Cl, likely from marine sources rather than biomass burning, was present on a large number of particles. While the SAFARI campaign and other recent biomass burning campaigns note a considerable amount of tar balls, our TEM analysis did not observe many other than on filters RF10 and RF11, which were aged for approximately 1 and 2 days, respectively. ORACLES and CLARIFY aerosol are generally very aged, and so this finding implies a reduction in tar balls in very aged BB plumes.

SAFARI was near source and focused on BBA, and online AMS and SP2 analysis for CLARIFY and ORACLES was focused on nitrates, sulfates, organic, BC and ammonium. Our TEM analysis extends this data set through the finding of an abundance of marine salts with varying levels of processing. In general, sea salt aerosol collected in the MBL were less aged than those in the FT, as evidenced by Cl depletion. Cl was mostly, but not always, depleted in the FT compared to aerosols found in the MBL which had higher levels of Cl. The presence of Cl and, on some filters, freshly emitted NaCl in the free troposphere suggests mixing of the MBL and FT in some regions, likely through convection and turbulent mixing at the top of the BL.

We found evidence of BBA interaction with the MBL as well as marine salts affected by BB air, which has not been as of now reported in these campaigns. Mixing of marine air with BB air affects sea salts because of Cl replacement by nitrate, as the BB plumes had elevated levels of NO_x to drive Cl out of the SSA. Reciprocally, BBA was influenced through, for example BC mixing with sodium sulfates and sodium nitrates and the presence of Na on large number of BB particles.

We found high levels of Cl collocated with K and S in CLARIFY aerosol, particularly those collected in the MBL, and this suggests Cl gas species condensation or HCl uptake onto BB K-salts. The uniformity and ubiquity of Cl-containing aerosol particles on three CLARIFY filters suggests that particles on these filters have been uniformly processed and the existence of areas dominated by Cl aerosol. Further, the high density of Cl spatially on these filters implies HCl condensation onto existing particles which have been recently formed and processed uniformly.

560 There is considerable mixing of Na with BBA through what we believe is aqueous processing of particles, through, for example either cloud drop coalescence or drizzle washout of aerosol and subsequent evaporation. TEM particles show evidence of aqueous processing, with varying ratios of soluble components throughout a single particle. Particle morphology also show evidence of cloud processing, with soluble components more significantly affected by time in cloud than insoluble components such as black carbon.

565 TEM analysis indicates an increase in organic aerosol volatility with BB plume age based on the higher fraction of organic which evaporated in the TEM chamber in CLARIFY compared to ORACLES. Che et al. (submitted) noted SOA formation in the first ~70 hours of BB aging; our results suggest that the secondary organic which forms may be more volatile than the initial organic emitted from biomass burning. There have been different explanations for the vertical structure of single scattering albedo near Ascension Island, with Taylor et al. (2020) and Wu et al. (2020) suggesting a partitioning of inorganic ammonium nitrate onto existing particles at colder temperatures, and Dobraki et al. (2021) hypothesizing that the SSA differences are due to scattering organic material that is lost from BBA. Sedlacek et al. (2021) also found a loss of organic material coating BC with plume age in ORACLES; further the authors define different regimes for BBA where organic coating on black carbon increases in the first few hours after emission, the coating mass then plateaus after a several hours to several days when there are competing chemical physical processes such as photochemistry, SOA production, fragmentation and oxidation, and after several days of aging there is material loss due to cloud processing, volatility, and bleaching of brown carbon. While there are different explanations for the vertical structure of single scattering albedo near Ascension Island as well as mechanisms for organic loss with age, our results indicate that higher volatility organic is associated with aging; therefore we hypothesize that photolysis and fragmentation of carbon chains in the organic is the predominant mechanism for the apparent higher volatility of aged organic.

580 While studies on combustion types show differences in primary particle types in terms of mixing, amount of organic and elemental composition, for example for particles formed in the flaming and smoldering phase (Liu et al. 2017), these studies are for fresh particles, unlike the very aged combustion aerosol found in ORACLES and CLARIFY. Due to the considerable processing of organic aerosol and the noted effects of the MBL on BBA, it appears that aqueous processing, photolysis, and interaction with the MBL are the key drivers in physical and chemical properties such as mixing state and elemental composition of very aged BBA, rather than source.

Data Availability

590 Data are publicly available at the ORACLES and CLARIFY archives: <http://data.ceda.ac.uk/badc/faam/data/2017> and <https://espo.nasa.gov/oracles/archive/browse/oracles/id14>. Data not on this website can be provided by request.

