#### 48 ABSTRACT

BACKGROUND: Benign adrenal tumors are commonly discovered on cross-sectional imaging.
Mild autonomous cortisol secretion (MACS) is regularly diagnosed but its impact on
cardiometabolic disease in affected individuals is ill-defined.

52 **OBJECTIVE:** To determine cardiometabolic disease burden and steroid excretion in persons with
53 benign adrenal tumors with and without MACS.

54 **DESIGN:** Cross-sectional study.

55 SETTING: 14 endocrine secondary/tertiary care centers (recruitment 2011-2016).

56 **PARTICIPANTS:** 1305 prospectively recruited persons with benign adrenal tumors.

MEASUREMENTS: Cortisol excess was defined by clinical assessment and the 1mg-overnight
dexamethasone suppression test (serum cortisol <50 nmol/L: non-functioning adrenal tumor</li>
[NFAT]; 50-138 nmol/L: possible MACS [MACS-1]; >138 nmol/L and absence of typical clinical
Cushing's syndrome [CS] features: definitive MACS [MACS-2]). Net steroid production was
assessed by multi-steroid profiling of 24-hour urine by tandem mass spectrometry.

62 **RESULTS:** Of the 1305 participants, 49.7% had NFAT (n=649; 64.1% women), 34.6% MACS-63 1 (n=451; 67.2% women), 10.7% MACS-2 (n=140; 73.6% women), and 5.0% CS (n=65; 86.2% women). Prevalence and severity of hypertension were higher in MACS-2 and CS than NFAT 64 65 (adjusted prevalence ratios (aPRs) for hypertension: MACS-2 1.15 [95%CI 1.04-1.27], CS 1.37 66 [95%CI 1.16-1.62]; aPR for use of ≥3 anti-hypertensives: MACS-2 1.31 [95%CI 1.02-1.68], CS 2.22 [95% CI 1.62-3.05]). Type 2 diabetes was more prevalent in CS than NFAT (aPR 1.62 [95% CI 67 68 1.08-2.42]), and more likely to require insulin therapy in MACS-2 (aPR 1.89 [95%CI 1.01-3.52]) 69 and CS (aPR 3.06 [95%CI 1.60-5.85]). Urinary multi-steroid profiling revealed an increase in glucocorticoid excretion from NFAT over MACS-1 and MACS-2 to CS whilst androgen excretion
decreased.

72 LIMITATIONS: Cross-sectional design, selection bias possible.

73 **CONCLUSION:** MACS is a cardiometabolic risk condition that predominantly affects women

and warrants regular assessment for hypertension and type 2 diabetes.

Research.

#### 80 INTRODUCTION

Adrenal masses are discovered in approximately 5% of cross-sectional imaging studies (1, 2). 81 82 Benign adrenal tumors are the most common underlying entity; in the largest prospective study to 83 date, ENSAT EURINE-ACT (3), they represented 1513 (89.7%) of 1686 incidentally discovered 84 adrenal masses. Benign adrenal masses can be non-functioning adrenal tumors (NFAT) or 85 autonomously overproduce steroids, most frequently cortisol. Clinically overt cortisol excess, Cushing's syndrome (CS), usually presents with typical clinical signs including proximal 86 87 myopathy and purple striae (4). CS is rare but potentially life-threatening due to the metabolically 88 adverse consequences of cortisol excess, including type 2 diabetes, hypertension, and dyslipidemia, the main drivers of increased cardiovascular mortality in the affected persons (4, 5). 89 Mild autonomous cortisol secretion (MACS), previously also termed subclinical CS, is regularly 90 91 diagnosed in persons with benign adrenal tumors. MACS is defined by failure to suppress serum 92 cortisol sufficiently after overnight administration of 1mg dexamethasone (6), but in the absence 93 of the typical clinical signs of cortisol excess. Previous case series identified MACS in up to 35% 94 of persons with benign adrenal tumors, making it the most common hormonal abnormality 95 observed in this population (6, 7). However, while CS is a well-established cause of increased 96 cardiometabolic morbidity and mortality, the evidence regarding the impact of MACS on 97 cardiometabolic disease risk is scarce and heterogeneous. In a recent systematic review and meta-98 analysis of studies reporting on the prevalence of cardiometabolic comorbid conditions in persons 99 with NFAT and MACS (8), hypertension was the most common occurrence (64.0% in MACS vs. 100 58.2% in NFAT). Persons with MACS were more likely to present with prediabetes (50.0% vs. 101 14.4%) and type 2 diabetes (28.1% vs. 14.4%), while the prevalence of dyslipidemia was at a 102 similar level in MACS and NFAT (approximately 34%). However, evidence regarding the cardiometabolic risk of persons with MACS is almost exclusively derived from observational
studies of small sample size, thereby limiting the interpretation of the results.

