Ongoing declines among the world's coral reefs<sup>1,2</sup> require novel approaches to sustain these ecosystems and the millions of people who depend on them<sup>3</sup>. A presently untapped approach that draws on theory and practice in human health and rural development<sup>4,5</sup> is systematically identifying and learning from the 'outliers'- places where ecosystems are substantially better ('bright spots') or worse ('dark spots') than expected, given the environmental conditions and socioeconomic drivers they are exposed to. Here, we compile data from more than 2,500 reefs worldwide and develop a Bayesian hierarchical model to generate expectations of how standing stocks of reef fish biomass are related to 18 socioeconomic drivers and environmental conditions. We then identified 15 bright spots and 35 dark spots among our global survey of coral reefs, defined as sites that had biomass levels more than two standard deviations from expectations. Importantly, bright spots were not simply comprised of remote areas with low fishing pressure- they include localities where human populations and use of ecosystems resources is high, potentially providing novel insights into how communities have successfully confronted strong drivers of change. Alternatively, dark spots were not necessarily the sites with the lowest absolute biomass and even included some remote, uninhabited locations often considered near-pristine<sup>6</sup>. We surveyed local experts about social, institutional, and environmental conditions at these sites to reveal that bright spots were characterised by strong sociocultural institutions such as customary taboos and marine tenure, high levels of local engagement in management, high dependence on marine resources, and beneficial environmental conditions such as deepwater refuges. Alternatively, dark spots were characterised by intensive capture and storage technology and a recent history of environmental shocks. Our

Despite substantial international conservation efforts, many of the world's ecosystems continue to decline<sup>1,7</sup>. Most conservation approaches aim to identify and protect places of high ecological integrity under minimal threat<sup>8</sup>. Yet, with escalating social and environmental drivers of change, conservation actions are also needed where people and nature coexist, especially where human impacts are already severe<sup>9</sup>. Here, we highlight an approach for implementing conservation in coupled human-natural systems focused on identifying and learning from outliers - places that are performing substantially better than expected, given the socioeconomic and environmental conditions they are exposed to. By their very nature, outliers deviate from expectations, and consequently can provide novel insights on confronting complex problems where conventional solutions have failed. This type of positive deviance, or 'bright spot' analysis has been used in fields such as business, health, and human development to uncover local actions and governance systems that work in the context of widespread failure<sup>10,11</sup>, and holds much promise in informing conservation. To demonstrate this approach, we compiled data from 2,514 coral reefs in 46 countries, states, and territories (hereafter 'nation/states') and developed a Bayesian hierarchical model to generate expected conditions of how standing reef fish biomass (a key indicator of resource availability and ecosystem functions <sup>12</sup>) was related to 18 key environmental variables and socioeconomic drivers (Box 1; Extended Data Tables 1,2; Methods). A key and significant finding from our global analysis is that the size and accessibility of the nearest market, more so than local or national population pressure, management, environmental conditions, or national socioeconomic context, was the strongest driver of reef fish biomass globally (Box 1).

Next, we identified 15 'bright spots' and 35 'dark spots' among the world's coral reefs, defined as sites with biomass levels more than two standard deviations higher or lower than expectations from our global model, respectively (Fig. 1; Methods; Extended Data Table 3). Rather than simply identifying places in the best or worst condition, our bright spots approach reveals the places that most strongly defy expectations. Using them to inform the conservation discourse will certainly challenge established ideas of where and how conservation efforts should be focused. For example, remote places far from human impacts are conventionally considered near-pristine areas of high conservation value<sup>6</sup>, yet most of the bright spots we identified occur in fished, populated areas (Extended Data Table 3), some with biomass values below the global average. Alternatively, some remote places such as parts of the NW Hawaiian Islands underperform (i.e. were identified as dark spots). Detailed analysis of why bright spots can evade the fate of similar areas facing equivalent stresses will require a new research agenda gathering detailed site-level information on social and institutional conditions, technological innovations, external influences, and ecological processes<sup>13</sup> that are simply not available in a global-scale analysis. To catalyse this process, we surveyed local experts about these issues for the 15 bright spots, 35 dark spots, and 14 average sites with biomass values closest to model expectations (Methods). Bright spots were characterised by substantial local engagement in the management process, higher dependence on coastal resources, and the presence of sociocultural governance institutions such as customary tenure or taboos (Fig. 2, Methods). For example, in one bright spot, Karkar Island, Papua New Guinea, resource use is restricted through an adaptive rotational harvest system based

on ecological feedbacks, marine tenure that allows for the exclusion of fishers from outside the local village, and initiation rights that limit individuals' entry into certain fisheries<sup>14</sup>. Bright spots were also generally proximate to deep water, which may help provide a refuge from disturbance for corals and fish<sup>15</sup> (Fig. 2, Extended Data Fig. 6). Conversely, dark spots were distinguished by having fishing technologies allowing for more intensive exploitation, such as fish freezers and potentially destructive netting, as well as a recent history of environmental shocks (e.g. coral bleaching or cyclone; Fig. 2). The latter is particularly worrisome in the context of climate change, which is likely to lead to increased coral bleaching and more intense cyclones <sup>16</sup>. Our global analyses highlight two novel opportunities to inform coral reef governance. The first is to use bright spots as agents of change to expand the conservation discourse from the current focus on protecting places under minimal threat<sup>8</sup>, toward harnessing lessons from places that have successfully confronted high pressures. Our bright spots approach can be used to inform the types of investments and governance structures that may help to create more sustainable pathways for impacted coral reefs. Specifically, our initial investigation highlights how investments that strengthen fisheries governance, particularly issues such as participation and property rights, could help communities to innovate in ways that allow them to defy expectations. Conversely, the more typical efforts to provide capture and storage infrastructure, particularly where there are environmental shocks and local-scale governance is weak, may lead to social-ecological traps<sup>17</sup> that reinforce resource degradation beyond expectations. Effectively harnessing the potential to learn from both bright and dark spots will require scientists to increase research efforts in these

places, NGOs to catalyze lessons from other areas, donors to start investing in novel solutions, and policy makers to ensure that governance structures foster flexible learning and experimentation. Indeed, both bright and dark spots may have much to offer in terms of how to creatively confront drivers of change, identify the paths to avoid and those offering novel management solutions, and prioritizing conservation actions. Critically, the bright spots we identified span the development spectrum from low income (Solomon Islands and Papua New Guinea) to high (territories of the USA and UK; Fig. 1), showing that lessons about effective reef management can emerge from diverse places.

