21

22 ***Abstract***

23 Predation is an important selection pressure acting on organisms, with organisms evolving
24 diverse anti-predator strategies to combat it. One such widespread strategy is chemical
25 defense in which organisms either synthesize or extrinsically acquire defensive chemicals.
26 Little is known about the intraspecific transfer of such chemicals and if such chemicals
27 acquired from conspecifics can also serve as defense against predation. Here, we used adults
28 of the turnip sawfly, *Athalia rosae*, which can acquire *neo*-clerodane diterpenoids
29 (‘clerodanoids’) *via* pharmacophagy after exposure to the plant, *Ajuga reptans*. We show that
30 clerodanoid access mediates protection against predation by mantids for the sawflies, both in
31 a no-choice feeding assay and a microcosm setup. Moreover, even indirect access to
32 clerodanoids, via nibbling on conspecifics that had access to the plant, resulted in protection
33 against predation albeit to a much lower degree than direct access. Furthermore, sawflies that
34 had no direct access to clerodanoids were less consumed by mantids when they were grouped
35 with conspecifics that had direct access. Most, but not all, of such initially undefended
36 sawflies could acquire clerodanoids from conspecifics that had direct access to the plant,
37 although in low quantities. Together our results demonstrate that clerodanoids serve as
38 chemical defense that can be intraspecifically transferred. Moreover, the presence of
39 chemically defended individuals in a group can confer protection onto conspecifics that had
40 no direct access to clerodanoids, suggesting a ‘herd-protection’ effect.

45

46 **1. Introduction**

47 Predation is an important biotic factor that many organisms in the wild encounter. To defend
48 themselves, organisms exhibit a wide diversity of anti-predator strategies (Edmunds, 1974;
49 Eisner *et al.*, 2005; Bergen & Beldade, 2019; Rowland *et al.*, 2020). Chemical defense is one
50 such anti-predator strategy that is widespread amongst organisms, ranging from
51 microorganisms (Matz *et al.*, 2008) to multicellular organisms (Santos *et al.*, 2016; Pančić &
52 Kiørboe, 2018; Sugiura, 2020). Such defensive chemicals can either be synthesized *de-novo*
53 or acquired extrinsically, for example, from the host plant diet (Opitz & Müller, 2009; Erb &
54 Robert, 2016; de Castro *et al.*, 2021). For example, the oleander aphid, *Aphis nerii*, sequesters
55 cardenolides from its host plant species, and utilizes these defensive compounds against both
56 vertebrate and invertebrate predators (Züst *et al.*, 2018). Alternatively, organisms can
57 specifically take up defensive chemicals independently of nutritional requirements, e.g. *via*
58 pharmacophagy (Boppré, 1984; Nishida, 2014; Paul *et al.*, 2021b). For example, adults of
59 some danaine butterfly species actively incorporate defensive chemicals like pyrrolizidine
60 alkaloids from sources such as dried plant parts (Lawson *et al.*, 2021; Tea *et al.*, 2021). While
61 these acquired chemicals confer protection on the individual taking them up, it is less well-
62 elucidated whether and how this protection can extend to conspecifics that may not have
63 access to these chemicals directly from the source.

64 The possibility that chemically defended individuals confer protection from predation on
65 initially undefended conspecifics, what we coin as ‘herd-protection’, could be realized *via*
66 different means. For example, individuals could acquire such chemicals not only directly from
67 the (plant) source but also indirectly via intraspecific (Lawson *et al.*, 2021; Paul *et al.*, 2021a)
68 or interspecific (Hashimoto & Hayashi, 2014; Tea *et al.*, 2021) interactions. Such indirectly
69 acquired chemicals could then be used in the context of defense against predation.

70 Alternatively, after attacking a chemically defended individual, a predator may be deterred

71 from attacking even chemically undefended conspecifics if it associates the phenotype with
72 chemical defense by learned aversion or avoidance (Berenbaum & Miliczky, 1984;
73 Hämäläinen *et al.*, 2020; Tuttle *et al.*, 2021). This phenomenon is often seen in combination
74 with automimicry, wherein undefended individuals (mimics) benefit from the unpalatability
75 of defended individuals (models) (Brower *et al.*, 1970; Aubier *et al.*, 2017). Furthermore,
76 unpalatability or unprofitability of organisms is often associated with bright or aposematic
77 coloration that functions as warning signal to predators (Cyriac & Kodandaramaiah, 2019;
78 Kikuchi *et al.*, 2021). There is usually positive density-dependence in aposematism, such that
79 conspicuous warning signals are more effective when they are common (Chouteau *et al.*,
80 2016; Kikuchi *et al.*, 2021).