Here we report a cross-sectional study investigating the clinical characteristics, cardiometabolic
burden, and urinary steroid excretion in 1305 prospectively recruited persons with benign adrenal
tumors and different degrees of cortisol excess.

#### 108 METHODS

#### 109 Subject selection

110 Persons with benign adrenal tumors were drawn from the ENSAT EURINE-ACT study (3), which 111 had prospectively recruited adults ( $\geq 18$  years) with newly diagnosed adrenal tumors >1cm from 112 2011 to 2016 through 14 secondary and tertiary care centers with expertise in the management of 113 adrenal tumors in 11 countries, participating in the European Network for the Study of Adrenal 114 Tumors (ENSAT; www.ensat.org). We included all EURINE-ACT participants who were 115 diagnosed with benign adrenocortical adenomas and had undergone standardized endocrine 116 assessment for exclusion of cortisol excess (9, 10), with measurement of endocrine parameters 117 carried out in the recruitment center. We excluded participants with confirmed primary 118 aldosteronism diagnosed according to current guidelines (11) and participants with cortisol excess 119 due to bilateral macronodular adrenal hyperplasia. We included 1305 (82%) of 1588 otherwise 120 eligible persons with benign adrenal tumors, as 283 had no available results for the 1-mg overnight 121 dexamethasone suppression test (1mg-DST) that is required for the diagnosis of MACS (Fig. 1). 122 In accordance with recent guidelines (6), we defined the presence of MACS as failure to suppress 123 morning serum cortisol concentration to <50 nmol/L after administration of 1mg dexamethasone orally at 11 pm the preceding night (1mg-DST) in the absence of clinical features indicative of CS 124

(e.g. proximal myopathy, moon face, dorsocervical and supraclavicular fat pads, purple striae).
Persons with MACS were further subdivided into MACS-1 (possible autonomous cortisol
secretion; serum cortisol in the 1mg-DST 50-138 nmol/L) and MACS-2 (definitive autonomous
cortisol secretion; serum cortisol in the 1mg-DST >138 nmol/L) (6). Persons with current or recent
(<6 months) intake of drugs known to alter steroid synthesis or metabolism were excluded. All</li>
centers had ethical approval for pseudonymized phenotype recording in the online ENSAT
database and all participants of the EURINE-ACT study provided written informed consent.

132 We used the information available at the time of adrenal tumor diagnosis (baseline assessment). 133 Variables obtained through the online ENSAT database included demographic data (sex, age, body 134 mass index, BMI), tumor characteristics (maximum diameter and location), information about cardiometabolic morbidity (hypertension, dysglycemia, dyslipidemia), and endocrine test results 135 136 (adrenocorticotropic hormone, ACTH; serum dehydroepiandrosterone sulfate, DHEAS; 24-hour urinary free cortisol, UFC). We then asked each site to review the available information against 137 their local databases to obtain any variables that were missing in the online ENSAT database (for 138 139 details see Appendix Table 1).

#### 140 Definitions of cardiometabolic outcomes

We calculated the prevalence of hypertension, prediabetes, type 2 diabetes, and dyslipidemia considering the clinical information available at the time of adrenal tumor diagnosis. We also identified subjects with a more severe clinical phenotype, specifically those with hypertension treated with  $\geq$ 3 anti-hypertensives and those requiring insulin to manage their type 2 diabetes (for details see **Appendix Table 1**).

*Hypertension:* Participants were considered as having hypertension if they had a doctor diagnosisor if they were prescribed medications for hypertension.

148 *Treatment with*  $\geq$ *3 anti-hypertensives:* Participants with hypertension were chosen for a subgroup 149 analysis to study prescription of  $\geq$ 3 antihypertensives as an outcome, in line with established 150 American Heart Association criteria (12).

151 *Glucose metabolism status:* Participants were considered as having type 2 diabetes if they had a 152 doctor diagnosis or if they were prescribed antidiabetic medications. Prediabetes and type 2 153 diabetes were also diagnosed based on glycated hemoglobin results according to American 154 Diabetes Association criteria (13).

