## ABSTRACT

Stay cables are prone to vibrations due to their low inherent damping. This paper presents an approach for systematic identification of beneficial passive absorbers layouts consisting of damper, spring and inerter. The inerter is a one-port mechanical element with the property that the applied force is proportional to the relative acceleration between its terminals. In this work, a finite element taut cable model, with vibration absorber represented by its admittance function, is firstly established. Two performance measures, depending on the length of the cable and the forcing conditions, are introduced to assess the effect of candidate absorbers. Potential advantages of low-complexity inerter-based absorber layouts are then systematically investigated, with corresponding element values in these layouts identified. Building on this, the effect of series compliance is also examined for beneficial absorber layouts. It is shown that, up to a certain inertance, which depends on the stiffness of the series compliance, the performance advantages over a viscous damper can be maintained, or even enlarged in some cases, if the element values are properly tuned.

## INTRODUCTION

Stay cables are widely used in cable-stayed bridges and other civil engineering structures in order to carry static loads, but they are often observed to experience large amplitude vibrations. The exact excitation mechanisms are rather complex, but possible causes include aerodynamic forcing

24 on the cables such as galloping (Den Hartog 1933; Macdonald and Larose 2006), wake galloping  
25 (Tokoroa et al. 2000), rain–wind excitation (Hikami and Shiraishi 1988; Matsumoto et al. 1990)  
26 and excitation from deck or pylon motion (Lilien and Da Costa 1994; Macdonald 2016). However,  
27 large cable vibrations are more often caused by aerodynamic forcing which introduces aero-elastic  
28 instabilities. The motion of the cable in the wind causes changes in the aerodynamic forces which  
29 is often taken to be equivalent to negative damping. The classical instance of this is across-wind  
30 galloping (Den Hartog 1933), which often affects electricity transmission lines, especially with  
31 ice accretion. More generally, galloping can occur in a three-dimensional environment, such  
32 as for inclined bridge cables in skew wind (Macdonald and Larose 2006). When the negative  
33 aerodynamic damping is greater in magnitude than the structural damping, the vibrations grow  
34 exponentially (until nonlinearity may limit the amplitude at some large value). Other than changing  
35 the aerodynamic shape, which is not always possible or economic, the solution to galloping is  
36 to provide sufficient structural damping. For rain-wind excitation (Hikami and Shiraishi 1988;  
37 Matsumoto et al. 1990), which is the most common cause of large cable vibrations on cable-stayed  
38 bridges, it is generally considered also to be equivalent to some form of negative aerodynamic  
39 damping and it has been found to be inhibited by providing a certain level of damping (Caetano  
40 2007). As a result, for limiting vibrations due to aerodynamic forcing on the cables, the damping  
41 ratio is often considered as the key parameter.

42 Adding viscous dampers to cables is a commonly-used method for introducing extra damping.  
43 Several studies have been carried out to understand the dynamic behavior. A universal curve have  
44 been presented for estimating the modal damping of stay cables with a viscous damper close to  
45 one of the supports (Pacheco et al. 1993), then an analytical formula for the universal curve was  
46 derived based on complex cable modes (Krenk 2000). Subsequently, Main and Jones extended  
47 these studies by revealing the importance of damper-induced frequency shifts in characterizing the  
48 response of the system (Main and Jones 2002). It has been shown that, the optimum damping ratio  
49 for a certain mode will be larger if the damper is located closer to an anti-node. However, for ease  
50 of installation and maintenance, they are usually located close to the deck end of the cable, up

51 to about 5% of the length along the cable (Cu and Han 2015). Tuned mass dampers (TMDs) are  
52 another type of passive absorber device that has been used in practice on cables. It has been shown  
53 that TMDs can be more effective than viscous dampers if they are fixed at the same location along  
54 the cable (Cai et al. 2006).

55 An alternative is to use a vibration suppression device incorporating an inerter. The inerter  
56 was proposed as an ideal two terminal mechanical element (Smith 2002), with the property that  
57 the applied force is proportional to the relative acceleration between its two terminals. The inerter  
58 has fundamentally enlarged the range of absorbers that can be realized mechanically. Furthermore,  
59 via gearing, the inertance (i.e. the constant of proportionality between the relative acceleration  
60 and force, with dimensions of mass) can be much larger than the physical mass of the device.  
61 Performance advantages have been identified for road vehicles (Smith and Wang 2004; Jiang et al.  
62 2015a), railway vehicles (Wang et al. 2009; Wang et al. 2012; Jiang et al. 2015b), aircraft landing  
63 gear systems (Liu et al. 2015; Li et al. 2017a; Li et al. 2017b), and civil engineering structures  
64 (Ikago et al. 2012; Lazar et al. 2014; Yang 2016; Zhang et al. 2017; Makris and Kampas 2016;  
65 Bakis et al. 2017). For vibration suppression of cables, the potential benefits of adding a tuned  
66 inerter damper (TID) system has been analyzed (Lazar et al. 2016). A practical tuning methodology  
67 for the TID was proposed to minimize the displacement amplitude at the mid-span of the cable  
68 for excitation from motion of both supports. However, cable vibrations caused by aerodynamic  
69 forcing on the cables, which is usually more problematic have not been considered for inerter-based  
70 absorbers.

71 Two performance measures are introduced in this paper to quantify the damping performance  
72 of the absorbers. As the lowest frequency mode is often most susceptible to vibrations (Gimsing  
73 and Georgakis 2011), one performance measure is the minimum damping ratio of any modes with  
74 natural frequencies close to that of the first mode of the undamped cable, without considering  
75 higher frequency modes. However, long cables or cables in extreme conditions may be susceptible  
76 to vibrations in multiple modes, so the second measure takes higher modes into consideration. In  
77 addition, the effects of series compliance to the absorber are introduced, since the connections at

78 either end of the absorber, to the support and to the cable, may not be fully rigid.

79 In this paper, the potential to enhance the damping performance of a cable, for passive absorber  
80 layouts with three element or less is presented. The approach adopted enables candidate layouts,  
81 i.e. specific connections of spring damper and inerter elements, to be explored in a systematic  
82 manner. First, a finite element cable model is integrated with an admittance function representing a  
83 general vibration absorber. All possible absorber layouts with no more than one damper, one inerter  
84 and one spring each, as well as two proposed performance measures, are then introduced. After  
85 that, the optimum performance of the modes with frequencies close to that of the first mode of the  
86 undamped cable for all candidate layouts are identified, and the corresponding parameter values are  
87 presented. Similar analysis, using the second measure to account for the effect on higher frequency  
88 modes, is then implemented and results are presented. Finally, the effect of series compliance is  
89 addressed for the two most beneficial layouts obtained in the previous section, before conclusions  
90 are drawn.