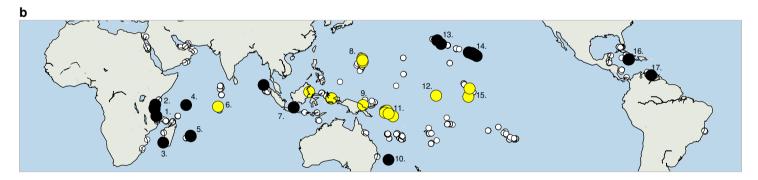

A second opportunity stems from a renewed focus on managing the socioeconomic drivers that shape reef conditions. Many social drivers are amenable to governance interventions, and our comprehensive analysis (Box 1) shows how an increased policy focus on social drivers such as markets and development could result in improvements to reef fish biomass. For example, given the important influence of markets in our analysis, reef managers, donor organisations, conservation groups, and coastal communities could improve sustainability by developing interventions that dampen the negative influence of markets on reef systems. Markets not only affect price and price variability for reef products<sup>18</sup>, creating incentives for overexploitation, but also influence people's behavior<sup>19</sup>, including their willingness to cooperate in the collective management of natural resources<sup>20</sup>. A portfolio of market interventions, including eco-labelling and sustainable harvesting certifications, fisheries improvement projects, and value chain interventions have been developed within large-scale industrial fisheries<sup>21-23</sup>. There is considerable scope for adapting these interventions to artisanal coral reef fisheries in both local and regional markets.

However, these interventions need to be coupled with mechanisms to ensure an equitable distribution of benefits<sup>24</sup> as well as effective policy reforms, such as limited entry or total allowable catch limits, supply chain traceability, and investments in local management capacity to ensure that fisheries are exploited at sustainable levels and livelihood benefits are secured.

The long-term viability of coral reefs will ultimately depend on international action to reduce carbon emissions<sup>16</sup>. However, fisheries remain a pervasive source of reef degradation, and local-level fisheries governance is crucial to sustaining ecological processes that give reefs the best chance of coping with global environmental change<sup>25</sup>. Effectively doing so will require novel approaches to conservation that embrace reefs as coupled human-natural systems and seek to confront, rather than avoid, drivers of change. By emulating the lessons learned from bright spots and dampening the drivers of reef exploitation, we can create a brighter future for the world's coral reefs.

# 223 Figures

**Figure 1** | **Bright and dark spots among the world's coral reefs.** (a) Each site's deviation from expected biomass (y-axis) along a gradient of nation/state mean biomass (x-axis). Sites with biomass values >2 standard deviations above or below expected values were considered bright and dark spots, respectively. The 15 bright and 35 dark spots are indicated with yellow and black dots respectively. Each grey vertical line represents

a nation/state in our analysis. Nation/states with bright or dark spots are labelled and numbered, corresponding to the numbers in panel b. There can be multiple bright or dark spots in each nation/state, thus the 50 bright and dark spots are distributed among 17 nation/states. As a conservative precaution, we did not consider a site bright or dark spot if there were fewer than 5 sites sampled in a nation/state (Methods); consequently there is one site with biomass levels lower than 2 SD below expectations that is not labelled as a dark spot. BIOT= British Indian Ocean Territory (Chagos); PNG= Papua New Guinea; CNMI= Commonwealth of the Northern Mariana Islands; NWHI= Northwest Hawaiian Islands; PRIA= Pacific Remote Island Areas. (b) Map highlighting bright spots and dark spots with large circles, and other sites in small circles. Bright spots are mostly concentrated on islands of the Pacific and Southeast Asia, while dark spots are spread among every major tropical ocean basin.

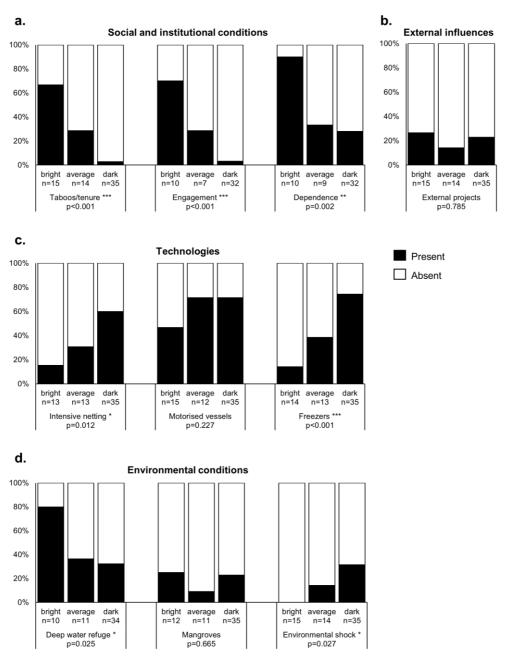

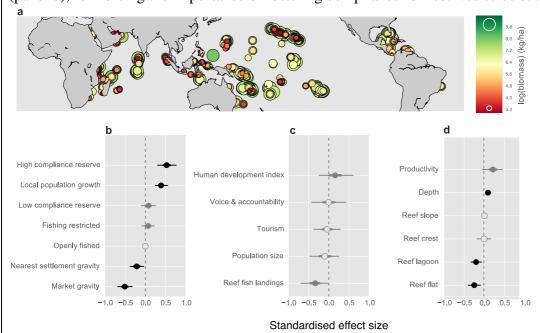

Figure 2 | Differences in social and environmental conditions between bright spots, dark spots, and 'average' sites. \*=p<0.05, \*\*=p<0.01, \*\*\*=p<0.001. P values are determined using Fisher's Exact test. Intensive netting includes beach seine nets, surround gill nets, and muro-ami.