Author contribution

MS, H. Coe, and CD designed the research. JH, H. Coe, JR, PZ, AN are PIs of the campaigns. JT, MSR, PW, SP, PZ, AN performed field work or provided support for filter collection. CD performed laboratory analysis. CD and

595 H. Che provided figures. CD, H. Che, MS and LZ analyzed data sets. CD led the paper writing, and all co-authors contributed to ideas and writing.

Competing interests

The authors declare that they have no conflict of interest.

795

Figure 1 The location of filter sampling and back trajectories related to each filter, including altitude for ORACLES 2017-18 (upper panel), and CLARIFY 2017 (lower panel). Map colors relate to MODIS land cover types.

800

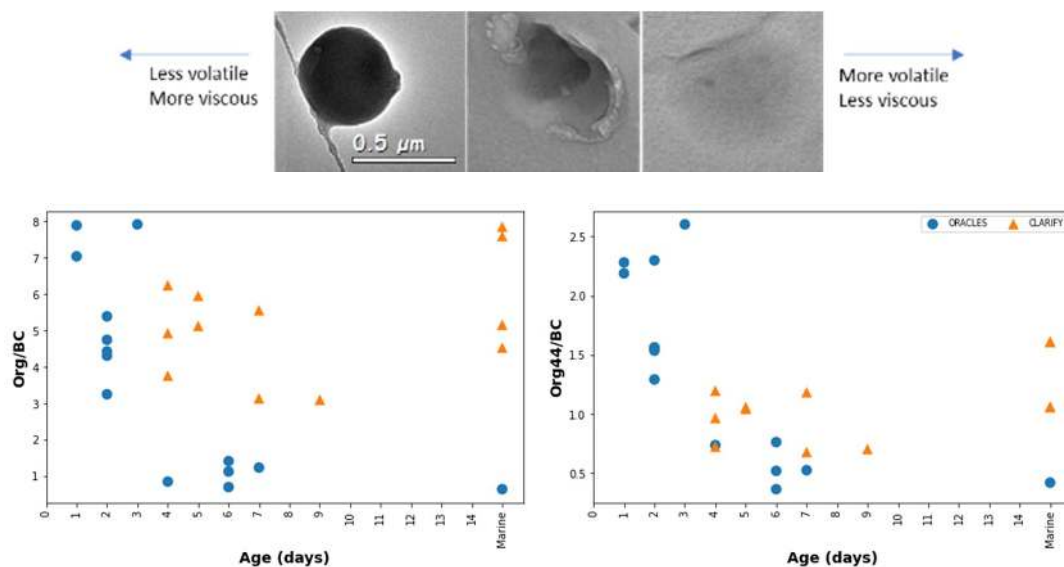

Figure 2 (left) AMS organic fraction vs filter organic fraction and (right) f44 vs f43 space for ORACLES and CLARIFY campaigns with filters marked as triangles for ORACLES and squares for CLARIFY. Samples collected below-cloud are outlined with a black border.

805

810

Figure 3 Example of different viscosity/volatility organic aerosol (top panel) showing more round and viscous particles for ORACLES (on the left), and more volatile for CLARIFY (middle and right top panels) and Org/BC and Org44/BC ratios with time from fire source (bottom panel)

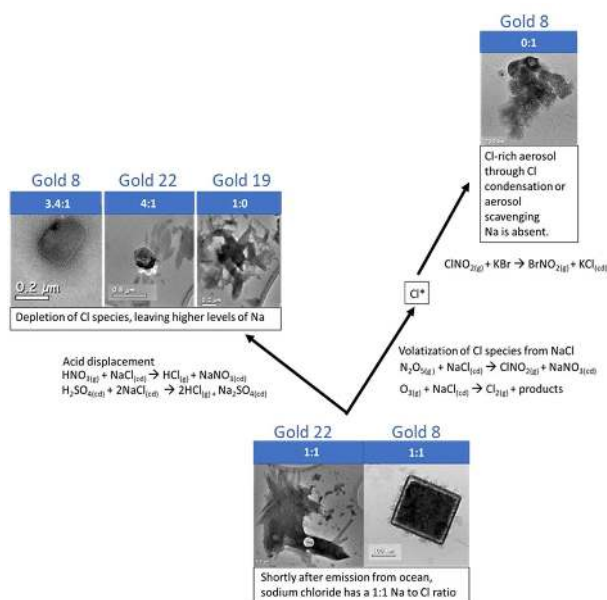

815

Figure 4 Potassium salt in a core-shell morphology around a refractory BC core (left) and organic with interstitial K-salt (right). Note the difference in scale between the two images.