## 91 **MATHEMATICAL APPROACH**

92 In this section, a finite element model of a cable combined with an arbitrary linear passive  
93 absorber layout is introduced. Subsequently, all candidate absorber layouts with no more than one  
94 damper, inerter and spring each are presented. Two performance measures are then introduced to  
95 assess the damping performance. Following that, optimization results of a viscous damper only  
96 layout is discussed and compared with previous studies, showing the validity of proposed approach.

### 97 **Cable models with admittance functions representing absorbers**

98 A mathematical model of a cable is built using the finite element method. Lumped masses rather  
99 than bar elements are used here for the benefit of calculation efficiency, which will be discussed in  
100 detail at the end of this subsection.

101 The tension along the cable is denoted as  $T$ , the total mass of the cable is  $M$ , and the total length  
102 of the cable is  $L$ . The effects of inclination and sag of the cable are neglected as well as the cable's  
103 out-of-plane motion and its elasticity. An example of a taut cable model with  $n$  DOF is shown in  
104 Fig. 1. There are  $n$  masses, each of mass  $m$  spread along the cable and two masses of mass  $m/2$

105 connected directly to the supports. Hence,  $m = M/(n + 1)$ . These masses divide the cable into  
 106  $n + 1$  elements, each of length  $l = L/(n + 1)$ . The  $a^{th}$  mass has an associated vertical position  $x_a$ ,  
 107 which equals zero at equilibrium. Since the masses at the end-points are connected directly to the  
 108 supports,  $x_0$  and  $x_{n+1}$  always equal zero.

109 The displacement of the masses from their equilibrium positions leads to an angle  $\theta_a$  between  
 110 mass  $a$  and mass  $a + 1$ . As the displacements are small compared to the element length  $L/(n + 1)$ ,  
 111 the angle  $\theta_a$  can be presented as:

$$112 \quad \theta_a = \arcsin\left(\frac{x_{a+1} - x_a}{L/(n + 1)}\right) \quad (1)$$

113 The circular natural frequency of the first mode of the undamped cable model can be expressed  
 114 as:

$$115 \quad \omega_o = \pi \left(\frac{T}{ML}\right)^{0.5} \quad (2)$$

116 The equation of motion for mass  $a$ , without any external force, can be expressed as:

$$117 \quad m\ddot{x}_a = T \sin(\theta_a) - T \sin(\theta_{a-1}) \quad (3a)$$

118 Similarly, the equation of motion for mass  $a_f$ , where the absorber is located, can be expressed  
 119 as:

$$120 \quad m\ddot{x}_{a_f} = T \sin(\theta_{a_f}) - T \sin(\theta_{a_f-1}) + F(t) \quad (3b)$$

121 where  $F(t)$  is the force provided by the absorber. By substituting Eqs. (1) and (2) into Eqs. (3a)  
 122 and (3b), Eqs. (4a) and (4b) can be obtained as below:

$$123 \quad \frac{1}{n + 1} \ddot{x}_a = (n + 1) \cdot \left(\frac{\omega_o}{\pi}\right)^2 \cdot (x_{a+1} - 2x_a + x_{a-1}) \quad (4a)$$

$$124 \quad \frac{1}{n + 1} \ddot{x}_{a_f} = (n + 1) \cdot \left(\frac{\omega_o}{\pi}\right)^2 \cdot (x_{a_f-1} - 2x_{a_f} + x_{a_f+1}) + \frac{F(t)}{M} \quad (4b)$$

Taking Laplace transforms of both sides of Eqs. (4a) and (4b), Eqs. (5a) and (5b) are obtained:

$$\frac{1}{n+1} s^2 \tilde{x}_a = (n+1) \cdot \left(\frac{\omega_o}{\pi}\right)^2 \cdot (\tilde{x}_{a-1} - 2\tilde{x}_a + \tilde{x}_{a+1}) \quad (5a)$$

$$\frac{1}{n+1} s^2 \tilde{x}_{a_f} = (n+1) \cdot \left(\frac{\omega_o}{\pi}\right)^2 \cdot (\tilde{x}_{a_f-1} - 2\tilde{x}_{a_f} + \tilde{x}_{a_f+1}) + \frac{Y(s)}{M} \cdot s \cdot \tilde{x}_{a_f}(s) \quad (5b)$$

where tildes indicate Laplace transforms and  $Y(s) = \tilde{F}(s)/[s \cdot \tilde{x}_{a_f}(s)]$  represents the admittance function of the absorber, which is defined as the ratio of force to velocity.

It has been shown that all  $Y(s)$  representing linear, passive absorbers are positive-real functions (Brune 1931). By arranging the displacement of each mass in the vector  $\mathbf{x} = [x_1, x_2, x_3, \dots, x_n]^T$ , Eqs. (5a) and (5b) can be rewritten in matrix form as:

$$\mathbf{M}s^2\tilde{\mathbf{x}} + \mathbf{C}s\tilde{\mathbf{x}} + \mathbf{K}\tilde{\mathbf{x}} = \mathbf{0} \quad (6)$$

In Eq. (6), the elements of matrices  $\mathbf{M}$ ,  $\mathbf{C}$  and  $\mathbf{K}$  are respectively described in Eqs. (7a)-(7c), in which  $\delta_{ij}$  is the Kronecker delta function.

$$m_{ij} = \frac{1}{n+1} \delta_{ij} \quad (7a)$$

$$c_{ij} = 0, \text{ except } c_{a_f a_f} = -Y(s)/M \quad (7b)$$

$$k_{ij} = (n+1) \cdot \left(\frac{\omega_o}{\pi}\right)^2 \cdot (2\delta_{ij} - \delta_{i(j+1)} - \delta_{i(j-1)}) \quad (7c)$$

Complex eigenvalues of the system (represented by  $[\lambda \quad \lambda^{*T}]^T$ ) are calculated as roots of Eq. (8), where  $\lambda = [\lambda_1, \lambda_2, \lambda_3, \dots]$ ,  $\mathbf{0}$  is the square null matrix of size  $n$  and  $\mathbf{I}$  is the identity matrix of size  $n$ .

$$\det \left( \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} - \begin{bmatrix} s\mathbf{I} & \mathbf{0} \\ \mathbf{0} & s\mathbf{I} \end{bmatrix} \right) = 0 \quad (8)$$

It should be noted that  $\mathbf{C}$  is a function of  $s$ , so the eigenvalues of the system cannot be found by conventional numerical methods. However, Eq. (8) is still fundamentally valid, giving a polynomial

149 in  $s$ , the roots of which are the eigenvalues. By using a similar finite element model of a cable  
 150 with a TID (Lazar et al. 2016), in which the internal DOFs of the TID was explicitly represented  
 151 in the matrix equation of motion, making the vector  $\mathbf{x}$   $(n + 1)$  elements long and the matrices  $\mathbf{M}$ ,  
 152  $\mathbf{C}$  and  $\mathbf{K}$  of size  $(n + 1) \times (n + 1)$ . Using that method, the matrices need to be reformulated for  
 153 each alternative absorber layout. The advantage of the method presented here is that a system with  
 154 any passive linear absorber can be represented by Eq. (6) and Eqs. (7a)-(7c), with  $\mathbf{x}$  always being  $n$   
 155 elements long and the matrices  $\mathbf{M}$ ,  $\mathbf{C}$  and  $\mathbf{K}$  always of size  $n \times n$ . The only difference for different  
 156 absorber layouts is the positive-real admittance function  $Y(s)$  representing the absorber.