*Type 2 diabetes requiring insulin:* Participants with type 2 diabetes were chosen for a subgroupanalysis to study insulin therapy as an outcome.

Dyslipidemia: The prescription of lipid-lowering agents was considered as a proxy for dyslipidemia. We only considered subjects taking lipid-lowering agents other than for secondary cardiovascular prevention, after excluding those with a history of stroke, cerebral hemorrhage, cerebral thrombosis, ischemic heart disease, or angina, in line with American College of Cardiology/American Heart Association criteria (14).

#### 162 Urine multi-steroid profiling

Each study participant provided a 24-hour urine sample that was sent for centralized measurement at the Steroid Metabolome Analysis Core, Institute of Metabolism and Systems Research, Birmingham, UK. Multi-steroid profiling was carried out by liquid chromatography-tandem mass spectrometry (LC-MS/MS) with quantification of the 24-hour urinary excretion of 16 distinct steroid metabolites (**Appendix Table 2** and **Appendix Fig.1**), as previously described (3). Multisteroid profiling results in persons with MACS-1, MACS-2, and CS were compared to those with NFAT.

#### 170 Statistical analysis

171 Poisson regression with robust variance (15) was fitted to obtain crude and adjusted prevalence 172 ratios (PR) of hypertension, prediabetes, type 2 diabetes, and dyslipidemia in persons with MACS-173 1, MACS-2, and CS using NFAT as the reference group. The models were adjusted for age, sex, 174 and BMI. In order to provide prevalence ratios using Poisson models, the categorical glucose 175 metabolism outcome variable was replaced with two separate binary outcomes: (a) dysglycemia 176 (combination of pre-diabetes and type 2 diabetes – subjects with NFAT and normal glucose 177 metabolism were used as the reference) and (b) type 2 diabetes (the combined group of subjects 178 with NFAT and with either pre-diabetes or normal glucose metabolism was used as the reference). 179 In sub-groups of subjects with hypertension and type 2 diabetes, Poisson regression models were 180 fitted to estimate the crude and adjusted PRs of treatment with  $\geq 3$  anti-hypertensives and insulin 181 use, respectively. Missing data for the clinical outcomes were replaced using multiple imputation 182 using chained equations through logistic models with the following covariates: age, sex, and BMI category. Resistant hypertension, type 2 diabetes and insulin treatment were imputed within a 183 184 conditional sample of subjects with hypertension, dyslipidemia, and type 2 diabetes, respectively. 185 Outside these conditional samples, missing values for these variables were replaced with the 186 conditional constant (0/absent).

Associations between continuous outcomes, including 24-hour urine steroid excretion, were determined by linear regression after log-transformation of all outcomes to reduce skewness in the dataset. Associations between the log-transformed outcome and the variable of interest were reported as sympercents (16) and all models were adjusted for age, sex, and BMI. Statistical analyses were carried out using Stata Statistical Software: Release 16 (College Station, TX: StataCorp LLC) and GraphPad Prism 9 (San Diego, CA: GraphPad Software Inc.).

#### **Role of the funding source**

194 The funders of the study had no role in study design, data collection, data analysis, data 195 interpretation, or writing of the report. The corresponding author had access to all the data and had 196 final responsibility for the decision to submit for publication.

197 **RESULTS** 

#### 198 Clinical and endocrine characteristics

199 Between 2011 and 2016, 1305 persons with newly diagnosed non-aldosterone producing 200 adenomas underwent a 1mg-DST and were prospectively assessed for clinical signs of cortisol 201 excess (Fig. 1, Appendix Table 3). Less than half of them achieved normal suppression of serum cortisol after the 1mg-DST (NFAT n=649, 49.7%). The vast majority of those with abnormal 202 203 results lacked the distinctive clinical features of overt cortisol excess (MACS-1, n=451 [34.6%]; 204 MACS-2, n=140 [10.7%]), while 65 (5.0%) were diagnosed with clinically overt CS including 37 205 incidentally discovered cases. Women represented 67.3% of the subjects included in the study and 206 the female predominance was most pronounced in MACS-2 (73.6%) and CS (86.2%) (Table 1). The median age at the time of adrenal tumor diagnosis was 60 years (interquartile range 52-67 207 208 years). Subjects with MACS were older than those with NFAT (Fig. 2A). By contrast, CS was 209 diagnosed at a younger age (median 48 years, interquartile range 38-60 years) (Table 1). Subjects 210 with abnormal 1mg-DST results had larger adrenal tumors, with over half of those with tumors >2 211 cm failing to suppress serum cortisol during the 1mg-DST (Fig. 2B).