#### Box 1

Drawing on a broad body of theoretical and empirical research in the social sciences<sup>24,26,27</sup> and ecology<sup>2,6,28</sup> on coupled human-natural systems, we quantified how reef fish biomass (panel a) was related to distal social drivers such as markets, affluence, governance, and population (panels b,c), while controlling for well-known environmental conditions such as depth, habitat, and productivity (panel d) (Extended Data Table 1, Methods). In contrast to many global studies of reef systems that are focused on demonstrating the severity of human impacts<sup>6</sup>, our examination seeks to uncover potential policy levers by highlighting the relative role of specific social drivers. Critically, the strongest driver of reef fish biomass (i.e. the largest standardized effect size) was our metric of potential interactions with urban centres, called market gravity<sup>29</sup> (Extended Data Fig. 1, 2, 3; Methods). Specifically, we found that reef fish biomass decreased as the size and accessibility of markets increased (Extended Data Fig. 2b, and Extended Data Fig. 3). Somewhat counter-intuitively, fish biomass was higher in places with high local human population growth rates, likely reflecting human migration to areas of better environmental quality<sup>30</sup>-a phenomenon that could result in increased degradation at these sites over time. We found a strong positive, but less certain relationship (i.e. a high standardized effect size, with >75% of the posterior distribution above zero) with the Human Development Index, meaning that reefs tended to be in better condition in wealthier nation/states (panel c). Our analysis also confirmed the role that marine reserves can play in sustaining biomass on coral reefs, but only when compliance is high (panel b), reinforcing the importance of fostering compliance for reserves to be successful.

Global patterns and drivers of reef fish biomass. (a) Reef fish biomass [in (log)kg/ha] among 918 study sites across 46 nations/states. For illustration purposes and to avoid the overlap of sites in a global map, we display sites as points that vary in size and colour proportional to amount of fish biomass, with small, red dots indicating low fish biomass and large, green dots indicating high biomass. b-d) Standardised effect size of local scale social drivers, nation/state scale social drivers, and environmental covariates, respectively. Parameter estimates are Bayesian posterior median values, 95% uncertainty intervals (UI; thin lines), and 50% UI (thick lines). Black dots indicate that the 95% UI does not overlap 0; Grey closed circles indicates that 75% of the posterior distribution lies to one side of 0; and grey open circles indicate that the 50% UI overlaps 0.

#### 242 Methods

243

262

263

264

244	Scales	of	data

- Our data were organized at three spatial scales: reef (n=2514), site (n=918), and nation/state (n=46).
- i) reef (the smallest scale, which had an average of 2.4 surveys/transects hereafter 'reef').
- 249 ii) site (a cluster of reefs). We clustered reefs together that were within 4km of 250 each other, and used the centroid of these clusters (hereafter 'sites') to 251 estimate site-level social and site-level environmental covariates (Extended 252 Data Table 1). To make these clusters, we first estimated the linear distance 253 between all reefs, then used a hierarchical analysis with the complete-254 linkage clustering technique based on the maximum distance between reefs. 255 We set the cut-off at 4km to select mutually exclusive sites where reefs 256 cannot be more distant than 4km. The choice of 4km was informed by a 3-257 year study of the spatial movement patterns of artisanal coral reef fishers, 258 corresponding to the highest density of fishing activities on reefs based on 259 GPS-derived effort density maps of artisanal coral reef fishing activities<sup>31</sup>. 260 This clustering analysis was carried out using the R functions 'helust' and 261 'cutree', resulting in an average of 2.7 reefs/site.
  - iii) Nation/state (nation, state, or territory). A larger scale in our analysis was 'nation/state', which are jurisdictions that generally correspond to individual nations (but could also include states, territories, overseas regions, or extremely remote areas within a state such as the northwest Hawaiian

Islands; Extended Data Table 2), within which sites and reefs were nested for analysis.

i)

# **Estimating Biomass**

Reef fish biomass can reflect a broad selection of reef fish functioning and benthic conditions 12,32-34, and is a key metric of resource availability for reef fisheries. Reef fish biomass estimates were based on instantaneous visual counts from 6,088 surveys collected from 2,514 reefs. All surveys used standard belt-transects, distance sampling, or point-counts, and were conducted between 2004 and 2013. Where data from multiple years were available from a single reef, we included only data from the year closest to 2010. Within each survey area, reef associated fishes were identified to species level, abundance counted, and total length (TL) estimated, with the exception of one data provider who measured biomass at the family level. To make estimates of biomass from these transect-level data comparable among studies, we:

Retained families that were consistently studied and were above a minimum size cut-off. Thus, we retained counts of >10cm diurnally-active, non-cryptic reef fish that are resident on the reef (20 families, 774 species), excluding sharks and semi-pelagic species (Extended Data Table 4). We also excluded three groups of fishes that are strongly associated with coral habitat conditions and are rarely targets for fisheries (Anthiinae, Chaetodontidae, and Cirrhitidae). We calculated total biomass of fishes on each reef using standard published species-level length-weight relationship parameters or those available on FishBase<sup>35</sup>. When length-weight relationship parameters were not available for a species, we used the parameters for a closely related species or genus.

291 ii) Directly accounted for depth and habitat as covariates in the model (see 292 "environmental conditions" section below); 293 Accounted for any potential bias among data providers (capturing iii) 294 information on both inter-observer differences, and census methods) by 295 including each data provider as a random effect in our model. 296 297 Biomass means, medians, and standard deviations were calculated at the reef-scale. 298 All reported log values are the natural log. 299 300 **Social Drivers** 301 1. Local Population Growth: We created a 100km buffer around each site and used 302 this to calculate human population within the buffer in 2000 and 2010 based on the 303 Socioeconomic Data and Application Centre (SEDAC) gridded population of the world database<sup>36</sup>. Population growth was the proportional difference between the 304 305 population in 2000 and 2010. We chose a 100km buffer as a reasonable range at 306 which many key human impacts from population (e.g., land-use and nutrients) might 307 affect reefs<sup>37</sup>. 308 309 2. Management: For each site, we determined if it was: i) unfished- whether it fell 310 within the borders of a no-take marine reserve. We asked data providers to further 311 classify whether the reserve had high or low levels of compliance; ii) restricted -312 whether there were active restrictions on gears (e.g. bans on the use of nets, 313 spearguns, or traps) or fishing effort (which could have included areas inside marine 314 parks that were not necessarily no take); or iii) fished - regularly fished without 315 effective restrictions. To determine these classifications, we used the expert opinion

of the data providers, and triangulated this with a global database of marine reserve boundaries<sup>38</sup>.