157 The roots of Eq. (8), i.e.  $[\lambda \ \lambda^{*\Gamma}]^T$ , are in complex conjugate pairs. The number of pairs is  
 158 given by  $n$  plus the number of internal DOFs of the absorber. However, normally only a few pairs,  
 159 representing low frequency modes, are of interest. Either eigenvalue  $\lambda_e$  (with positive imaginary  
 160 part,  $e = 1, 2, 3, \dots$ ) or its complex conjugate eigenvalue  $\lambda_e^*$  can be used to calculate damping ratio  
 161  $\zeta_e$  and circular natural frequency  $\omega_e$  of mode  $e$  of the damped cable, which respectively are:

$$162 \quad \zeta_e = -\text{Re}(\lambda_e) / \sqrt{\text{Re}(\lambda_e)^2 + \text{Im}(\lambda_e)^2} \quad (9a)$$

$$163 \quad \omega_e = \sqrt{\text{Re}(\lambda_e)^2 + \text{Im}(\lambda_e)^2} \quad (9b)$$

165 The number of DOF of the cable,  $n$ , should be large enough to limit the error due to the finite  
 166 element approximation. In order to balance accuracy and computational time, lumped masses  
 167 rather than bar elements are used and a suitable number of DOF is selected. From preliminary  
 168 analysis for a number of absorber layouts, it was typically found that a lumped mass model with  
 169 99 DOFs provides similar accuracy to a bar element model with 60 DOFs, but the bar element  
 170 model took approximately twice the computational time. This is because the mass matrix for the  
 171 bar element model is non-diagonal, which leads to a non-trivial inverse in Eq. (8). Hence for  
 172 similar accuracy, the lumped mass model is more computationally efficient. The maximum relative  
 173 difference in the damping ratio  $\zeta_e$  between lumped mass models with 99 and 999 DOFs was found  
 174 to be typically less than 0.1%, considering only low frequency modes with natural frequencies

below  $6.5\omega_o$ . Therefore, a 99 DOF lumped mass model is used for the analysis in the present study. Furthermore, since the present study is more focused on a systematic approach to identify beneficial absorber layouts, and also for a fair comparison, the location of all candidate absorbers in this study is set to be at 5% length of the whole cable.

### Candidate absorber layouts and non-dimensionalized parameters

In previous study (Lazar et al. 2016), only one specific layout, namely a TID structure is considered. Taking into account the fact that less complicated layouts are more preferred due to space and weight limits in mechanical structures, all absorber layouts with no more than one damper, inerter and spring each are considered as candidate layouts. Because neither an inerter nor a spring can dissipate energy, a damper must be present in each candidate layout. Apart from a viscous damper only, there are in total four two-element and eight three-element absorber layouts that contain one damper, which then cover all layouts that need to be considered. These are respectively shown in Fig. 2 and Fig. 3. For each layout, one terminal is connected to the cable at mass  $a_f$  and the other is attached to a fixed support. The admittance functions of all candidate absorber layouts are summarized in Table 1.

For generality, the parameters of the absorber layouts are presented in non-dimensional form. Here, the non-dimensional inertance, damping coefficient and stiffness of the absorber elements are defined as  $b' = b/M$ ,  $c' = (c/M)/(\omega_o/\pi)$  and  $k' = (k/M)/(\omega_o/\pi)^2$  respectively. The circular natural frequencies  $\omega_e$  of the damped system and the location of the damper relative to the total length of the cable  $a_f$  are also presented in non-dimensional form as  $\omega' = \omega_e/\omega_o$  and  $a'_f = a_f/(n + 1)$ , respectively. Since the location of all candidate absorbers has been set to be at 5% length of the whole cable, thus  $a'_f = 0.05$ .

### Two performance measures

Two different performance measures are used for optimization analysis in the present study. For shorter cables, the lowest frequency mode (i.e. the first mode) is often susceptible to vibrations, while vibrations of other modes can be neglected (Gimsing and Georgakis 2011). As the absorbers may affect the system's first natural frequency or introduce extra modes, it is proposed to consider

202 all modes in the frequency range from 0 to  $1.5\omega_o$  to cover all modes in the vicinity of the first  
203 undamped mode of the cable. Therefore, the critical damping ratio  $\zeta_c$ , which is defined as the  
204 lowest damping ratio of all modes in the frequency range from 0 to  $1.5\omega_o$ , is introduced as the key  
205 parameter to identify the effectiveness of the absorber layouts. The first performance measure is  
206 the optimum critical damping ratio denoted  $\zeta_{c,opt}$  without considering higher frequency modes.

207 Since longer cables, or cables in extreme conditions, may suffer from vibrations in multiple  
208 modes, in some cases more low-frequency modes should be considered. Therefore, for the second  
209 performance measure, a constraint on the modes with higher frequencies is included. Hence, the  
210 second measure is  $\zeta_{c,opt}$  with an extra constraint to ensure that the damping ratios of modes with  
211 natural frequencies in the range  $[1.5\omega_o - 6.5\omega_o)$  are no less than those for a cable with a viscous  
212 damper optimized for the first mode. For simplicity, the damping ratios for the cable with a viscous  
213 damper are taken to be those from the universal curve (Pacheco et al. 1993).

214 For each performance measure, for a given non-dimensional inertance, the optimum critical  
215 damping ratio  $\zeta_{c,opt}$  is found by using the Matlab optimization command ‘patternsearch’ followed  
216 by ‘fminsearch’ for fine-tuning of the parameters. The same approach has been used for optimizing  
217 absorbers for different applications (Smith and Wang 2004; Wang et al. 2009; Jiang et al. 2015b;  
218 Zhang et al. 2017; Li et al. 2017b). The maximum critical damping ratio  $\zeta_{c,max}$  is defined as the  
219 maximum  $\zeta_{c,opt}$ , that can be achieved for any inertance.