81 Understanding how the presence of chemically defended individuals affects the rest of the
82 population is an important question as studies have shown that there can be intraspecific
83 variation in chemical defense, with some individuals lacking chemical defenses entirely (Best
84 *et al.*, 2018; Prudic *et al.*, 2019; Sculfort *et al.*, 2020; Mattila *et al.*, 2021). Such variation
85 could arise if the defensive chemicals have an associated cost, for example, for acquisition
86 and/or maintenance of the chemical defense (Dimarco & Fordyce, 2017). Variation may also
87 be influenced by intrinsic factors such as the age, sex, reproductive phase or immunological
88 status of the individuals (Smilanich *et al.*, 2009; Zvereva & Kozlov, 2015; Arias *et al.*, 2016).
89 In such scenarios with intraspecific variation in chemical defense, the degree of protection
90 from predation for chemically undefended individuals depends on the frequency of defended
91 and non-defended individuals (Gamberale-Stille & Guilford, 2004; Finkbeiner *et al.*, 2018).
92 At higher density of chemically defended individuals, the motivation of predators could be
93 reduced to search for undefended prey (Skelhorn *et al.*, 2011), it may be harder to detect
94 undefended prey (Gamberale-Stille & Guilford, 2004; Skelhorn *et al.*, 2011), or more
95 undefended individuals could indirectly access the chemicals and gain protection.

96 An excellent model system for examining the effect of defensive chemicals in deterring
97 predation both directly and indirectly is the turnip sawfly, *Athalia rosae* (Hymenoptera:
98 Tenthredinidae). The larvae of this species are well-studied for sequestering metabolites, i.e.
99 glucosinolates, of their Brassicaceae host plants, which act as defense against various
100 invertebrate and vertebrate predators (Müller & Brakefield, 2003; Müller & Arand, 2007;
101 Opitz *et al.*, 2010; Matsubara & Sugiura, 2017). The bright orange adults still contain
102 glucosinolates sequestered by the larvae (Müller & Sieling, 2006) but do not seem to be
103 protected by these compounds against predators such as birds and lizards (Vlieger *et al.*,
104 2004; Boevé & Müller, 2005). However, *A. rosae* adults can additionally acquire other
105 specialized metabolites, *neo*-clerodane diterpenoids (potentially together with other
106 compounds, hereafter called clerodanoids), by pharmacophagy from certain plant species,
107 such as *Ajuga reptans* or *Clerodendrum trichotomum* (both Lamiaceae) (Kawai *et al.*, 1998).
108 Some of the clerodanoids found in insect bodies are likely slightly modified metabolic
109 products from plant derived clerodanoids (Amano *et al.*, 1999; Paul *et al.*, 2021a). Moreover,
110 these compounds can be acquired indirectly by nibbling on conspecifics that were exposed to
111 plant material (Paul *et al.*, 2021a). While effects of clerodanoids on mating behavior have
112 been shown previously (Amano *et al.*, 1999; Paul & Müller, 2021), empirical evidence for
113 other functions such as in defense against predation is scarce and indirect (Nishida & Fukami,
114 1990). In the laboratory, the cultures are usually maintained without *A. reptans* leaves,
115 suggesting that clerodanoid access is not essential for the sawflies' survival (Paul *et al.*,
116 2021b, 2021a; Paul & Müller, 2021). Moreover, there is evidence for associated costs of
117 clerodanoid uptake in *A. rosae*, such that adults with clerodanoid access exhibit a reduced
118 lifespan (Zanchi *et al.*, 2021). Thus, most likely there is intraspecific variation in clerodanoid
119 status by *A. rosae* in the wild.

120 We aimed to study whether uptake of clerodanoids can function as defense against predation
121 both for focal individuals that directly acquire these compounds after access to plants, and
122 indirectly for other conspecifics that come into contact with the focal individuals. Therefore,
123 we observed the response of mantid predators in no-choice feeding assays to sawflies that
124 either had access to clerodanoids directly from plants or indirectly from conspecifics or had
125 no access (experiment 1). Next, we investigated survivorship of sawflies with or without
126 clerodanoid access in both presence and absence of a predator (experiment 2). Lastly, we
127 investigated if the presence of sawflies with clerodanoid access conferred protection from
128 predation on conspecifics with no clerodanoid access and if this varied with their relative
129 abundance (experiment 3). We also investigated the clerodanoid acquisition of sawflies from
130 different treatments using chemical analysis (experiment 3). We predicted that both direct and
131 indirect clerodanoid acquisition should lead to protection from predation by the mantids.
132 Furthermore, presence of chemically defended sawflies should confer protection from
133 predation on conspecifics, with protection increasing with proportion of chemically defended
134 individuals in the group. We also expect sawflies without clerodanoid access that were
135 grouped with conspecifics with clerodanoid access to acquire clerodanoids.

