Laboratory experiments and seismology have created a clear picture of the major minerals expected to comprise the deeper parts of Earth's mantle. Finds of some of these phases in super-deep diamonds have confirmed part of this picture [1-5]. A striking exception is the high-pressure perovskite structured polymorph of CaSiO₃. This mineral – inferred to be the fourth most abundant in Earth - has never been found in nature. As the major host for Ca and heat-producing elements K, U and Th in the transition zone and lower mantle, it is critical to establish its presence. Here we document the first discovery of the perovskite-structured polymorph of CaSiO₃ in nature, included within a diamond from the Cullinan kimberlite, South Africa. The mineral is intergrown with ~ 6% CaTiO₃. The Ti-rich nature of this association indicates a bulk composition consistent with derivation from basaltic oceanic crust subducted to pressures equivalent to depths of the uppermost lower mantle. The relatively heavy carbon isotopic composition of the surrounding diamond, $\delta^{13}\text{C} = -2.3 \pm 0.5\%$, together with the pristine high-pressure CaSiO₃ structure, provides evidence of the recycling of oceanic crust and surficial carbon to lower mantle depths.

A key goal of solid Earth geosciences is to establish the mineralogy of Earth's mantle throughout its depth as it acts a primary control on mantle dynamics and chemistry. Diamonds are unique windows in this regard, providing access to the deepest intact material from Earth's interior through included minerals. Over three decades, a growing number of studies have used a class of diamonds known as "super-deep" diamonds to study mantle processes in the deep sublithospheric mantle, the transition zone and the lower mantle¹⁻⁶. Pioneering studies¹⁻³ suggested that some of the

42 assemblages included within super-deep diamonds represented samples of the lower mantle and
43 transition zone, variably retrogressed to lower pressures. Later studies cautioned that some of these
44 assemblages and minerals might originate at shallower depths^{7,8}, though still beneath the
45 lithosphere.

46

47 The most common minerals found within super-deep diamonds are ferropericlasite [(Mg,Fe)O] and
48 CaSiO_3 ^{1-3,9}. Ferropericlasite is stable at most pressure and temperature conditions in the mantle and
49 hence, when found as a single inclusion within diamond, this mineral cannot be considered an
50 unambiguous indicator of a super-deep origin⁷.

51

52 The CaSiO_3 phase found within super-deep diamonds typically has the crystal structure of
53 walstromite ($\text{BaCa}_2\text{Si}_3\text{O}_9$)^{1,6,8,9}. Perovskite-structured CaSiO_3 (Ca-Pv) is considered one of the most
54 important components in the Earth's lower mantle, comprising approximately 7% of a peridotitic
55 mantle composition and ~23% of the volume of a subducted mid-ocean ridge basalt slab⁹⁻¹¹. As
56 such, it is likely to be the fourth most abundant terrestrial mineral. Within a peridotitic lower
57 mantle, Ca-Pv is the dominant sink for Ca and for incompatible elements, including the key heat-
58 producing elements K, U and Th¹². However, Ca-Pv has so far never been found in nature and even
59 high-pressure laboratory experiments have failed to quench it as a metastable phase at the Earth's
60 surface. While initial studies of super-deep diamonds made a clear case for the presence of Ca-Pv¹⁻
61 ⁴, their structure was either undetermined or documented to be the lower-pressure polymorph -
62 CaSiO_3 -walstromite - and interpreted as a back-transformation of perovskite-structured CaSiO_3 .
63 The CaSiO_3 -perovskite to CaSiO_3 -walstromite phase transformation would require a volume
64 change¹³ of about 28% that is impossible for diamond to accommodate due to its extremely high
65 bulk modulus¹⁴. The absence of healed fractures in the diamond host studied by ¹³ implies that
66 CaSiO_3 -walstromite, in that case, is unlikely to represent inverted CaSiO_3 -perovskite. Plastic
67 deformation of the diamond lattice could accommodate some of the volume change necessary for

68 the inclusion's phase transformation. Although plastic deformation is well documented in super-
69 deep diamonds¹⁵, it has never been quantified and the amount of deformation would have to be
70 substantial. Thus, though some super-deep diamonds with documented phase assemblages that
71 include ferropericlaase, enstatite (inverted bridgmanite) and/or CaSiO₃-walstromite are likely to have
72 originated from lower mantle depths^{1-4,9}, there remains some ambiguity hence finding an un-
73 retrogressed silicate perovskite would provide very powerful confirmation of lower mantle
74 sampling by some super-deep diamonds.