220 Based on the lumped mass model with 99 DOFs, the results of the eigenvalue analysis for a  
221 viscous damper only (Layout I) are presented in Fig. 4 for a range of damping coefficients  $c'$ . Fig. 4a  
222 shows the relationship between critical damping ratio  $\zeta_c$  and non-dimensional damping coefficient  
223  $c'$ . This follows the universal curve (Pacheco et al. 1993), and similar results from other literatures  
224 (Krenk 2000; Main and Jones 2002). The optimum critical damping ratio  $\zeta_{c,opt} = 0.0264$  is found  
225 by using the proposed optimization method, which matches with the maximum value on the curve,  
226 showing the validity of the proposed optimization approach. Fig. 4b shows the corresponding non-  
227 dimensional natural frequency  $\omega'$ , which indicates that the viscous damper has marginal influence  
228 on the frequency of the first mode.

## OPTIMUM PERFORMANCE OF CANDIDATE ABSORBERS

In this section, the optimum performance of all candidate absorbers is analyzed, with and without the constraint considering higher modes. Optimum critical damping ratios  $\zeta_{c,opt}$  are identified, for all candidate layouts. For the layouts contain an inerter, inerters with non-dimensional inertance  $b'$  ranging from 0 to 2.5 are considered as this covers the maximum optimum critical damping ratio for all the layouts. Results for the beneficial absorber layouts are summarized compared. Since lower inertance is easier and typically less expensive to realize, more detailed discussions focus on  $b'$  from 0 to 0.5.

### Optimization results for absorbers considering first mode only

As vibrations of the first mode are usually considered critical, this subsection aims to find the largest critical damping ratio  $\zeta_c$  for the first mode without considering the effect on higher modes. All absorber layouts incorporating an inerter can provide a greater maximum optimum critical damping ratio than that for a viscous damper only, with suitable values of inertance. The optimization results for all candidate layouts are presented below.

#### *Absorbers with two elements*

For absorber layouts with two elements, layouts that can provide a larger maximum optimum critical damping ratio than a damper only are considered beneficial. The optimum critical damping ratios  $\zeta_{c,opt}$  of both Layouts II-1 and II-2 (one damper in parallel or series with one spring), are found to be  $\zeta_{c,opt} = 0.026$ , which is the same as that for the viscous damper only. The corresponding non-dimensional damping coefficient and stiffness are respectively  $c' = 6.430$ ,  $k' = 0$  for Layout II-1 and  $c' = 6.430$ ,  $k' = \infty$  for Layout II-2 (i.e. both without the spring). In fact, for any tested  $c'$  in the range of 0 to 30, adding a spring always decreases the damping ratio for these two layouts. Therefore, these two layouts are not beneficial. Hence, only Layouts II-3 and II-4 (one damper in parallel or series with one inerter) are discussed below, together with the damper only (i.e. Layout I).

Fig. 5 presents a 3-D shaded surface plot of the critical damping ratio  $\zeta_c$  for Layout II-3 with  $0 \leq b' \leq 2.5$  and  $0 \leq c' \leq 20$ . The bold solid curve indicates the optimum critical damping

256 ratio for a given inertance. In Fig. 6a, the solid curve presents the optimum critical damping ratio  
257 as a function of the inertance, which corresponds to the bold solid curve in Fig. 5, while, the  
258 dashed curve shows the damping ratio for a simultaneously occurring non-critical mode also in the  
259 frequency range  $0 < \omega' \leq 1.5$ . The corresponding natural frequencies of both modes are shown  
260 in Fig. 6b. The lines for other layouts in Figs. 7-10 are consistent in style with those presented in  
261 Fig. 6.

262 As shown in Fig. 6a, with  $b' = 0$ , as expected, the optimized critical damping ratio is the same  
263 as that for a viscous damper only. For  $b' > 0$ , Layout II-3 provides a greater optimum critical  
264 damping ratio than that for a viscous damper only for any inertance  $b'$  investigated. It can be seen  
265 from the solid curve that among all the optimized results with varying  $b'$ , the maximum optimum  
266 critical damping ratio  $\zeta_{c,max}$  is 0.155 for  $b' = 1.760$ , i.e. 5.9 times that for a viscous damper only.  
267 As  $b'$  increases from zero, the damping ratio of the original first mode (the mode with the lowest  
268 natural frequency, which is the initially the critical one) increases, but that of the original second  
269 mode decreases. At  $b' = 1.760$ , the damping ratios of the two modes are equal and above that  
270 value the damping ratio of the second mode is lower than that of the first mode, so the second  
271 mode becomes the critical one. It can be seen from Fig. 6b that the natural frequency of the second  
272 mode decreases as  $b'$  increases and at  $b' = 1.760$  there is a switch of which mode is the critical  
273 one. It is notable that in all cases the natural frequency of the critical mode is similar to that of the  
274 original undamped first mode, showing that the frequency is not greatly influenced by the absorber.  
275 At  $b' = 1.76$ , the solutions for the critical and the non-critical modes cross over each other, which  
276 leads to the break point seen in Fig. 5 and Fig. 6a.

277 Fig. 7 presents the optimization results for Layout II-4. The results are of a similar form to those  
278 for Layout II-3. Layout II-4 is hence another beneficial layout compared with a viscous damper only  
279 if the non-dimensional inertance is sufficiently large. It can be seen from Fig. 7a that among all the  
280 optimized results with varying  $b'$ , Layout II-4 can provide  $\zeta_{c,max} = 0.159$  for  $b' = 2.250$ , which is  
281 marginally better than the maximum for Layout II-3. However, Layout II-4 has the drawback that  
282 large optimum critical damping ratio  $\zeta_{c,opt}$  cannot be achieved with relatively small  $b'$ .  $\zeta_{c,opt}$  for

283 Layout II-4 is larger than that of a viscous damper if  $b' > 1.15$ . Similar to the case for Layout II-3,  
284 the break point at  $b' = 2.250$  in Fig. 7a is due to a switch of which mode is the critical one and it  
285 can be seen in Fig. 7b that the natural frequency of the critical mode is always close to that of the  
286 original undamped first mode.

### 287 *Absorbers with three elements*

288 For all eight possible three element absorber layouts shown in Fig. 3, based on the optimization  
289 results, only Layouts III-3, III-4, III-5 and III-6 can provide greater optimum critical damping  
290 ratio  $\zeta_{c,opt}$  than layouts with fewer elements (Layouts I, II-3 and II-4) with relatively small non-  
291 dimensional inertance  $b'$ . Among these four layouts, Layout III-6 is less preferable than the other  
292 three due to  $\zeta_{c,opt}$  being lower for a wide range of  $b'$ . Therefore, only results for Layouts III-3, III-4  
293 and III-5 are discussed and compared here.