3. Gravity: We adapted the economic geography concept of gravity, also called interactance<sup>39</sup>, to examine potential interactions between reefs and: i) major urban centres/markets (defined as provincial capital cities, major population centres, landmark cities, national capitals, and ports); and ii) the nearest human settlements (Extended Data Fig. 1). This application of the gravity concept infers that potential interactions increase with population size, but decay exponentially with the effective distance between two points. Thus, we gathered data on both population estimates and a surrogate for distance: travel time.

### Population estimations

We gathered population estimates for: 1) the nearest major markets (which includes national capitals, provincial capitals, major population centres, ports, and landmark cities) using the World Cities base map from ESRI<sup>TM</sup>; and 2) the nearest human settlement within a 500km radius using LandScan<sup>TM</sup> 2011 database. The different datasets were required because the latter is available in raster format while the former is available as point data. We chose a 500km radius from the nearest settlement as the maximum distance any non-market fishing activities for fresh reef fish are likely to occur.

### Travel time calculation

Travel time was computed using a cost-distance algorithm that computes the least 'cost' (in minutes) of travelling between two locations on a regular raster

grid. In our case, the two locations were either: 1) the centroid of the site (i.e. reef cluster) and the nearest settlement, or 2) the centroid of the site and the major market. The cost (i.e. time) of travelling between the two locations was determined by using a raster grid of land cover and road networks with the cells containing values that represent the time required to travel across them<sup>40</sup> (Extended Data Table 5), we termed this raster grid a *friction-surface* (with the time required to travel across different types of surfaces analogous to different levels of friction). To develop the friction-surface, we used global datasets of road networks, land cover, and shorelines:

- Road network data was extracted from the Vector Map Level 0 (VMap0) from the National Imagery and Mapping Agency's (NIMA) Digital Chart of the World (DCW®). We converted vector data from VMap0 to 1km resolution raster.
- Land cover data were extracted from the Global Land Cover 2000<sup>41</sup>.
- -To define the shorelines, we used the GSHHS (Global Self-consistent, Hierarchical, High-resolution Shoreline) database version 2.2.2.

These three friction components (road networks, land cover, and water bodies) were combined into a single friction surface with a Behrmann map projection. We calculated our cost-distance models in R<sup>42</sup> using the *accCost* function of the 'gdistance' package. The function uses Dijkstra's algorithm to calculate least-cost distance between two cells on the grid and the associated distance taking into account obstacles and the local friction of the landscape<sup>43</sup>. Travel time estimates over a particular surface could be affected by the infrastructure (e.g. road quality) and types of technology used (e.g. types of boats). These

types of data were not available at a global scale but could be important modifications in more localised studies.

## Gravity computation

- i) To compute the gravity to the nearest market, we calculated the population of the nearest major market and divided that by the squared travel time between the market and the site. Although other exponents can be used<sup>44</sup>, we used the squared distance (or in our case, travel time), which is relatively common in geography and economics. This decay function could be influenced by local considerations, such as infrastructure quality (e.g. roads), the types of transport technology (i.e. vessels being used), and fuel prices, which were not available in a comparable format for this global analysis, but could be important considerations in more localised adaptations of this study.
- ii) To determine the gravity of the nearest settlement, we located the nearest populated pixel within 500kms, determined the population of that pixel, and divided that by the squared travel time between that cell and the reef site.

As is standard practice in many agricultural economics studies<sup>45</sup>, an assumption in our study is that the nearest major capital or landmark city represents a market. Ideally we would have used a global database of all local and regional markets for coral reef fish, but this type of database is not available at a global scale. As a sensitivity analysis to help justify our assumption that capital and landmark cities were a reasonable proxy for reef fish markets, we tested a series of candidate models that predicted biomass based on: 1) cumulative gravity of all cities within 500km; 2) gravity of the nearest city; 3) travel time to the nearest city; 4) population of the nearest city; 5) gravity to the nearest human population above 40

people/km<sup>2</sup> (assumed to be a small peri-urban area and potential local market); 6) the travel time between the reef and a small peri-urban area; 7) the population size of the small peri-urban population; 8) gravity to the nearest human population above 75 people/km<sup>2</sup> (assumed to be a large peri-urban area and potential market); 9) the travel time between the reef and this large peri-urban population; 10) the population size of this large peri-urban population; and 11) the total population size within a 500km radius. Model selection revealed that the best two models were gravity of the nearest city and gravity of all cities within 500km (with a 3 AIC value difference between them; Extended Data Table 6). Importantly, when looking at the individual components of gravity models, the travel time components all had a much lower AIC value than the population components, which is broadly consistent with previous systematic review studies<sup>46</sup>. Similarly, travel time to the nearest city had a lower AIC score than any aspect of either the peri-urban or urban measures. This suggests our use of capital and landmark cities is likely to better capture exploitation drivers from markets rather than simple population pressures. This may be because market dynamics are difficult to capture by population threshold estimates; for example some small provincial capitals where fish markets are located have very low population densities, while some larger population centres may not have a market. Downscaled regional or local analyses could attempt to use more detailed knowledge about fish markets, but we used the best proxy available at a global scale.