75

76 Here we investigated an inclusion within a diamond from the Cullinan Mine, Gauteng Province,
77 Republic of South Africa. The Cullinan kimberlite is Group I in character, i.e., its chemistry and Sr-
78 Nd-Hf isotope signatures are thought to reflect a melt source from beneath the lithospheric mantle,
79 within the Earth's convecting mantle¹⁶. Cullinan mine is renowned for producing exceptionally
80 large diamonds such as the Cullinan diamond^{6,17}, most of which have been suggested to be super-
81 deep diamonds⁶.

82

83 The 31×26×10 μm³ CaSiO₃ inclusion in diamond, exposed by polishing, was revealed by X-ray
84 diffraction, Raman spectroscopy and electron backscatter diffraction to have a perovskite structure.
85 To our knowledge, this represents the first finding of a non-reverted silicate perovskite-structured
86 CaSiO₃ phase found in nature and the first, including those synthesized in the laboratory, to be
87 preserved with its high-pressure structure at the surface of the Earth.

88

89 Cathodoluminescence imaging of the host diamond surrounding the Ca-Pv inclusion (Fig. 1) reveals
90 multiple growth zones and a complex internal structure, typical of super-deep diamonds^{4,18}. FTIR
91 spectroscopy (Extended Data Figure 1) of the diamond host indicates a nitrogen content of 34 ppm,
92 with 97% in the B-aggregated form, i.e., the diamond host is type IaB. The low nitrogen content and
93 very high level of B aggregation are typical characteristics of other super-deep diamonds^{4,19}

94 indicating prolonged residence at the high temperatures expected at transition zone and lower
95 mantle depths.

96

97 The chemical composition of the CaPv inclusion, determined by electron microprobe, yields a
98 nearly pure CaSiO_3 composition ($\text{Ca}_{0.98}\text{Si}_{0.98}\text{O}_3$), with minor impurities of Ti, Al, Fe, Mg totaling
99 0.04 atoms per formula unit (Extended Data, Table 1).

100

101 Backscatter electron imaging and EDS element maps (Fig. 2) show that the Ca-Pv crystal includes
102 14 irregular areas of CaTiO_3 -perovskite between 1 and 7-8 μm with a stoichiometry of \sim
103 $\text{Ca}(\text{Ti}_{0.92}\text{Si}_{0.07}\text{Al}_{0.02})\text{O}_3$. The size and abundance of the CaTiO_3 intergrowths within this Ca-Pv is
104 very similar to the texture and abundance of inclusions reported in CaSiO_3 -walstromite phases
105 reported from Juina super-deep diamonds²⁰. The 2D exposed surface of our Ca-Pv inclusion makes
106 accurate estimation of its bulk composition difficult, but image analysis indicates that the host
107 crystal, in bulk may have up to 6% by volume CaTiO_3 . CaTiO_3 -perovskite is a common mineral in
108 nature and is stable well into the lower mantle²¹. In contrast, CaPv retaining its perovskite structure
109 has no experimentally synthesised analogues at room temperature and pressure, unless significant
110 CaTiO_3 is dissolved within its structure (~ 34 mol %²¹), far more than the CaTiO_3 component
111 observed here. However, our discovery of natural CaPv, trapped in a diamond, with < 2 mol %
112 CaTiO_3 component in the CaSiO_3 -rich portion of the inclusion, indicates that unlike experiments,
113 there must be natural P-T-t pathways that are capable of the metastable preservation of this phase.