Table 2 Black Carbon Mixing State by campaign. FT/BL, BC-Salt and BC-Organic refer to internally mixed particles

	BC – Salt	BC – Organic	BC - external
ORACLES BL	0.78	0.00	0.22
ORACLES FT	0.53	0.31	0.16
CLARIFY BL	0.50	0.29	0.21
CLARIFY FT	0.67	0.07	0.26

820 **Figure 5** Schematic showing different stages of sea salt conversion with example mechanisms. The particles are from CLARIFY filters and range from sea salts which have been freshly emitted to Cl-depleted particles containing nitrates and sulfates. Cl aerosol formation is also shown. Na:Cl ratios showing depletion of Cl with sea salt conversion are shown in the bar above each particle image.

825 **Figure 6** Assorted sea salt particles. (a) ~1.5 micron rounded NaCl; Gold 1 (b) CaSO₄; Gold 1 (c) NaCl and Mg; Gold 1 (d) Na₂SO₄ with K; Gold 1 (e) NaNO₃ mixed with BC; Gold 24 (f) BC encapsulated in Na₂SO₄ with K; Gold 1

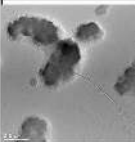

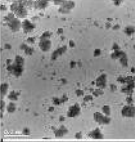

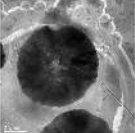

Table 3 Na dominant aerosols on CLARIFY filters with sampling location, CO levels, time from source, and percentage of particles on the filter with either Na or Cl. The ratios represent the weight percent ratio per particle, averaged across all particles with the elements of interest on each filter.

	Altitude (m)	Above/Below cloud	CO (ppbv)	Time from fire (days)	Particles with Na or Cl (%)	Avg Na wt%	Avg Cl wt%	Na/Cl	Na/S	Representative particle and filter summary
Gold_1	323	Below	108	marine	98	10.6	10.7	7.2	5.2	 Na and Cl with vary levels of Cl depletion; some Na with S; large NaCl particles; BC mixed with NaSO ₄
Gold_8	3902	Above	204	7	100	13.7	12.6	4.3	NA	 Mostly Cl particles without Na although some NaCl 1:1 crystals
Gold_9	2813	Above	329	4	37	5.8		NA	13.1	 No Cl present; Na mixed with BC and BB salts, sodium nitrate
Gold_10	2918	Above	158	5	74	5.4		NA	5.4	 No Cl present; sodium sulfate, BC mixed with Na
Gold_11	319	Below	70	15	80	19.2	4.7	6.1	8.1	 NaCl, ammonium chloride, sodium sulfate, Na with depleted Cl all present
Gold_19	1969	Above	212	7	29	3.7		NA	2.0	 Na sulfate, BC mixed with Na sulfate; no Cl, BC with Na, P, S, K, Ca
Gold_20	329	Below	130	marine	90	3.4	0.6	12.0	3.5	 BC mixed with Na; NaS crystals; NaCl but most particles Cl depleted
Gold_21	2357	Above	177	6	36	1.1		NA	0.8	 Trace amounts of sodium, no marine salts noted
Gold_22	2139	Below	128	9	77	12.5	8.7	3.9	3.3	 Na ₂ SO ₄ , NaCl
Gold_23	3500	Above	273	4	63	7.6	0.5	20.2	3.7	 Low levels of Cl, BC mixed with Na, S, K
Gold_24	1950	Above	331	4	77	2.3		NA	1.9	 Sodium nitrate mixed with BC

830

Table 4 Cl dominant aerosol on CLARIFY filters

Filter ID	Altitude (m)	Above/ Below cloud	CO (ppbv)	Time from fire (days)	Particle image & description
Gold_14	2845	Above	262	6	 N and Cl dominant spectra; uniform particles across filter
Gold_15	329	Below	158	marine	 C and Cl particles with small amount of K; uniform particles across filter
Gold_18	332	Below	119	marine	 Ca and Mg with Cl; uniform particles across filter