4. Human Development Index (HDI): HDI is a summary measure of human development encompassing: a long and healthy life, being knowledgeable, and having

415 a decent standard of living. In cases where HDI values were not available specific to 416 the State (e.g. Florida and Hawaii), we used the national (e.g. USA) HDI value. 417 418 5. Population Size: For each Nation/state, we determined the size of the human 419 population. Data were derived mainly from census reports, the CIA fact book, and 420 Wikipedia. 421 422 6. Tourism: We examined tourist arrivals relative to the nation/state population size 423 (above). Tourism arrivals were gathered primarily from the World Tourism 424 Organization's Compendium of Tourism Statistics. 425 426 7. National Reef Fish Landings: Catch data were obtained from the Sea Around Us 427 Project (SAUP) catch database (www.seaaroundus.org), except for Florida, which 428 was not reported separately in the database. We identified 200 reef fish species and 429 taxon groups in the SAUP catch database<sup>47</sup>. Note that reef-associated pelagics such as 430 scombrids and carangids normally form part of reef fish catches. However, we chose 431 not to include these species because they are also targeted and caught in large 432 amounts by large-scale, non-reef operations. 433 434 8. Voice and Accountability: This metric, from the World Bank survey on 435 governance, reflects the perceptions of the extent to which a country's citizens are 436 able to participate in selecting their government, as well as freedom of expression, 437 freedom of association, and a free media. In cases where governance values were not 438 available specific to the Nation/state (e.g. Florida and Hawaii), we used national (e.g. 439 USA) values.

**Environmental Drivers** 

1. Depth: The depth of reef surveys were grouped into the following categories: <4m,</li>
 4-10m, >10m to account for broad differences in reef fish community structure
 attributable to a number of inter-linked depth-related factors. Categories were
 necessary to standardise methods used by data providers and were determined by pre-

existing categories used by several data providers.

2. *Habitat:* We included the following habitat categories: i) Slope: The reef slope habitat is typically on the ocean side of a reef, where the reef slopes down into deeper water; ii) Crest: The reef crest habitat is the section that joins a reef slope to the reef flat. The zone is typified by high wave energy (i.e. where the waves break). It is also typified by a change in the angle of the reef from an inclined slope to a horizontal reef flat; iii) Flat: The reef flat habitat is typically horizontal and extends back from the reef crest for 10's to 100's of metres; iv) Lagoon / back reef: Lagoonal reef habitats are where the continuous reef flat breaks up into more patchy reef environments sheltered from wave energy. These habitats can be behind barrier / fringing reefs or within atolls. Back reef habitats are similar broken habitats where the wave energy does not typically reach the reefs and thus forms a less continuous 'lagoon style' reef habitat. Due to minimal representation among our sample, we excluded other less prevalent habitat types, such as channels and banks. To verify the sites' habitat information, we used the Millennium Coral Reef Mapping Project (MCRMP) hierarchical data<sup>48</sup>, Google Earth, and site depth information.

3. Productivity: We examined ocean productivity for each of our sites in mg C / m2 / day (http://www.science.oregonstate.edu/ocean.productivity/). Using the monthly data for years 2005 to 2010 (in hdf format), we imported and converted those data into ArcGIS. We then calculated yearly average and finally an average for all these years. We used a 100km buffer around each of our sites and examined the average productivity within that radius. Note that ocean productivity estimates are less accurate for nearshore environments, but we used the best available data.

Analyses

We first looked for collinearity among our covariates using bivariate correlations and variance inflation factor estimates (Extended Data Fig. 4. Extended Data Table 7)

variance inflation factor estimates (Extended Data Fig. 4, Extended Data Table 7).

This led to the exclusion of several covariates (not described above): i) *Geographic Basin* (Tropical Atlantic, western Indo-Pacific, Central Indo-Pacific, or eastern Indo-Pacific); ii) *Gross Domestic Product* (purchasing power parity); iii) *Rule of Law* (World Bank governance index); iv) *Control of Corruption* (World Bank governance index); and v) *Sedimentation*. Additionally, we removed an index of climate stress, developed by Maina et al. <sup>49</sup>, which incorporated 11 different environmental conditions, such as the mean and variability of sea surface temperature due to repeated lack of convergence for this parameter in the model, likely indicative of unidentified multi-collinearity. All other covariates had correlation coefficients 0.7 or less and Variance Inflation Factor scores less than 5 (indicating multicolinearity was not a serious concern). Care must be taken in causal attribution of covariates that were significant in our model, but demonstrated colinearity with candidate covariates that were removed during the aforementioned process. Importantly, the covariate that

exhibited the largest effect size in our model, market gravity, was not strongly collinear with other candidate covariates.

To quantify the multi-scale social, environmental, and economic factors affecting reef fish biomass we adopted a Bayesian hierarchical modelling approach that explicitly recognized the three scales of spatial organization: reef (j), site (k), and nation/state (s).

In adopting the Bayesian approach we developed two models for inference: a null model, consisting only of the hierarchical units of observation (i.e. intercepts-only) and a full model that included all of our covariates (drivers) of interest. Covariates were entered into the model at the relevant scale, leading to a hierarchical model whereby lower-level intercepts (averages) were placed in the context of higher-level covariates in which they were nested. We used the null model as a baseline against which we could ensure that our full model performed better than a model with no covariate information. We did not remove 'non-significant' covariates from the model because each covariate was carefully considered for inclusion and could therefore reasonably be considered as having an effect, even if small or uncertain; removing factors from the model is equivalent to fixing parameter estimates at exactly zero - a highly-subjective modelling decision after covariates have already been selected as potentially important<sup>50</sup>.

The full model assumed the observed, environmental-scale observations of fish biomass  $(y_{ijks})$  were modelled using a noncentral-T distribution, allowing for fatter tails than typical log-normal models of reef fish biomass<sup>32</sup>.