Plasma ACTH was negatively associated with 1mg-DST results (Appendix Table 4), which was
reflected in a progressive decrease in ACTH from MACS-1 over MACS-2 to CS (Table 1, Fig.
2C). Serum DHEAS had a similar trend, but the differences among groups were less pronounced
(Appendix Table 4, Fig. 2D).

10

Persons with MACS were almost twice as likely to present with bilateral tumors than persons with
NFAT (30.1% vs. 16.5%) (Table 1). Persons with bilateral tumors had abnormal 1mg-DST results
in 62.3% and presented with larger adrenal masses (the maximum diameter of the larger adrenal
mass was considered), lower plasma ACTH, and higher 24-hour UFC (Appendix Table 5).

220 Cardiometabolic disease burden

In comparison to NFAT, subjects with MACS-2 and CS showed higher prevalence of hypertension
(age-, sex-, and BMI-adjusted prevalence ratios [aPRs] 1.15 [95%CI 1.04-1.27] and 1.37 [95%CI
1.16-1.62], respectively) (Table 2, Fig. 3A) and more often required ≥3 anti-hypertensives,
increasing with the degree of cortisol excess (MACS-2 aPR 1.31 [95%CI 1.02-1.68] and CS aPR
2.22 [95%CI 1.62-3.05]) (Table 2, Fig. 3B).

The prevalence of type 2 diabetes was increased in subjects with CS (aPR 1.62 [95%CI 1.08-2.42]). In a subgroup analysis of persons with type 2 diabetes, both MACS-2 and CS more often required insulin treatment (aPR 1.89 [95%CI 1.01-3.52] and 3.06 [95%CI 1.60-5.85], respectively) (Table 2, Fig. 3B).

230 The prevalence of dyslipidemia did not differ from NFAT in MACS and CS.

None of the available clinical or biochemical characteristics (such as tumor diameter, 1mg-DST
results considered as a continuous variable, plasma ACTH, serum DHEAS, and 24-hour UFC)
correlated in a clinically meaningful way with the presence of cardiometabolic disease in the
EURINE-ACT study participants (Appendix Table 6).

Patients with bilateral adrenal tumors more often required  $\geq 3$  anti-hypertensives (43.4% vs. 35.2%)

- in unilateral tumors; aPR 1.28 [95%CI 1.06-1.55]) and were more frequently diagnosed with
- 237 dysglycemia (58.3% vs. 49.7%; aPR 1.15 [95%CI 1.02-1.31]) (Appendix Table 5). When we

further stratified these observations according to the 1mg-DST results, only patients with bilateral
tumors and MACS had an increased cardiometabolic burden (Appendix Table 5).

#### 240 Urinary steroid excretion

When compared to NFAT, persons with MACS-1, MACS-2, and CS showed a gradual decrease in the 24-hour urinary excretion of androgen metabolites (androsterone, etiocholanolone, dehydroepiandrosterone [DHEA]) and of pregnenetriol (5-PT), the metabolite of the immediate DHEA precursor 17-hydroxypregnenolone, (**Table 3**). Conversely, we observed a progressive increase in the 24-hour urinary excretion of cortisol and tetrahydro-11-deoxycortisol (THS), the metabolite of the immediate cortisol precursor 11-deoxycortisol. In MACS-2 and CS, the excretion of cortisone was also increased (**Table 3**).

#### 248 **DISCUSSION**

249 In this cross-sectional study, we showed that persons with benign adrenal tumors diagnosed with 250 MACS-2 and adrenal CS had an increased prevalence and severity of hypertension as compared 251 to NFAT. Persons with adrenal CS were also more likely to have a diagnosis of type 2 diabetes 252 and persons with MACS-2 and CS who had type 2 diabetes more often required insulin therapy to 253 achieve adequate glycemic control. Our data demonstrate that persons with MACS-2 carry an 254 increased cardiometabolic burden similar to that observed in CS, even if they do not display typical 255 features of clinically overt cortisol excess. We also show progressive changes in steroid excretion 256 in all four adrenal tumor subgroups, with decreased androgen and increased glucocorticoid 257 precursor excretion already present in persons with NFAT and increased glucocorticoid excretion 258 in MACS-1.