294 It can be seen in Fig. 8 that among all the optimum results with varying  $b'$ , Layout III-3 can  
295 provide a maximum optimum critical damping ratio of  $\zeta_{c,max} = 0.159$ , for  $b' = 2.250$ , which is  
296 the same as Layout II-4, but Layout III-3 is more effective than Layout II-4 when  $b' < 2.250$ .  
297 For any optimum critical damping ratio with a given  $b' \leq 2.250$ , the two modes of the system  
298 with non-dimensional frequency  $\omega' < 1.5$  provide the same damping ratio and very similar natural  
299 frequencies. This shows that the inerter and the spring provide a resonance to target the first mode.  
300 When  $b' = 2.250$ , the two modes bifurcate, since the corresponding non-dimensional stiffness  
301 reaches infinity. For  $b' \geq 2.250$  the optimum results are the same as for Layout II-4, i.e. the spring  
302 in Layout III-3 has become a rigid connection.

303 The Layout III-4 is equivalent to a TMD when one terminal is grounded (Lazar et al. 2016). As  
304 shown in Fig. 9, among all the optimum results with varying  $b'$ , Layout III-4 can provide a maximum  
305 optimum critical damping ratio  $\zeta_{c,max} = 0.159$ , for non-dimensional inertance of  $b' = 2.250$  (the  
306 same as for Layout II-4). However, compared with Layout II-4, Layout III-4 is more effective when  
307  $b'$  is smaller. Similar to the results of Layout III-3, Layout III-4 also has the property that for any  
308  $\zeta_{c,opt}$  for given  $b' \leq 2.250$ , the two modes of the system with  $\omega' \leq 1.5$  provide the same damping  
309 ratio and very similar natural frequencies. When  $b' = 2.250$  the two modes bifurcate since the

310 non-dimensional stiffness  $k'$  for the optimum result reduces to zero. Since  $k'$  cannot physically be  
311 negative, for  $b' > 2.250$ ,  $\zeta_{c,opt}$  is the same as for Layout II-4.

312 It can be seen in Fig. 10 that among all the optimum results with varying non-dimensional  
313 inertance  $b'$ , Layout III-5 can provide  $\zeta_{c,max} = 0.155$ , for  $b' = 1.760$ , which is the same as for  
314 Layout II-3. Due to resonance provided by the inerter and spring, for  $0.065 \leq b' \leq 1.760$ , optimized  
315 results for Layout III-5 are better than those for Layout II-3. The two modes of the system with  
316  $\omega' < 1.5$  provide the same damping ratio and very similar frequencies. When  $b' > 1.760$  or  
317  $b' < 0.065$ , the optimized results for Layout III-5 are the same as those for Layout II-3, which lead  
318 to kinks in Fig. 10a. The optimum value of  $k'$  is then infinity, so the spring acts as a rigid link.

### 319 **Optimization results for absorbers with the higher mode constraint**

320 The optimization measures considering six modes is similar to that previously described,  
321 except that the additional constraint is implemented to consider the performance of higher modes.  
322 Optimization results show that for two-element layouts, Layouts II-3 and II-4 can provide better  
323 results than a viscous damper only, and for three element Layouts III-4 and III-6 perform better  
324 than the other three element layouts.

325 As shown in Fig. 11a, for Layout II-3 with non-dimensional inertance  $b' = 0$ , as expected, the  
326 optimized critical damping ratio is the same as that for a viscous damper only, i.e.  $\zeta_{c,opt} = 0.026$ .  
327 For  $b' > 0.170$  the constraint affects the results, so  $\zeta_{c,opt}$  is lower with the constraint than without  
328 it. For  $b' > 0$ , Layout II-3 provides a slightly greater optimum critical damping ratio than a damper  
329 only. It can be seen from the solid curve that among all the optimized results with varying  $b'$ ,  $\zeta_{c,max}$   
330 is 0.028 for  $b' = 0.160$ . When optimized with  $b' < 0.170$  without the constraint, the damping  
331 ratio of the higher modes are all above the constraint. Therefore, results both with and without  
332 the constraint are the same. In Fig. 11b, the crosses show the damping ratio for the higher modes  
333 for the optimized system with  $b' = 0.195$ . The optimum critical damping ratio  $\zeta_{c,opt}$  is restricted  
334 by the damping ratio of the sixth mode, which is on the boundary provided by the solution of the  
335 viscous damper. However, for  $b' > 0.195$ , the sixth mode cannot meet the boundary condition that  
336 no worse than that for a viscous damper optimized for the first mode. Therefore, the solid curve in

337 Fig. 11a terminates. Similar situations can occur for the other layouts.

338 Fig. 11c shows the optimization results for Layout II-4. The maximum optimum critical  
339 damping ratio  $\zeta_{c,max}$  with the constraint is 0.062 for  $b' = 2.172$ , which is much greater than for a  
340 damper only, but large inertance is required. The solid curve starts at  $b' = 0.390$  since for small  $b'$   
341 the damping ratio of the second mode cannot satisfy the constraint. For  $b' > 1.500$ , the optimum  
342 solution is limited by the sixth mode, giving reduced result compared with the case without the  
343 constraint.

344 Based on the optimization results, it is found that with suitable amount of inertance, all candidate  
345 layouts with three elements can provide greater  $\zeta_{c,opt}$  than layouts with fewer elements (i.e. Layouts  
346 I, II-3 and II-4). Since Layouts III-4 and III-6 are the most beneficial ones, therefore, their results  
347 are discussed in detail below.

348 Fig. 12a shows the optimization results for Layout III-4. The maximum optimum critical  
349 damping ratio  $\zeta_{c,max}$  is 0.141 for  $b' = 1.47$ . The solid curve allowing the additional constraint starts  
350 at  $b' = 0.390$  since below that the damping ratio of the second mode cannot satisfy the constraint.  
351 For  $b' < 0.90$ , the optimum solution is limited by the second mode and for  $b' > 1.40$  it is limited  
352 by the sixth mode. For  $0.9 \leq b' \leq 1.4$ , the results are not limited by the additional constraint, so  
353 the optimum solution is the same as when only considering the critical damping ratio.

354 Fig. 12b shows the optimization results for Layout III-6. The maximum optimum critical  
355 damping ratio  $\zeta_{c,max}$  is 0.033 for  $b' = 0.215$ . When  $b' < 0.070$ , the corresponding  $k'$  becomes a  
356 rigid connection, and it can be simplified to Layout II-3. For  $b' > 0.340$ , since the corresponding  
357 stiffness  $k' = 0$ , Layout III-6 reduce to a damper only, so there is no further change in  $\zeta_{c,opt}$ .

### 358 **Summary for all beneficial layouts**

359 Although inerters can realize large inertance by using gearing, with relatively small actual  
360 mass (Smith 2002), in practice it is difficult and currently uneconomical to realize an inerter with  
361 extremely large inertance. Therefore, only two element layouts that can provide better optimum  
362 critical damping ratio than a damper only, and some most beneficial three element layouts with  
363 relatively small non-dimensional inertance within the range,  $0 \leq b' \leq 0.5$ , are compared and

364 illustrated in Figures.