 $\log(y_{ijks}) \sim NoncentralT(\mu_{ijks}, \tau_{reef}, 3.5)$ 

- $\mu_{ijks} = \beta_{0jks} + \beta_{reef} X_{reef}$
- $\tau_{reef} \sim U(0,100)^{-2}$

- with  $X_{reef}$  representing the matrix of observed environmental-scale covariates and
- $\beta_{reef}$  the array of estimated reef-scale parameters. The  $\tau_{reef}$  (and all subsequent  $\tau$ 's)
- were assumed common across observations in the final model and were minimally
- informative<sup>50</sup>. Using a similar structure, the environmental-scale intercepts ( $\beta_{0iks}$ )
- were structured as a function of site-scale covariates ( $X_{sit}$ ):

524 
$$\beta_{0jks} \sim N(\mu_{jks}, \tau_{sit})$$

- $\mu_{iks} = \gamma_{0ks} + \gamma_{sit} X_{sit}$
- $\tau_{sit} \sim U(0,100)^{-2}$

- with  $\gamma_{sit}$  representing an array of site-scale parameters. Building upon the hierarchy,
- 529 the site-scale intercepts  $(\gamma_{0ks})$  were structured as a function of state-scale covariates
- $(X_{sta})$ :

532 
$$\gamma_{0ks} \sim N(\mu_{ks}, \tau_{sta})$$

- $\mu_{ks} = \gamma_{0s} + \gamma_{sta} X_{sta}$
- $\tau_{sta} \sim U(0,100)^{-2}$

- Finally, at the top scale of the analysis we allowed for a global (overall) estimate of
- 537 average log-biomass ( $\mu_0$ ):

 $\gamma_{0s} \sim N(\mu_0, \tau_{glo})$ 

 $\mu_0 \sim N(0.0, 1000)$ 

 $\tau_{glo} \sim U(0,100)^{-2}$ .

The relationships between fish biomass and environmental, site, and state scale drivers was carried out using the PyMC package<sup>51</sup> for the Python programming language, using a Metropolis-Hastings (MH) sampler run for 10<sup>6</sup> iterations, with a 900,000 iteration burn in, leaving 10,000 samples in the posterior distribution of each parameter; these long burn-in times are often required with a complex model using the MH algorithm. Convergence was monitored by examining posterior chains and distributions for stability and by running multiple chains from different starting points and checking for convergence using Gelman-Rubin statistics<sup>52</sup> for parameters across multiple chains; all were at or close to 1, indicating good convergence of parameters across multiple chains.

Overall model fit

We conducted posterior predictive checks for goodness of fit (GoF) using Bayesian p-values<sup>40</sup> (BpV), whereby fit was assessed by the discrepancy between observed or simulated data and their expected values. To do this we simulated new data ( $y_i^{new}$ ) by sampling from the joint posterior of our model ( $\theta$ ) and calculated the Freeman-Tukey measure of discrepancy for the observed ( $y_i^{obs}$ ) or simulated data, given their expected values ( $\mu_i$ ):

 $D(y|\theta) = \sum_{i} (\sqrt{y_i} - \sqrt{\mu_i})^2$ 

yielding two arrays of median discrepancies  $D(y^{obs}|\theta)$  and  $D(y^{new}|\theta)$  that were then used to calculate a BpV for our model by recording the proportion of times  $D(y^{obs}|\theta)$  was greater than  $D(y^{new}|\theta)$  (Extended Data Fig. 5). A BpV above 0.975 or under 0.025 provides substantial evidence for lack of model fit. Evaluated by the Deviance Information Criterion (DIC), the full model greatly outperformed the null model ( $\Delta$ DIC=472).

To examine homoscedasticity, we checked residuals against fitted values. We also checked the residuals against all covariates included in the model, and several covariates that were not included in the model (primarily due to collinearity), including: 1) *Atoll* - A binary metric of whether the reef was on an atoll or not; 2) *Control of Corruption:* Perceptions of the extent to which public power is exercised for private gain, including both petty and grand forms of corruption, as well as 'capture' of the state by elites and private interests. Derived from the World Bank survey on governance; 3) *Geographic Basin*- whether the site was in the Tropical Atlantic, western Indo-Pacific, Central Indo-Pacific, or eastern Indo-Pacific; 4) *Connectivity* – we examined 3 measures based on the area of coral reef within a 30km, 100km, and 600km radius of the site; 5) *Sedimentation*; 6) *Coral Cover* (which was only available for a subset of the sites); 7) *Climate stress*<sup>49</sup>; and 8) *Census method*. The model residuals showed no patterns with these eight additional covariates, suggesting they would not explain additional information in our model.

587 Bright and dark spot estimates

Because the performance of site scale locations are of substantial interest in uncovering novel solutions for reef conservation, we defined bright and dark spots at the site scale. To this end, we defined bright (or dark) spots as locations where expected site-scale intercepts ( $\gamma_{0ks}$ ) differed by more than two standard deviations from their nation/state-scale expected value ( $\mu_{ks}$ ), given all the covariates present in the full hierarchical model:

 $SS_{spot} = |(\mu_{ks} - \gamma_{0ks})| > 2[SD(\mu_{ks} - \gamma_{0ks})].$ 

This, in effect, probabilistically identified the most deviant sites, given the model, while shrinking sites toward their group-level means, thereby allowing us to overcome potential bias due to low and varying sample sizes that can lead to extreme values from chance alone. As a conservative precaution, we did not consider a site a bright or dark spot if the group-level (i.e. nation/state) mean had fewer than 5 estimates (sites).

Analysing conditions at bright spots

We surveyed data providers and other experts about key social, institutional, and environmental conditions at the 15 bright spots, 35 dark spots, and 14 sites that performed most closely to model specifications. Research on bright spots in agricultural development<sup>13</sup> highlights several potential mechanisms, which formed the basis of our exploration. These include:

i) Environmental/ecological processes (e.g. recruitment & connectivity). We examined whether sites were within 5km of mangroves and deep-water refuges, and whether there had been any major environmental disturbances