These findings were generated utilizing the largest ever prospectively recruited group of persons with benign adrenal tumors, participants of the ENSAT EURINE-ACT study (3). We classified subjects into four subgroups, NFAT, MACS-1, MACS-2, and CS, based on 1mg-DST results and clinical presentation, according to the criteria defined in the 2016 European Society of Endocrinology/ENSAT guidelines on adrenal incidentalomas (6).

264 Increased cardiometabolic risk is a well-established feature of clinically overt CS, while the 265 evidence regarding a metabolically adverse impact of MACS has been limited by small study sizes 266 and heterogeneous definitions of diagnosis and clinical outcomes (8). However, a picture of 267 increased cardiometabolic disease burden and frailty in persons with MACS has emerged from 268 previous studies (8, 17-21). Our data demonstrate in a large prospective group that failure to 269 suppress serum cortisol in the 1mg-DST increased the prevalence of cardiometabolic disease in 270 persons with MACS-2 and CS. Though cardiometabolic disease burden was not increased in 271 MACS-1, urinary multi-steroid profiling by mass spectrometry demonstrated decreased androgen 272 excretion and increased excretion of cortisol. Our steroid data suggest that NFAT, MACS-1 and 273 MACS-2 represent a gradually progressive continuum, which is also supported by the fact that 274 approximately 9% of subjects with NFAT develop MACS over time (8). To explore this further, 275 we stratified the EURINE-ACT NFAT group at a more granular level according to their 1mg-DST 276 result, demonstrating an increased cardiometabolic burden with each 10 nmol/L increment in 277 serum cortisol in the 1-mg DST (Appendix Fig. 2). We speculate that a subgroup of subjects with 278 NFAT may have underlying autonomous cortisol secretion that is not detected when applying the 279 current diagnostic criteria for cortisol excess, namely the 1mg-DST.

In our study of 1305 persons with benign adrenal tumors, 45.3% fulfilled the diagnostic criteria
for MACS according to 1mg-DST results. The prevalence of MACS in our study is higher than

13

282 previously reported, though direct comparison is hampered because of the heterogeneous 283 approaches to the definition of MACS prior to the 2016 consensus (6), including different DST 284 protocols and cut-offs and combination of DST results with other parameters such as ACTH, 24-285 hour urinary free cortisol excretion, and salivary cortisol (8). However, a retrospective study in 286 198 persons with adrenal incidentalomas diagnosed MACS in 34.8% of cases according to the 287 same diagnostic criteria we used in this study (7). A very recent study (26) reported increased 288 mortality in patients with adrenal incidentaloma who had a serum cortisol of 83 nmol/L or higher 289 in the 1-mg DST, which increased in persons with a post-dexamethasone cortisol of 138 nmol/L 290 or higher, i.e. MACS-2, adding further evidence to a continuum of gradually increasing 291 cardiometabolic burden.

Persons included in the study were predominantly women and more than half of those were over the age of 60 at the time of adrenal tumor diagnosis; the demographics of our prospectively recruited study participants resemble those of large retrospective studies on adrenal incidentalomas (27-29). We also found that the proportion of women increased with the degree of cortisol excess,

corroborating previous observations that cortisol excess predominantly affects women (7, 30).

Previous smaller studies found that subjects with bilateral and larger tumors are more likely to be diagnosed with MACS (31, 32). We found in our much larger study that individuals with MACS and bilateral tumors were more frequently diagnosed with dysglycemia and prescribed ≥3 anti-hypertensives. We did not include subjects with cortisol excess due to primary bilateral macronodular adrenal hyperplasia in whom this diagnosis had been ascertained by typical imaging findings, positive family history and/or documentation of gene mutations in germline DNA.

regularly presents with MACS. Thus, some further cases of undiagnosed primary bilateral
macronodular adrenal hyperplasia in our study cannot be ruled out (33).

306 Strengths of our study include the prospective recruitment, the large sample size, the standardized 307 classification of different degrees of cortisol excess, and the 24-hour urine multi-steroid profiling 308 carried out by a centralized tandem mass spectrometry assay. To our knowledge, this is the largest 309 prospective study to establish the extent of the cardiometabolic disease burden in persons with 310 benign adrenal tumors with and without cortisol excess.