114

115 X-ray diffraction data show the CaSiO_3 inclusion to have the perovskite structure. The small size of
116 the inclusion (thickness estimated by confocal Raman spectroscopy to be ≤ 10 μm) and its
117 entrapment within the diamond host resulted in only a limited number of measured diffraction
118 reflections ($n=91$), of which only 9 were unique (Extended Data Table 2). The full 91 reflections
119 were used to refine the Ca-Pv unit-cell parameters to yield:

120 $a = 5.397(4) \text{ \AA}, b = 5.404(4) \text{ \AA}, c = 7.646(4) \text{ \AA}, Volume = 223.0(3) \text{ \AA}^3.$

121 However, alternative unit-cell refinements using other numerical approaches could provide
122 significantly different unit-cell parameters that may differ by greater than 1%, due to the relatively
123 poor accuracy and precision of the d -spacings measured here. These larger than normal
124 uncertainties are typical when studying minerals of this size and arise not just from the limited
125 number of reflections but also due to the measurements being performed using an area detector,
126 which provides lower precision in d -spacing determination than a point detector. Such relatively
127 large uncertainty on the cell parameters makes any comparison with the unit cell volume of CaTiO₃
128 –perovskite unreliable, even though we can define the two structures as being very similar. Ewald
129 projections along the three crystallographic axes (Fig. 3a) indicate an orthorhombic unit-cell. The
130 unit-cell together with the chemical composition define the mineral to be perovskite-structured
131 CaSiO₃. Recent numerical simulations on “host-inclusion” systems²², indicate that an inclusion
132 partly exposed to atmospheric pressure only loses a portion of its residual pressure, as a function of
133 the elastic properties of both the host mineral and the inclusion. The Ca-Pv inclusion studied here is
134 partly exposed at the diamond surface but with 2/3 of its volume still buried in the diamond host.
135 Thus, any measurements on this grain would be affected by some residual “pressure” still acting on
136 the inclusion, which in turn affects the X-ray diffraction data and Raman spectra.

137

138 Raman spectra (Fig. 3b) for the inclusion show that the CaTiO₃ perovskite spectrum is in excellent
139 agreement with CaTiO₃-perovskite Raman data from the RRUFF database²³ (Extended Data Fig. 2).
140 The CaSiO₃ and CaTiO₃ spectra are similar. Small differences are evident due to the presence of
141 two Raman peaks for the CaSiO₃ spectrum, which could belong to the lower-pressure CaSiO₃
142 polymorph wollastonite-2M²³. This wollastonite polymorph is not stable at pressures higher than 3
143 GPa along a mantle geotherm²⁴, well below the diamond stability field. Hence its presence seems
144 likely due to minor partial inversion of the Ca-Pv phase owing to the polishing of the sample to
145 expose the inclusion, as reported in previous work²⁵.

146

147 The EBSD measurements collected on several areas of the grain provide no evidence that
148 amorphous portions are present and confirm that the CaSiO₃ zones have perovskite-structure (Fig.
149 4). A typical EBSD pattern collected on the CaSiO₃ area (red circle), shown as the relative non-
150 indexed EBSD pattern (Fig. 4) is complex and could not be indexed by a single phase. Indexing the
151 pattern by using a combination of reference EBSD patterns for CaTiO₃-perovskite (Fig. 4c) and
152 wollastonite-2M (Fig. 4d), accounts for the observed pattern, confirming the conclusions from X-
153 ray and Raman work, that CaSiO₃ is present in this diamond with a perovskite-type structure.

154

155 We suggest that the natural Ca-Pv found trapped within our super-deep diamond originated as a
156 result of unmixing, of the high-pressure solid solution Ca(Ti,Si)O₃. If the two phases exsolved from
157 a homogenous bulk composition, this phase would contain ~ 3.9% TiO₂.