835

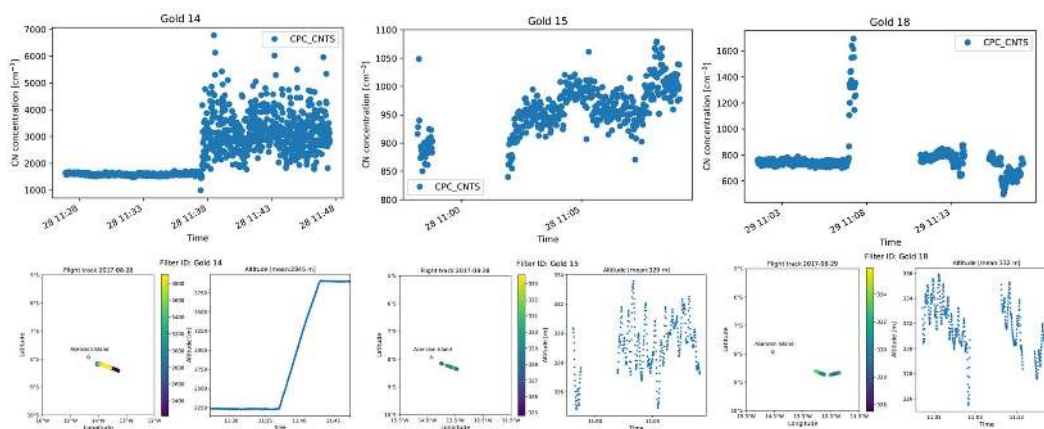

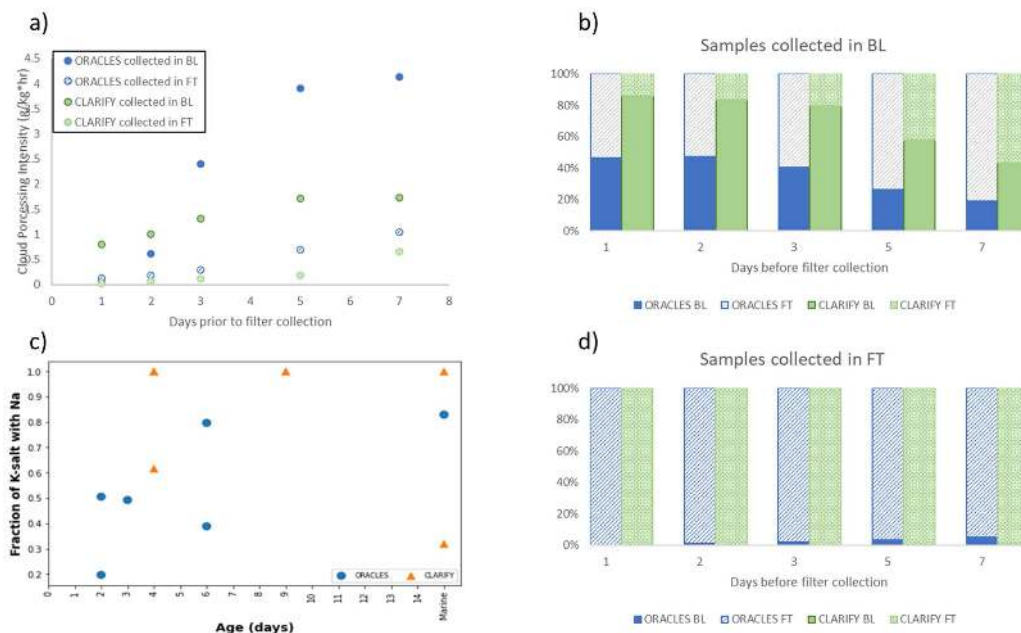

Figure 7 (upper panel) particle count concentration during filter collection time for the three Cl dominant filters, Gold14, Gold15, and Gold18, as detailed in Table 4, and (lower panel-left column) flight track, and (lower panel-right column) altitude

840

845

Figure 8 Panel a) BL and FT ORACLES and CLARIFY cloud processing intensity b) Time spent in BL and FT for samples collected in the BL in the days prior to filter collection C) Fraction of K-salt, per filter, mixed with Na d) Fractional time spent in BL and FT for samples collected in the FT in the days prior to filter collection

Figure 9 Aqueous K-salt particle with varying levels of Na throughout particle, with Na:K weight ratio designated in red