311 Weaknesses of our study include its cross-sectional design, precluding the collection of 312 longitudinal data about cardiometabolic outcomes, and the absence of a comparator group of 313 persons who also underwent imaging under similar circumstance but without being diagnosed with 314 an adrenal tumor. Routine biochemical assessments were not standardized across participating 315 centers and not measured in a centralized fashion. However, while we acknowledge that results 316 for 24h UFC, plasma ACTH, and serum DHEAS should be interpreted with caution, inter-assay 317 variability of serum cortisol measurements is unlikely to affect the cut-off of 50 nmol/L used to 318 diagnose MACS (34). We could not include 283 (18%) of the overall 1588 eligible ENSAT 319 EURINE-ACT participants with benign adrenal tumors in this study as they had no recorded 1mg-320 DST results at the time of adrenal tumor diagnosis. Therefore, a degree of selection bias is possible 321 and should be taken into account when interpreting the high prevalence of MACS in our study. 322 However, 213 of the 283 persons excluded due to missing 1-mg DST results were recruited by the 323 four German centers who initially did not test their participants with the 1-mg DST, which makes 324 a relevant impact of selection bias unlikely.

In conclusion, our study demonstrates that MACS-2 and CS are clinically highly relevant
 metabolic risk conditions, which predominantly affect women and come with increased prevalence

15

327 of hypertension and type 2 diabetes, and present with a more severe clinical phenotype than 328 persons with NFAT. Affected individuals should receive a comprehensive cardiovascular risk 329 assessment at the time of adrenal tumor diagnosis, with particular attention to blood pressure and 330 glucose metabolism. Future studies are required to further dissect cardiometabolic risk in MACS-331 1 and NFAT and to identify biomarkers suitable for prediction of metabolic risk and assessment 332 of risk-mitigating interventions.

#### 333 Contributors

334 A.P. and W.A. designed the study, with contributions from I.B., V.C., A.S. and K.N. A.P. contributed to data collection, data analysis, data interpretation, and co-wrote the manuscript. A.S. 335 336 and K.N. performed statistical analyses and co-wrote the manuscript. A.J.S. reviewed the statistical analyses and edited the manuscript. A.E.T., L.C.G, and C.J. carried out the steroid excretion 337 338 analysis by mass spectrometry and edited the manuscript. I.B., V.C. S.T., K.L., M.M., D.A.D, 339 I.D.P., G.R, L.V.M., T.D., M.B., M.W.O.R., T.B., C.Z., T.D., A.D., M.A., A.K., D.L., J.R.M., 340 M.Q., G.A.U., M.C.D., F.B., A.T., M.F., M.I., M.T., D.K., W.F.Y. Jr, K.N.M., U.A., and D.A.V. 341 contributed to data collection and edited the manuscript. W.A. contributed to data analysis and 342 data interpretation, co-wrote the manuscript, and supervised all steps of the conduct of the study.

#### 456 **Figure legends**

#### 457 Figure 1: Flow-chart of patient inclusion.

#### 458 Figure 2: Endocrine assessment results.

Distribution of serum cortisol (median, range) after the 1mg-overnight dexamethasone suppression test (1mg-DST) according to age (A) and maximum tumor diameter (B) in subjects without clinical signs of Cushing's syndrome. Plasma ACTH (C) and serum DHEAS (D) measured in these subjects are shown as boxplots, with boxes representing median and interquartile range, and whiskers representing 5<sup>th</sup> to 95<sup>th</sup> centile. The dotted lines in panels A and B represent the cortisol cut-offs that separate non-functioning adrenal tumors (NFAT) from possible mild autonomous cortisol secretion (MACS-1) and definitive mild autonomous cortisol secretion (MACS-2).

#### 466 Figure 3: Impact of different degrees of cortisol excess on the cardiometabolic risk.

Poisson regression models with robust variance exploring the cardiometabolic risk of patients with mild autonomous cortisol secretion (MACS) and adrenal Cushing's syndrome (CS) in comparison to patients with non-functioning adrenal tumors (NFAT). Age-, sex-, and BMI-adjusted prevalence ratios and 95% confidence intervals are reported. Panel A: adjusted prevalence ratios for hypertension, dysglycemia, type 2 diabetes, and dyslipidemia. Panel B: adjusted prevalence ratios for treatment with  $\geq$ 3 anti-hypertensives (in subjects with hypertension) and insulin (in subjects with type 2 diabetes).

## Table 1: Demographics, radiological, and biochemical parameters of EURINE-ACT participants with benign adrenocortical adenomas who underwent assessment for cortisol excess.