365 For all absorber layouts without the higher modes constraint, Layouts II-3, II-4, III-3, III-4 and  
366 III-5 are considered beneficial. The performance improvements for these five layouts, including their  
367 beneficial inertance region, maximum improvement compared with a damper only (in percentage  
368 terms) and the maximum benefit for  $0 \leq b' \leq 0.5$  are summarized in Table 2.

369 For  $b' \leq 0.5$  the optimum critical damping ratios  $\zeta_{c,opt}$  of Layouts II-3 and II-4, and their  
370 corresponding non-dimensional damping coefficients  $c'$  are compared in Fig. 13, along with the  
371 results for a damper only. Layout II-3 provides higher  $\zeta_{c,opt}$  than Layout II-4 and a damper only  
372 in this range. Also, a lower damping coefficient is required than that of Layout I. Layout II-4 is  
373 only more beneficial than Layout II-3 for  $b' > 1.950$  and it can provide a slightly better maximum  
374 optimum critical damping ratio  $\zeta_{c,max} = 0.159$  compared with  $\zeta_{c,max} = 0.155$  for Layout II-3.  
375 However, for  $0 \leq b' \leq 0.5$ , only Layout II-3 is beneficial. Up to 34% increase in the critical  
376 damping ratio can be realized compared with a viscous damper only by Layout II-3, as shown in  
377 Table 2.

378 Without the higher mode constraint, the optimization results of the beneficial three-element  
379 absorber layouts, i.e. Layouts III-3, III-4 and III-5, are shown in Fig. 14 for  $b' < 0.5$ . Layout III-4  
380 provides the largest optimum damping ratio  $\zeta_{c,opt}$  over a wide range of non-dimensional inertance  
381 values  $b'$ , though the difference with the other two layouts are often small. For  $b' \leq 0.065$ ,  
382 Layout III-5 is most beneficial where it reduces to Layout II-3. For  $b' > 0.065$ , Layout III-5  
383 provides different solutions with greater  $\zeta_{c,opt}$ , which leads to the jump in  $c'$  in Fig. 14. For  
384  $0.065 < b' \leq 0.5$ , there is little difference in performance between the three element layouts,  
385 while much lower non-dimensional damping coefficients  $c'$  are required for Layouts III-4 and III-5  
386 compared with III-3. Fig. 14c shows that the corresponding non-dimensional stiffness  $k'$  are about  
387  $\pi^2$  times  $b'$  for all three layouts, indicating that the inerter and spring provide resonance to target  
388 the first mode.

389 With the higher mode constraint, only Layouts II-3, II-4, III-4 and III-6 are considered beneficial.  
390 The performance improvements of these four layouts are summarized in Table 3. The optimization

391 results show that Layout III-6 in the range  $0 \leq b' \leq 0.510$  and III-4 in the range  $0.510 \leq b' \leq 2.5$   
392 provides more beneficial optimized critical damping ratios than the other layouts. Layout III-4  
393 provides the overall optimum critical damping ratio, while Layout III-6 is still worth considering  
394 in practice, since it provides reasonable benefits with relatively small inertance. As is shown in  
395 Fig. 15, only Layouts II-3 and III-6 can provide results better than a viscous damper for  $b' \leq 0.5$ .  
396 Compared with the results without the constraint,  $c'$  and  $k'$  are of the same order of magnitude, but  
397 the higher mode constraint has greatly reduced  $\zeta_{c,opt}$  for all the beneficial absorber layouts.

### 398 **EFFECTS OF SERIES COMPLIANCE**

399 In practice, the connections at either end of the absorber, with the support and with the cable,  
400 may not be fully rigid. Apart from compliance of the connections themselves and of any axial  
401 linkage element, for common bridge cables made up of multiple parallel strands in an outer sheath,  
402 there may be relative movement between the sheath, to which the absorber is usually attached, and  
403 the structural strands inside. The lack of rigidity may be expected to reduce the performance of  
404 the absorber. In order to quantify this effect, a compliant element is introduced in series with the  
405 absorber. For simplicity, it is modeled as an ideal spring of non-dimensional stiffness  $k'_{sc}$ . The  
406 upper limit of possible stiffness values is considered infinite. The lower realistic limit is estimated  
407 using simplified assumptions. For vibrations of the main length of the cable (from the absorber to  
408 the other end) in a half sine wave mode shape, neglecting motion of the point where the absorber  
409 is attached and the short length of cable between that point and the near end, the force on the  
410 absorber is given approximately by  $T\theta_{af}$  (Fig. 1). The maximum value of  $\theta_{af}$  approximately  
411 equals  $\pi x_{max}/L$ , where  $x_{max}$  is the maximum displacement at the anti-node of the mode. If this  
412 force causes a deformation between the end of the absorber and the cable  $\gamma$ , the equivalent linear  
413 stiffness of the series spring,  $k_{sc}$ , is  $T\pi x_{max}/(L\gamma)$ . Hence the non-dimensional stiffness  $k'_{sc}$  is  
414 simply  $\pi x_{max}/\gamma$ . Typically, it is aimed for  $x_{max}$  to be limited to the diameter of the cable, which is  
415 typically about 200mm, whilst the deformation  $\gamma$  is estimated to be of the order of 10mm. Hence  
416 the minimum value of  $k'_{sc}$  in practice is estimated to be around 60. Therefore, to more than cover  
417 the range of expected values, in this study  $k'_{sc}$  is taken to be in the range of 10 to infinity.

418 The effects of series compliance are analyzed for both performance measures, with and without  
 419 the higher mode constraint. The higher mode constraint used here is the performance of a viscous  
 420 damper with the same series compliance, rather than the universal curve used in previous sections.  
 421 The beneficial layouts with two elements, i.e., Layouts II-3 and II-4, are not discussed here, as the  
 422 optimization results show that both layouts cannot achieve the same level of critical damping ratio  
 423 when series compliance is included. The effect of  $k'_{sc}$  on the beneficial layouts with three elements,  
 424 i.e. Layouts III-3<sub>sc</sub>, III-4<sub>sc</sub>, III-5<sub>sc</sub> and III-6<sub>sc</sub>, are investigated. The four layouts, including the  
 425 series compliance, are shown in Fig. 16.

426 Using the previously optimized parameter values, when the series compliance is added the  
 427 critical damping ratios decrease significantly for all four layouts. Given the detrimental effect, the  
 428 parameters of the absorbers should be re-optimized.