158 Our estimate of the stoichiometry of the original phase composition is:

159

160 This composition is consistent with those of CaSiO₃ crystallised in experiments from a MORB-like
161 bulk composition at ~ 24 GPa²⁶ and is similar to the CaSiO₃ - walstromite/CaTiO₃ intergrowths
162 found within Juina super-deep diamonds that were proposed to represent basalt-like compositions
163 subducted to lower mantle depths and later retrogressed during ascent to Earth's surface²⁰. The
164 preservation of the high-pressure perovskite structure in the case of the Cullinan inclusion proves
165 the derivation of such compositions from lower mantle depths.

166

167 The indicated subducted basaltic protolith of the Cullinan Ca-Pv inclusion suggests that we might
168 expect to observe some evidence of a crustal parentage in the C isotopic composition of the host
169 diamond. Its carbon isotopic composition is variable (Fig. 1; Extended Data: Table 3) with δ¹³C
170 values ranging from -2.3‰ to -4.6‰. The core region of the diamond, defined by CL-imaging (Fig.
171 1), contains the Ca-Pv inclusion and an average δ¹³C value of -2.3 ± 0.5‰, significantly lower than

172 the typical upper mantle value of -5.5% ²⁷. In contrast, the outer rim region of the diamond has a
173 composition (Mean $\delta^{13}\text{C}$ $-4.1 \pm 0.5\%$) that is closer to the normal mantle value. Crustal carbon
174 reservoirs have C isotopic compositions that are both heavier and lighter than the typical upper
175 mantle value. While isotopically lighter carbon (below -25%) has been found in super-deep
176 diamonds from Juina, proposed to be derived from subducted basalt protoliths^{20,28}, heavier carbon
177 isotopic compositions, such as those measured in the core of our Cullinan diamond, have also been
178 reported in super-deep diamonds from both Sao Luis/Juina (Brazil) and from Kankan (Guinea)¹⁸⁻²⁰.
179 If the $\delta^{13}\text{C}$ value of -2.3% is compared with the median value (-4.91%) of 1473 published analyses
180 of lithospheric diamonds containing peridotitic inclusions – a group of diamonds usually accepted
181 to have minimal subducted influence²⁷ - it can be defined as an outlier, beyond 3 times the median
182 absolute deviation. Such anomalously heavy C isotopic compositions are thought to reflect a greater
183 influence of subducted carbonate in the fluid that formed these super-deep diamonds^{18,19}. The C
184 isotope compositions of the rim of the Cullinan diamond (Fig. 1) may represent an overgrowth that
185 grew under upper mantle conditions, or from a distinct source of carbon in the lower mantle.
186 Regardless, the isotopically heavy $\delta^{13}\text{C}$ values of the portion of the diamond containing the Ca-Pv
187 inclusion lends support to its origin from a subducted basaltic protolith.

188

189 Our discovery of perovskite-structured CaSiO_3 in a super-deep diamond firmly establishes this
190 phase as a component in Earth's deep mantle, confirming previous suggestions that lower pressure
191 CaSiO_3 polymorphs included in these diamonds may represent retrogressed Ca-Pv^{1-4,9}. The
192 estimated original bulk composition of the Cullinan Ca-Pv inclusion is consistent with compositions
193 stable in subducted oceanic basalt protoliths at ~ 24 GPa, in the uppermost lower mantle²⁶. Our
194 finding thus confirms the expectation from calculation¹⁰ and high-pressure experiments^{21,25}, that Ca-
195 Pv is the chief Ca-bearing phase in the lower mantle in both basic and ultrabasic compositions,
196 reaching up to 23 vol% in MORB-like compositions²⁶. The combined bulk composition of the Ca-
197 Pv phase found here provides overwhelming evidence of the return of recycled oceanic crust into

198 Earth's lower mantle²⁰ while the relatively heavy C isotopic composition of the diamond in contact
199 with the inclusion indicates the subduction of crustal carbon to lower mantle depths.