612 environmental conditions were recorded as present/absent; 613 Social and institutional conditions. We examined the presence of ii) 614 customary management institutions such as taboos and marine tenure 615 institutions, whether there was a high level of engagement by local people 616 in management, whether there was high levels of dependence on marine 617 resources (whether a majority of local residents depend on reef fish as a 618 primary source of food or income). All social and institutional conditions 619 were recorded as presence/absence. Dependence on resources and 620 engagement were limited to sites that had adjacent human populations. All 621 other conditions were recorded regardless of whether there is an adjacent 622 community; 623 iii) Technological use/innovation. We examined the presence of motorised 624 vessels, intensive capture equipment (such as beach seine nets, surround 625 gill nets, and muro-ami nets), and storage capacity (i.e. freezers); and 626 External influences (such as donor-driven projects). We examined the iv) 627 presence of NGOs, fishery development projects, development initiatives 628 (such as alternative livelihoods), and fisheries improvement projects. All 629 external influences were recorded as present/absent then summarised into 630 a single index of whether external projects were occurring at the site. 631 632 To test for associations between these mechanisms and whether sites were more or 633 less bright, we used two complementary approaches. The link between the 634 presence/absence of the aforementioned mechanisms and whether a site was bright, 635 average, or dark was assessed using a Fisher's Exact Test. Then we tested whether the

such as coral bleaching, tsunami, and cyclones within the past 5 years. All

mean deviation in fish biomass from expected was similar between sites with presence or absence of the mechanisms in question (i.e. the presence or absence of marine tenure/taboos) using an ANOVA assuming unequal variance. The two tests yielded similar results, but provide slightly different ways to conceptualise the issue, the former is correlative while the latter explains brightness based on mechanisms, so we provide both (Figure 2, Extended Data Fig. 6).

Extended Data Table 2 | List of 'Nation/states' covered in study and their respective average biomass (plus or minus standard error) In most cases, nation/state refers to an individual country, but can also include states (e.g. Hawaii or Florida), territories (e.g. British Indian Ocean Territory), or other jurisdictions. We treated the NW Hawaiian Islands and Farquhar as separate 'nation/states' from Hawaii and Seychelles, respectively, because they are extremely isolated and have little or no human population. In practical terms, this meant different values for a few nation/state scale indicators that ended up having relatively small effect sizes, anyway (Fig. 1b): Population, tourism visitations, and in the case of NW Hawaiian Island, fish landings.

Nation/states	Average biomass	(± SE)
American Samoa	235.93	(± 17.75)
Australia	735.01	$(\pm 136.85)$
Belize	981.16	$(\pm 65.32)$

Extended Data Table 4 List of fish families included in the study, their common name, and whether they are commonly targeted in artisanal coral reef fisheries.

Note: Targeting of reef fishes can vary by location due to gear, cultural preferences, and a range of other considerations.

Fish family	Common family name	Fishery target
Acanthuridae	Surgeonfishes	Target
Balistidae	Triggerfishes	Non-target
Diodontidae	Porcupinefishes	Non-target
Ephippidae	Batfishes	Target
Haemulidae	Sweetlips	Target
Kyphosidae	Drummers	Target
Labridae	Wrasses and Parrotfish	Target >20cm
Lethrinidae	Emperors	Target
Lutjanidae	Snappers	Target
Monacanthidae	Filefishes	Non-target
Mullidae	Goatfishes	Target
Nemipteridae	Coral Breams	Target
Pinguipedidae	Sandperches	Non-target
Pomacanthidae	Angelfishes	Target >20cm
Serranidae	Groupers	Target
Siganidae	Rabbitfishes	Target
Sparidae	Porgies	Target
Synodontidae	Lizardfishes	Non-target
Tetraodontidae	Pufferfishes	Non-target
Zanclidae	Moorish Idol	Non-target

# 838 Extended Data Table 7 Model selection of potential gravity indicators and components.

Model	Covariates	AIC	Delta AIC
M2	Gravity of nearest city	2666.4	0
M1	Gravity of all cities in 500km	2669.5	3.1
M3	Travel time to nearest city	2700.0	33.6
M5	Gravity of nearest small peri-urban area (40 people/km2)	2703.9	37.5
M11	Total Population in 500km radius	2712.0	45.6
M9	Travel time to the nearest large peri-urban area (75 people/km2)	2712.1	45.7
M6	Travel time to nearest small peri-urban area (40 people/km2)	2713.8	47.4
M8	Gravity to the nearest large peri-urban area (75 people/km2)	2722.9	56.5
M7	Population of nearest small peri-urban area (40 people/km2)	2792.7	126.3
M4	Population of the nearest city	2812.8	146.5
M10	Population of the nearest large peri-urban area (75 people/km2)	2822.2	155.8
M0	Intercept only	2827.7	161.27