429 Layouts III-3<sub>sc</sub> and III-5<sub>sc</sub> have two springs in series. Therefore, if  $k'_{sc} \geq k'_o$ , where  $k'_o$  is the  
 430 original optimized non-dimensional stiffness without series compliance, they can be adjusted to  
 431 have identical properties to the original optimized layouts. The re-tuned  $k'$  can simply be calculated  
 432 as  $k' = 1/[(1/k'_o) - (1/k'_{sc})]$ . Since  $k'$  increases with  $b'$  (Fig. 14c), this is possible for  $b'$  up to a  
 433 certain value,  $b' < b'_m$ , at which  $k'_{sc} = k'_o$ , and the maximum value of  $\zeta_{c,opt}$  can be achieved. For  
 434  $b' > b'_m$  the performance of Layouts III-3<sub>sc</sub> and III-5<sub>sc</sub> rapidly decreases, but it is still larger than  
 435 that of without retuning  $k'$ .

436 For Layout III-4<sub>sc</sub> the two springs are not simply in series, so re-optimization of the absorber  
 437 layout is needed. Fig. 17a shows that, without re-optimization and without considering the higher  
 438 mode constraint, for  $k'_{sc}$  equal to 10, 100 and 1000, the maximum optimum critical damping ratio  
 439  $\zeta_{c,max}$  respectively are 83.0%, 47.2% and 2.7% of the original  $\zeta_{c,max}$  only. Similar results have also  
 440 been found for Layouts III-3<sub>sc</sub>, III-5<sub>sc</sub> and III-6<sub>sc</sub>. The re-optimized results for Layout III-4<sub>sc</sub> are  
 441 shown in Fig. 17b for the  $k'_{sc}$  equal to 10, 100 and 1000, as well as infinity. In each case, for  $b'$  up  
 442 to a certain value  $b'_m$ , indicated by crosses, the optimum critical damping ratio of the re-optimized  
 443 layout is at least as great as for the original layout. To achieve the optimum behavior, both the  
 444 non-dimensional damping coefficient  $c'$  and non-dimensional stiffness  $k'$  need to be adjusted. For

445  $b' > b'_m$ , the re-optimized  $\zeta_{c,opt}$  for Layout III-4<sub>sc</sub> cannot reach the original value, but it is still  
446 better than that without re-optimization.

447 Fig. 18 shows the relation of the maximum critical inertance  $b'_m$  and the corresponding optimum  
448 critical damping ratio  $\zeta_{c,opt}$  to the series compliance  $k'_{sc}$  for Layouts III-3<sub>sc</sub>, III-4<sub>sc</sub> and III-5<sub>sc</sub>. For  
449 all three layouts, when relatively stiff series compliance is considered, i.e.  $k'_{sc} \geq 100$ , only a  
450 marginal effect on  $\zeta_{c,opt}$ . When very soft series compliance is considered, taking the worst case of  
451  $k'_{sc} = 10$  as example, the re-optimized  $\zeta_{c,opt}$  still reaches 60% of the original  $\zeta_{c,max}$ . Also, when  
452  $k'_{sc} = 10$ , the maximum critical non-dimensional inertance  $b'_m \approx 0.6$  for all three layouts, indicating  
453 that within the range of inertance of most interest ( $b' \leq 0.5$ ), the same or even marginally better  
454  $\zeta_{c,opt}$  can be achieved compared with the case without the series compliances.

455 Considering the higher mode constraint, Layout III-6<sub>sc</sub> cannot reach the original optimum even  
456 if the absorber is returned. However, it is still much more beneficial than the case where the  
457 parameters are not retuned. For Layout III-4, the re-optimized results are presented in Fig. 19,  
458 showing that softer  $k'_{sc}$  can be beneficial if the system is returned. For a range of  $b'$ , which depends  
459 on  $k'_{sc}$ , the re-optimized system can still provide a critical damping ratio as good as, and in some  
460 cases significantly greater than the critical damping ratio provided by the original layout.

## 461 CONCLUSIONS

462 In this paper, a systematic approach to identify beneficial low-complexity inerter-based absorber  
463 layouts for cable vibration suppression is presented. A Finite Element (FE) model of the cable  
464 is firstly presented with various absorber layouts represented by admittance functions. Then,  
465 considering the first mode only and the first six modes, two performance measures are proposed.  
466 Based on the model, absorbers with different layouts are optimized. The performance of all possible  
467 absorber layouts with no more than one inerter, damper and spring is analyzed with non-dimensional  
468 inertance  $b'$  within the range of 0 to 2.5, with further focus on the more practical range of 0 to 0.5.  
469 The results show that all layouts incorporating with inerters can provide more beneficial optimum  
470 critical damping ratios than for a viscous damper only. Compared with two-element layouts for  
471 small inertance, three-element layouts can provide greater damping. Considering only the critical

472 damping ratio, three layouts with three elements are found to be most beneficial, offering much  
473 greater damping ratios than other layouts when the inerter is small. Including the higher mode  
474 constraint, two three-element layouts are found to be most beneficial, even though their performance  
475 is restricted by the constraint. Finally, the effects of series compliance are analyzed for the most  
476 beneficial layouts, showing that without re-optimization the series compliance is detrimental, as  
477 expected. However, up to a certain inertance, which depends on the series compliance, the  
478 absorbers can provide virtually the same, or in some cases even better performance as without the  
479 series compliance if the element values are properly retuned.

558 **List of Tables**

559 1 Admittance function  $Y(s)$  for all candidate absorbers . . . . . 24

560 2 Relative improvement of beneficial layouts without higher mode constraint . . . . . 25

561 3 Relative improvement of beneficial layouts considering constraint of higher modes . 26

**TABLE 1.** Admittance function  $Y(s)$  for all candidate absorbers

Layout	Admittance function	Layout	Admittance function
I	$c$	III-3	$1/[(1/bs) + (1/c) + (s/k)]$
II-1	$c + k/s$	III-4	$1/[1/(c + k/s) + (1/bs)]$
II-2	$1/[(1/c) + (s/k)]$	III-5	$1/[1/(c + bs) + (s/k)]$
II-3	$bs + c$	III-6	$1/[(1/bs) + (s/k)] + c$
II-4	$1/[(1/c) + (1/bs)]$	III-7	$1/[(s/k) + (1/c)] + bs$
III-1	$1/[(1/c) + (1/bs)] + (k/s)$	III-8	$bs + c + k/s$
III-2	$1/[1/(bs + k/s) + c]$		

**TABLE 2.** Relative improvement of beneficial layouts without higher mode constraint

Beneficial layout	Range of beneficial $b'$	Maximum improvement $b' \in (0, 2.5]$	Corresponding $b'$	Maximum improvement $b' \in (0, 0.5]$	Corresponding $b'$
II-3	(0, 2.5]	487%	1.760	34%	0.5
II-4	(1.150, 2.5]	502%	2.250	N/A	N/A
III-3	(0.080, 2.25]	502%	2.250	196%	0.5
III-4	(0, 20.25]	502%	2.250	203%	0.5
III-5	(0, 20.5]	487%	1.760	202%	0.5