200

201 ACKNOWLEDGEMENTS

202

203 Nature thanks Dr. Ben Harte and another anonymous reviewer for their contribution to the peer
204 review of this work. Margo Regier is thanked for proof-reading. FN is supported by the ERC
205 Starting Grant n. 307322. MK work and sample collection was possible due to an NSERC
206 Discovery grant. NK acknowledges funding from the Dr. Eduard Gübelin Association through a
207 2015 Dr. Eduard Gübelin research scholarship. DGP was funded by an NSERC CERC award. MA
208 was supported by the European Research Council (ERC) under the European Union's Horizon 2020
209 research and innovation program (grant agreement 714936) "TRUE DEPTHS" and by the SIR-
210 MIUR grant (RBSI140351) "MILE DEEP". Dr. Lucio Litti and Prof. Moreno Meneghetti of the
211 Laboratory of Nanostructures and Optics of Department of Chemical Sciences, University of
212 Padova, are thanked for their crucial help in acquiring and interpreting the Raman data.

213

214

215

216 AUTHOR CONTRIBUTIONS

217 FN conceived the study, wrote the initial manuscript and performed X-ray diffraction and micro-
218 Raman measurements. NK found the mineral, made original mineral identifications on a confocal
219 Raman spectrometer (EOAS, UBC), performed microprobe and CL measurements, prepared
220 samples for SIMS measurements and assisted with the manuscript preparation. MK supervised the
221 study of the Cullinan diamond collection acquired through JG, AEM and JD and assisted with
222 manuscript preparation. DGP made the geochemical interpretations and led the manuscript
223 revisions. MGP assisted with the manuscript preparation and crystallographic interpretations. NR,
224 MGP and MA assisted with the X-ray data interpretation. LP collected and interpreted the EBSD
225 data. JG, AEM and JD designed the sampling program.

317 projections (a) were made along three different orientations for CaSiO₃-perovskite. The projections were
318 obtained using CrysAlis software (Rigaku-Oxford Diffraction). Baseline corrected Raman spectra in (b)
319 compare spectra from the CaPv inclusion with that of CaTiO₃ - perovskite found as an intergrowth (Fig. 2a).
320 Raman spot size was $\sim 1.1 \mu\text{m}$, spectral resolution 3 cm^{-1} .

321 **Figure 4.** Electron backscatter diffraction (EBSD) images of the Ca-Pv inclusion in diamond. EBSD image
322 collected on the red circle (a) relative to the CaSiO₃ area of our inclusion. In (b) the non-indexed EBSD
323 pattern is shown, whereas in (c) and (d) the pattern was indexed with the CaTiO₃ and wollastonite-2M
324 reference patterns.

325

326

326 **On-line Methods**

327

328 **Micro-Raman spectroscopy**

329 The CaSiO₃-perovskite sample was analysed by a InVia Renishaw micro-Raman spectrometer installed at
330 the Department of Chemical Sciences, University of Padova. Spectra were baseline corrected. A 632.8 nm
331 excitation laser was used at a power of 7 mW. The Raman spectrum of the CaSiO₃-perovskite crystal was
332 collected for 40 seconds using a 50 \times objective with a spatial resolution of $1.1 \mu\text{m}$ and a spectral resolution
333 estimated to be $\sim 3 \text{ cm}^{-1}$. The most intense Raman peaks observed for the CaSiO₃-perovskite inclusion are, in
334 order of decreasing intensity (in cm^{-1}): 774, 247, 470, 337, 181 and 226.

335

336 A direct comparison between the Raman spectrum of natural CaSiO₃-perovskite with that of CaTiO₃
337 inclusions and those reported by the RRUFF Raman database²³ indicate that the two spectra are very similar.
338 A small but important difference is due to the presence of limited traces of wollastonite 2M on the natural
339 CaSiO₃-perovskite Raman spectrum (see peaks at 971 and 637 cm⁻¹), which, as expected, are not evident for
340 CaTiO₃ perovskite inclusions.

341

342 In terms of the Raman peak assignment, it must be noted that based on the results of [29], the broad Raman
343 bands in the 650-850 cm⁻¹ region are due to second order Raman scattering and that only the sharp peaks in
344 the 200-500 cm⁻¹ region are first-order Raman bands. For our purpose, however, the entire Raman spectrum
345 of natural CaSiO₃-perovskite is considered, regardless of the first or second order scattering, for a direct
346 comparison mainly with CaTiO₃ perovskite and wollastonite.