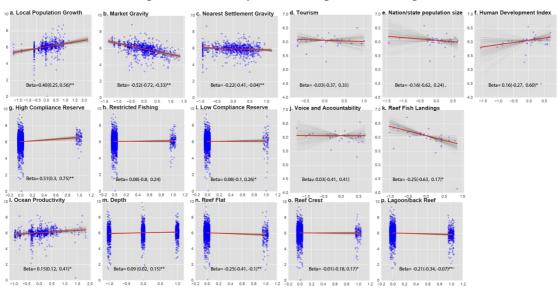

#### 842 Extended Data Figure Legends

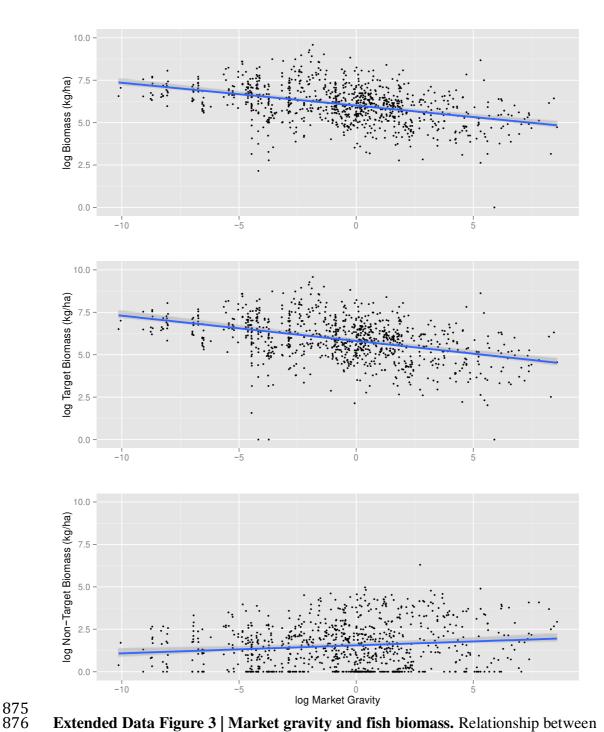

Extended Data Figure 1 | a) A heuristic of the gravity concept where interactions between people and reefs are a function of population size (p) and the time it takes to travel to the reef (tt). Beginning in the 1800s, the concept of 'gravity' has been applied to measure economic interactions, migration patterns, and trade flows<sup>29,54-56</sup>. Drawing on an analogy from Newton's Law of Gravitation, the gravity concept predicts that interactions between two points are positively related to their mass (i.e., population) and inversely related to the distance between them. Here, we adapt the gravity concept to examine interactions between people and reefs. We posit that human interactions with a reef will be a function of the population of a place (p) divided by the squared time it takes to travel (tt) to the reefs (i.e. travel time). Thus, gravity values could be similar for places that are large but far from the reefs (e.g.  $p_x = 30,000$  people,  $t_x = 10$ hours) as to those with small populations that are close to the reef (e.g.  $p_y = 300$  people,  $t_x = 10$  hour). We used travel time instead of linear distance

to account for the differences incurred by travelling over different surfaces (e.g. water, roads, tracks—see Methods). We developed gravity measures for the nearest human settlement and for the nearest major market (defined as provincial capitals, ports, and other large, populated places- see Methods). b) Gravity isoclines along gradients of population size and travel time.

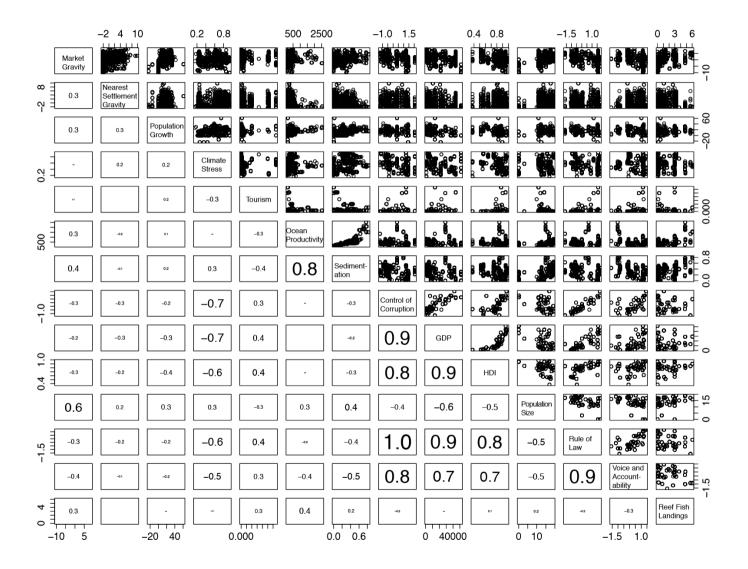

Extended Data Figure 2 | Marginal relationships between reef fish biomass and site-level social drivers. a) local population growth, b) market gravity, c) nearest settlement gravity, d) tourism, e) nation/state population size, f) Human development Index, g) high compliance marine reserve (0 is fished baseline), h) restricted fishing (0 is fished baseline), i) low compliance marine reserve (0 is fished baseline), j) voice and accountability, k) reef fish landings, l) ocean productivity; m) depth (-1= 0-4m, 0= 4-10m, 1=>10m), n) reef flat (0 is reef slope baseline), o) reef crest flat (0 is reef slope baseline). All X variables are standardized. \*\* 95% of the posterior density is either a positive or negative direction (Box 1); \* 75% of the posterior density is either a positive or negative direction.

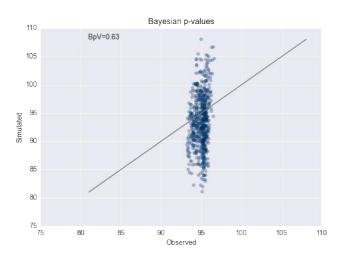

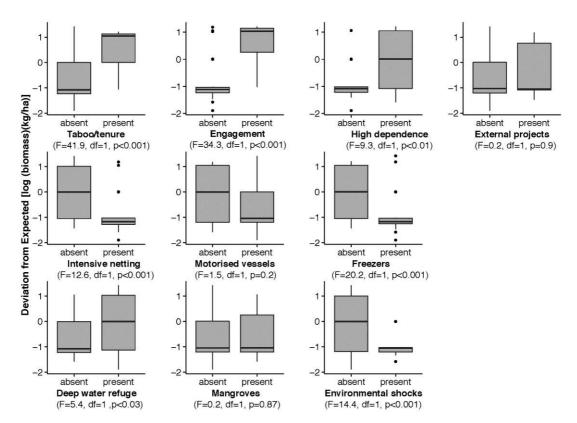

Extended Data Figure 3 | Market gravity and fish biomass. Relationship between market gravity and a) reef fish biomass; b) targeted reef fish biomass (using fish families targeted by artisanal fisheries specified in Extended Data Table 2); c) nontarget reef fish biomass. The strong relationship between gravity and reef fish biomass is very similar for the biomass of fishes generally targeted by artisanal fisheries, but very different for non-target fishes. This suggests that the relationship between market gravity and fish biomass is primarily driven by fishing, rather than other potential human impacts of urban areas (sedimentation, nutrients, pollution, etc.).

Extended Data Figure 4 Correlation plot of candidate continuous covariates before accounting for colinearity (Extended Data Table 7). Colinearity between continuous and categorical covariates (including biogeographic region, habitat, protection status, and depth) were analysed using boxplots.

**Extended Data Figure 5 | Model fit statistics**. Bayesian p Values (BpV) for the full model indicating goodness of fit, based on posterior discrepancy. Points are Freeman-Tukey differences between observed and expected values, and simulated and expected values. Plot shows no evidence for lack of fit between the model and the data.

Extended Data Figure 6 Box plot of deviation from expected as a function of the presence or absence of key social and environmental conditions expected to produce bright spots.