**TABLE 3.** Relative improvement of beneficial layouts considering constraint of higher modes

Beneficial layout	Range of beneficial $b'$	Maximum improvement $b' \in (0, 2.5]$	Corresponding $b'$	Maximum improvement $b' \in (0, 0.5]$	Corresponding $b'$
II-3	(0, 2.5]	8.96%	0.160	8.96%	0.160
II-4	(1.150, 2.5]	150%	2.25	N/A	N/A
III-4	(0.080, 2.25]	451%	2.25	N/A	N/A
III-6	(0, 2.25]	27.6%	0.215	27.6%	0.215

## List of Figures

1	Finite element model of a taut cable with an absorber . . . . .	29
2	Candidate absorber layouts with one or two elements . . . . .	30
3	Candidate absorber layouts with three elements . . . . .	31
4	Results for Layout I (viscous damper only). (a) Critical damping ratio and (b) corresponding non-dimensional natural frequency, versus non-dimensional damping coefficient . . . . .	32
5	3-D plot of damping ratio versus non-dimensional inertance and damping coefficient for Layout II-3 . . . . .	33
6	Optimization results for Layout II-3. (a) Damping ratio and (b) corresponding non-dimensional frequency, versus non-dimensional inertance . . . . .	34
7	Optimization results for Layout II-4. (a) Damping ratio and (b) corresponding non-dimensional frequency, versus non-dimensional inertance . . . . .	35
8	Optimization results for Layout III-3. (a) Damping ratio and (b) corresponding non-dimensional frequency, versus non-dimensional inertance . . . . .	36
9	Optimization results for Layout III-4. (a) Damping ratio and (b) corresponding non-dimensional frequency, versus non-dimensional inertance . . . . .	37
10	Optimization results for Layout III-5. (a) Damping ratio and (b) corresponding non-dimensional frequency, versus non-dimensional inertance . . . . .	38
11	Performance of two element layouts with and without the constraint. (a) Damping ratio for Layout II-3 versus non-dimensional inertance. (b) Damping ratios for Layout II-3 for higher modes optimized when $b' = 0.195$ . (c) Damping ratio for Layout II-4 versus non-dimensional inertance . . . . .	39
12	Optimized damping ratio versus non-dimensional inertance with and without the constraint. (a) Layout III-4 and (b) Layout III-6, optimum critical damping ratio versus non-dimensional inertance . . . . .	40

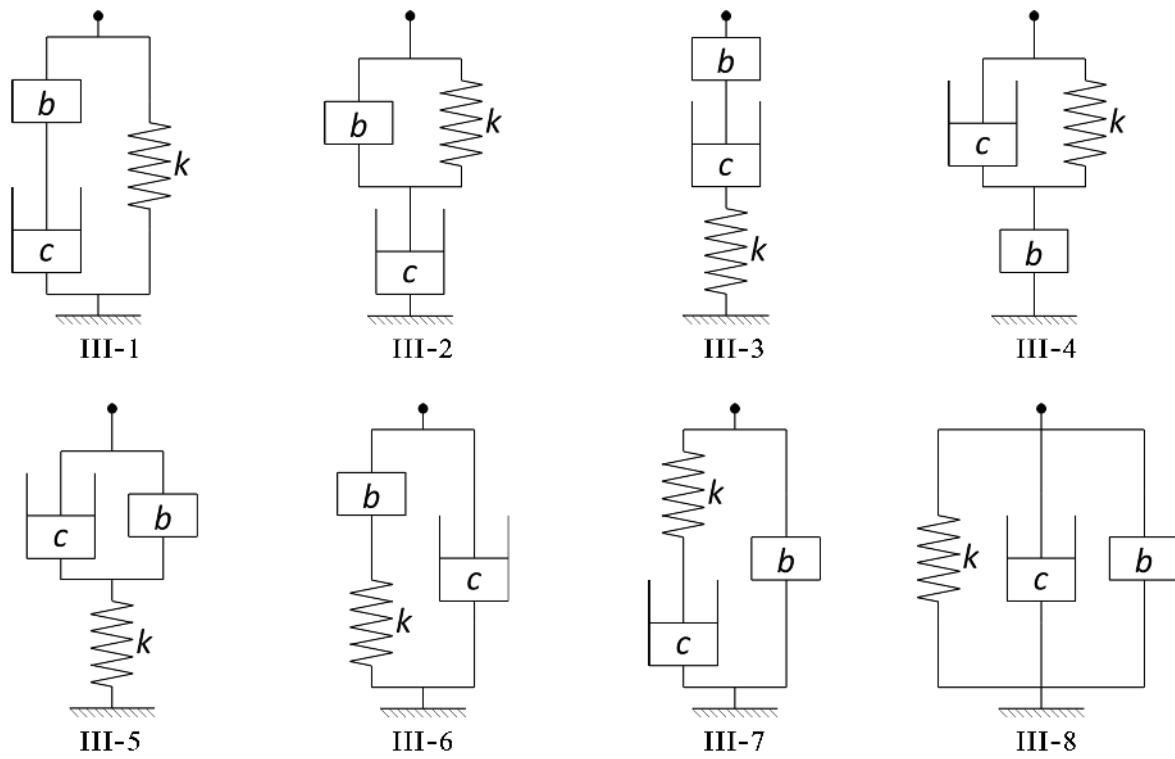

588	13	Optimization results for beneficial layouts with one or two elements without the	
589		higher mode constraint. (a) Damping ratio and (b) corresponding non-dimensional	
590		damping coefficient, versus non-dimensional inertance . . . . .	41
591	14	Optimization results for beneficial layouts with three elements without the higher	
592		mode constraint. (a) Damping ratio, (b) corresponding non-dimensional damp-	
593		ing coefficient and (c) corresponding non-dimensional frequency, versus non-	
594		dimensional inertance . . . . .	42
595	15	Optimization results for beneficial layouts with the higher mode constraint. (a)	
596		Damping ratio, (b) corresponding non-dimensional damping coefficient and (c)	
597		corresponding non-dimensional frequency, versus non-dimensional inertance . . .	43
598	16	Beneficial three-element layouts with added series compliance . . . . .	44
599	17	Critical damping ratios with different series compliance ( $k'_{sc}$ ) for Layout III-4 <sub>sc</sub> (a)	
600		with original optimized parameters (b) with re-optimized parameters . . . . .	45
601	18	Optimization results for Layouts III-3 <sub>sc</sub> , III-4 <sub>sc</sub> and III-5 <sub>sc</sub> . (a) Maximum critical	
602		inertance $b'_m$ and (b) corresponding optimum critical damping ratio $\zeta_{c,opt}$ , versus	
603		non-dimensional series compliance . . . . .	46
604	19	Optimum critical damping ratio for Layout III-4 <sub>sc</sub> , versus non-dimensional iner-	
605		tance for re-optimized results with the constraint of higher mode and different series	
606		compliance . . . . .	47