347

348 The strong similarity in the Raman spectra between CaTiO₃ and CaSiO₃ perovskites in Fig. 3b could be used
349 to invoke the possibility that the spectra are dominated by a larger underlying, unexposed portion of the
350 CaTiO₃ phase and also permit the possibility that the CaSiO₃ regions of the inclusion are amorphous, as we
351 would expect a general Raman shift for the CaSiO₃ bands toward higher wavenumbers. This possibility can
352 be discounted for a number of reasons. Firstly, the partially exposed inclusion is under some stress and this
353 will affect the Raman band shift depending on the elastic properties of the two perovskites. More
354 importantly, the Raman spectra of such a large amorphous area of CaSiO₃ would be totally distinct from that
355 measured here (Fig. 3b), and would be, in such a scenario, characterized by the presence of three very
356 intense Raman bands at ~ 370, 640 and 970 cm⁻¹ (depending on the P and T conditions^{30,31}). These Raman
357 bands are absent in the spectrum of the CaSiO₃ portion of the perovskite-structured inclusion in diamond.
358 Also, the spot size and confocal nature of the Raman measurements made here are too small to be
359 significantly influenced by the spatially associated CaTiO₃ intergrowth.

360

361 **Cathodoluminescence**

362 The cathodoluminescence SEM image (CL) shown in Figure 1 of the main text was obtained using a Philips
363 XL 30 scanning electron microscope with a CL attachment consisting of a Hamamatsu R376 photomultiplier

364 tube (EOAS UBC, Vancouver, Canada). The accelerating voltage was 20 keV and the electron beam current
365 was 100 μA .

366

367 **Infrared spectroscopy**

368 Infrared spectra were collected for the diamond hosting natural CaSiO_3 -perovskite on a Nicolet 6700 Fourier
369 transform infrared spectrometer (Vancouver, Canada). The absorbance spectra for a sample were measured
370 at maximum light transmission. Background spectra were collected for 120 s prior to the analysis and were
371 subtracted from each measured absorbance spectra. Count times for spectra were 40 seconds at a spectral
372 resolution of 0.5 cm^{-1} . The nitrogen concentration and aggregation were determined by the procedure
373 described in [32] using the spreadsheet ("FTIR analyser 3d") provided by John Chapman (Rio Tinto
374 Diamonds Ltd.). Preliminary processing and baseline determination were made using EssentialFTIR®
375 software. The analytical and processing error is $\pm 10\%$ (1 sigma, relative error). The FTIR spectrum of the
376 diamond from Cullinan studied here is shown in Extended Data Fig. 1.

377

378 **Electron Microprobe analysis**

379 Quantitative chemical analyses were undertaken on a fully automated CAMECA SX-50 electron microprobe
380 (University of British Columbia, Department of Earth, Ocean and Atmospheric Sciences), operating in the
381 wavelength-dispersion mode with the following operating conditions: excitation voltage, 15 kV; beam
382 current, 20 nA; peak count time, 20 s; background count-time, 10 s; actual spot diameter, 5 μm . Data
383 reduction was done using the 'PAP' $\phi(\rho Z)$ method³². Detection limits for most oxides were below 0.08 wt.%,
384 detection limits for Cr_2O_3 , MnO_2 , and NiO were less than 0.12 wt.%. Due to the crystal size of natural
385 CaSiO_3 -perovskite and the presence of inclusions of CaTiO_3 perovskite, we were able to perform only three
386 reliable analyses; the results are reported in EXTENDED DATA Table 1. Na and K were not analysed.