Values are reported as median (interquartile range), unless otherwise stated. Abbreviations: 1mg-DST, 1mg-overnight dexamethasone suppression test; ACTH, adrenocorticotropic hormone; BMI, body mass index; DHEAS, dehydroepiandrosterone sulfate; UFC, urinary free cortisol. NFAT, non-functioning adrenal tumors; MACS, mild autonomous cortisol secretion; CS, Cushing's syndrome.

	Overall cohort (n=1305)	NFAT (n=649)	MACS-1 (n=451)	MACS-2 (n=140)	Adrenal CS (n=65)
Women, n (%)	878 (67.3)	416 (64.1)	303 (67.2)	103 (73.6)	56 (86.2)
Age (years)	60 (52-67)	58 (51-65)	64 (56-71)	63 (54-69)	48 (38-60)
BMI (kg/m <sup>2</sup> )	29.0 (25.4-33.4)	29.4 (25.8-33.9)	28.8 (25.1-33.1)	28.6 (24.0-32.9)	28.7 (25.2-31.7)
- Lean (BMI <25), n (%)	292 (22.9)	129 (20.6)	106 (23.8)	42 (30.0)	15 (23.4)
- Overweight (BMI 25-30), n (%)	429 (33.6)	202 (32.2)	160 (35.9)	41 (29.3)	26 (40.6)
- Obesity (BMI ≥30), n (%)	556 (43.5)	296 (47.2)	180 (40.4)	57 (40.7)	23 (35.9)
Maximum tumor diameter (mm)*	26 (19-36)	22 (16-30)	30 (23-38)	32 (24-44)	30 (26-38)
Tumor location:					
- Left adrenal, n (%)	616 (47.2)	323 (49.8)	196 (43.5)	63 (45.0)	34 (52.3)
- Right adrenal, n (%)	391 (30)	219 (33.7)	119 (26.4)	35 (25.0)	18 (27.7)
- Bilateral, n (%)	298 (22.8)	107 (16.5)	136 (30.2)	42 (30.0)	13 (20.0)
Serum cortisol in the 1mg-DST (nmol/L)	51 (33-92)	33 (27-41)	72 (60-93)	200 (165-283)	435 (271-574)
Plasma ACTH (pmol/L)	2.38 (1.34-3.96)	3.00 (1.89-4.89)	2.20 (1.30-3.43)	1.43 (0.55-2.60)	0.66 (0.55-1.43)
Serum DHEAS (µmol/L)	1.40 (0.70-2.70)	1.90 (1.00-3.40)	1.14 (0.65-2.19)	0.83 (0.40-1.85)	0.54 (0.23-1.58)
24-hour UFC (nmol/24h)	132 (66-226)	127 (66-207)	141 (69-229)	130 (47-207)	472 (149-1319)
* For bilateral tumors, the maximum diameter o	f the larger adrenal mass	was considered.			

#### Table 2: Cardiometabolic disease burden in benign adrenocortical tumors with different degrees of cortisol excess.

Series of Poisson regression model with robust variance was employed to investigate the cardiometabolic burden of 1305 persons from the EURINE-ACT study. Unadjusted and adjusted prevalence ratios are reported; adjusted models included age, sex and BMI as covariates. Missing outcome data were replaced using multiple imputation using chained equations with age, sex, and BMI as covariates. Imputations for treatment with  $\geq$ 3 anti-hypertensives, type 2 diabetes and insulin treatment were conditional to patients with hypertension, dysglycemia and type 2 diabetes, respectively. Abbreviations: NFAT, non-functioning adrenal tumors; MACS, mild autonomous cortisol secretion; CS, Cushing's syndrome.

Table 3: 24-hour steroid metabolite excretion in persons with benign adrenocortical tumors and different degrees of cortisol excess. Steroid metabolites measured by liquid chromatography-tandem mass spectrometry (LC-MS/MS) of 24-h urine collected by persons with non-functioning adrenal tumors (NFAT), mild autonomous cortisol secretion (MACS-1 and MACS-2 listed separately), and adrenal Cushing's syndrome (CS). Values are reported as median (interquartile range) ( $\mu$ g/24h). The urinary excretion of each steroid metabolite in persons with MACS-1, MACS-2, and adrenal CS was compared to those with NFAT using a linear regression model with the log-transformed steroid metabolite as the outcome (adjusted for age, sex and BMI). Associations between the log-transformed outcome and the variable of interest are reported as sympercents.