850

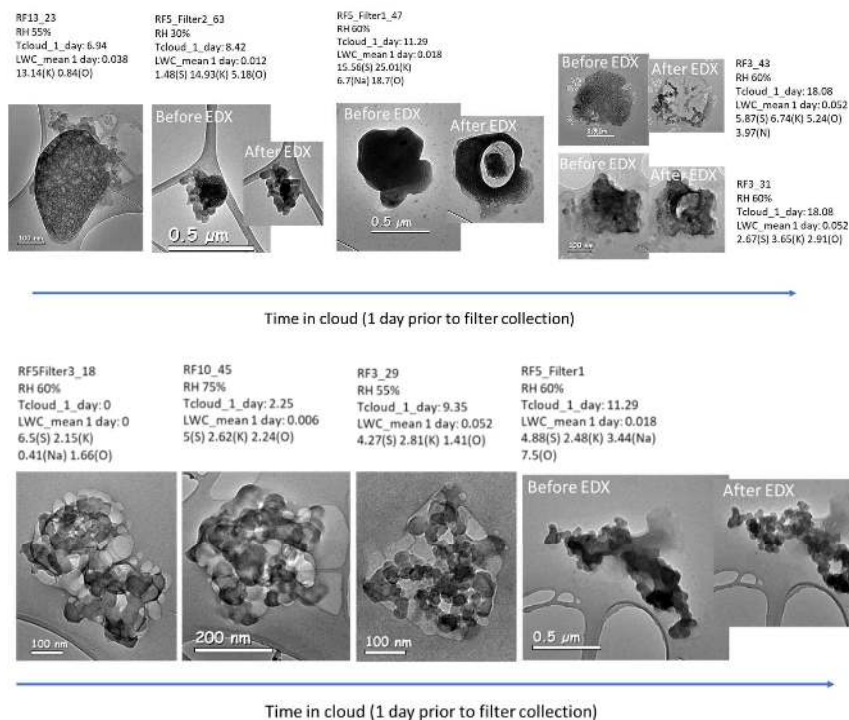

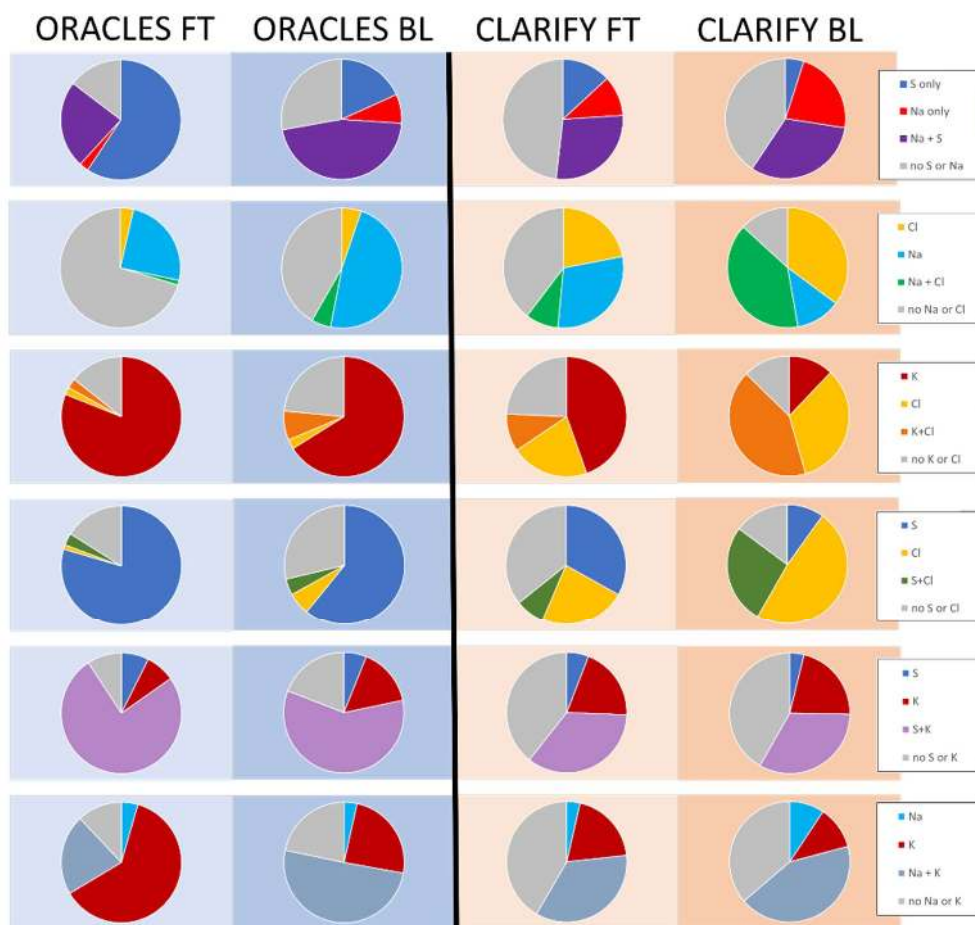

Figure 10 Potassium salt mixed with BC (top panel) and sulfur-organic and BC (bottom panel) as a function of time in cloud in the 24 hours prior to filter collection.

855

Figure 11 Elemental mixing states for select elemental pairs for CLARIFY (two left columns) and ORACLES (two right columns), separated by filter collection in the free troposphere and boundary layer