387

388 **Scanning Electron Microscopy and Energy Dispersive X-ray Spectroscopy**

389 Our newly discovered natural CaSiO_3 -perovskite was studied by SEM-EDS in order to investigate the
390 distribution of Ca, Si and Ti over the grain. We used a CamScan MX3000 electron microscope equipped
391 with a LaB6 source, four-quadrant solid state back-scattered electron (BSE) detector and an EDAX EDS

392 system for micro-analysis installed at the Department of Geosciences, University of Padova. The analytical
393 conditions were: accelerating voltage, 20 kV; filament emission, 13 nA; working distance, 27 mm. The
394 BSE image and the relative EDS Ca-Si-Ti map are shown in Figure 2.

395

396 **Single-crystal micro-X-ray diffraction**

397 Single-crystal X-ray diffraction measurements were performed using a Rigaku-Oxford Diffraction
398 Supernova goniometer installed at the Department of Geosciences, University of Padova, equipped with a
399 Dectris Pilatus 200 K area detector and a Mova X-ray microsource (MoK α -radiation) operating at 50 kV and
400 0.8 mA. The sample to detector distance was 68 mm. Data reduction was performed using the CrysAlis
401 software (Rigaku Oxford Diffraction). Diffraction data are reported in Extended Data Table 2 and are
402 compared to those of a reference CaTiO₃ measured on a single crystal³⁴ having the following unit-cell
403 parameters: a = 5.388(1) Å, b = 5.447(1) Å, c = 7.654(1) Å, V = 224.63(1) Å³.

404

405 **Carbon isotope analyses**

406 Carbon isotope compositions ($\delta^{13}\text{C}$), reported in EXTENDED DATA Table 3 were determined using a
407 Cameca IMS 7f-GEO secondary ion mass spectrometer (Caltech, USA). The polished diamond investigated
408 was pressed into an indium mount with a 1" diameter aluminium holder. Natural reference diamonds with
409 reference values of $\delta^{13}\text{C}$ between -13.6‰ ($2\sigma = 0.3$) and -2.5-2.6‰ ($2\sigma = 0.3$) were used to determine the
410 instrumental mass fractionation and drift before and after sample analyses. Diamonds were coated with gold
411 (20 nm). Analyses were conducted using $^{133}\text{Cs}^+$ at 10 keV impact energy and a beam current of ~4 nA. The
412 15 μm diameter $^{133}\text{Cs}^+$ primary-ion beam was used for pre-sputtering. During analysis, the ion beam
413 diameter was reduced to 5 μm . Secondary ions of ^{12}C and ^{13}C were extracted at -9 keV. No e-gun charge
414 compensation was required. The secondary ion energy bandwidth was 90 eV. $^{13}\text{C}/^{12}\text{C}$ - ratios were
415 measured using dual Faraday cups (FC1 for ^{12}C - and FC2 for ^{13}C -). The mass resolving power ($R = M/\Delta M$)
416 was 2900. The ^{12}C as well as ^{13}C ions were counted for 1 second, in each cycle (30 cycles in total). Total
417 time spent on each spot was 8 minutes. The standard deviation of the analyses is estimated at about 0.4 to 0.5
418 ‰ at the two-sigma (95% uncertainty) level.

419

420 **Electron Backscatter Diffraction**

421 EBSD analyses were performed at CNR-ICMATE (Padova, Italy) using a Quanta 200F FEG-ESEM (FEI
422 Company) operating in high vacuum mode at an accelerating voltage of 30 kV, emission 174 μ A, spot 4.5,
423 without any conductive coating. EBSD patterns were collected at 10 mm WD and 75° specimen tilt, using an
424 EDAX Digiview EBSD system. The instrument is controlled by the OIMTM 5.31 software, which contains a
425 large EBSD pattern database.

426

427 **Statistical analysis of diamond carbon isotope composition**

428 We used a compilation of 1473 C-isotope analyses of diamonds containing inclusions of lithospheric
429 peridotite paragenesis, from the dataset used by Huber (1981) [35]. We calculated the median absolute
430 deviation for this dataset using a bespoke Excel spread sheet, using formulae given in [36], using a *b* factor
431 of 1.4826 and a very conservative threshold factor of 3³⁶.