136

137 **2. Materials and Methods**

138 **(a) Experimental animals**

139 The individuals of *A. rosae* used in this experiment were taken from a laboratory culture
140 established using adults collected in the surroundings of Bielefeld, Germany, and
141 supplemented annually with field-caught insects. The culture was maintained in mesh cages
142 (60 x 60 x 60 cm) with overhead lighting in a laboratory at room temperature with a 16 h: 8 h
143 light: dark cycle and ~60% relative humidity. Multiple females and males were put in a cage

144 and provided with *Sinapis alba* (Brassicaceae) plants for the females to oviposit. Emerging
145 larvae were raised on *Brassica rapa* var. *pekinensis* (Brassicaceae) plants. Males and females
146 were collected and separated within two days of pupal eclosion. Adults were kept in a climate
147 chamber at 20 °C (16 h: 8 h light: dark cycle, 70 % relative humidity) before being used in
148 experiment 1 and 2, and were kept in the laboratory under culture conditions for experiment
149 3. All adults were fed a maintenance diet of a honey-water mixture (1:50 dilution). Adults
150 were allocated randomly to the different treatments of no clerodanoid access (C-), direct
151 clerodanoid access (C+) or indirect clerodanoid access (AC+). For the C+ treatment, adults
152 got access to a leaf section (0.8 cm²) of *A. reptans* for 48 hours, while for C- no *A. reptans*
153 leaf was provided. For the AC+ treatment, adults got access to a C+ conspecific of the same
154 sex (prepared as above) for 48 hours. *S. alba* plants were grown from seeds in a climate
155 chamber (20 °C, 16 h: 8 h light: dark, 70% r.h.), while *B. rapa* and *A. reptans* plants were
156 grown from seeds in a greenhouse (≥ 20 °C, 16 h: 8 h light: dark, 70% r.h.).

157 Twenty-three sixth instar individuals of *Hierodula patellifera* (Mantidae) were purchased
158 (www.interaquaristik.de) and reared in individual cages (20 cm x 20 cm x 20 cm) on a diet of
159 crickets in a climatized room (~20 °C) on a diet of crickets. The mantids used in the
160 experiment were not exposed to the sawflies before experiment 1, and were starved 48 hours
161 before experiment 1. Each mantid was offered a cricket before experiment 2 and 3 to avoid
162 starvation effects over the experimental days, and those individuals that did not consume the
163 cricket were excluded as mantids usually stop eating when nearing a molt.

164 **(b) Experiment 1: No-choice feeding assay to examine effect of clerodanoid access on**
165 **predator deterrence**

166 Mantids were placed individually in transparent containers (9.5 cm diameter, 20 cm height),
167 one C-, C+ or AC+ female sawfly was introduced in the container (figure 1a), and the mantid
168 response was noted. Each assay was conducted for 15 minutes unless the sawfly was

169 consumed before this, at which point the assay was terminated. The predator response
170 variables examined during the assay were number of attacks on sawfly, whether sawfly was
171 discarded after mouth contact (SI 1a,b), and whether sawfly was consumed (SI 1c).
172 Discarding after mouth contact was a distinct behavior by the mantid, and could clearly be
173 distinguished from the sawfly slipping or escaping from the mantid's grab. For individuals
174 that were attacked multiple times, we noted discarding as yes if the individual was discarded
175 after mouth contact even once.

176 Sawflies of all treatments were offered to all mantids but in different orders; six mantids
177 received *A. rosae* in the order C+, AC+, C-, seven in the order C-, C+, AC+, and seven in the
178 order AC+, C-, C+ (total number of replicates N = 20). Upon noticing the sawfly, the mantids
179 would orient for an attack. However, we did not compare the latency until attack, because the
180 position of the mantids and how readily they noticed the sawflies differed between replicates.
181 Two mantids did not attack sawflies of any of the treatments during the assay and were thus
182 excluded from analysis as these mantids afterwards molted. We did not examine the long-
183 term survivorship of sawflies that were discarded after attack by mantids, but damage to the
184 sawfly spanned the spectrum from none to lethal (SI 1a-c).

185 We expected mantids to attack C- sawflies but not AC+ or C+ sawflies, e.g., if there were any
186 repellent olfactory cues associated with uptake of clerodanoids by the sawflies. If AC+ or C+
187 individuals were attacked, we expected the mantids to discard the sawflies after tasting
188 deterrent compounds and thus not consume them.

189 **(c) Experiment 2: Microcosm experiment to investigate clerodanoid access effect on**
190 **survivorship in predator presence or absence**

191 We used a fully factorial design (clerodanoid access x mantid presence) to evaluate the effect
192 of clerodanoid acquisition on sawfly survival in the presence of a mantid predator in a

193 microcosm (figure 2a). The four treatments were C- sawfly without mantid (C-M-), C- sawfly
194 with mantid (C-M+), C+ sawfly without mantid (C+M-) and C+ sawfly with mantid (C+M+)
195 with a sample size of eleven, ten, ten, and eight, respectively. All trials were performed in
196 microcosm cages (25 cm diameter, 26 cm height) with a honey-water supply. The cages were
197 kept in a climate room at 20 °C (16 h: 8 h light: dark cycle, 70% relative humidity) for the
198 duration of the experiment. For each trial, we used five sawflies (three females and two
199 males) and one or no mantid. We counted the number of sawflies alive every half-day for
200 three days. For the mantid present trials, we also counted the number of sawflies ‘dead but not
201 consumed’ at the end of three days, as sawflies may be attacked but not necessarily always
202 completely consumed, e.g. if they are unpalatable. For these replicates, we calculated the
203 number of consumed individuals as the difference between initial number of sawflies and the
204 number of sawflies alive or ‘dead but not consumed’. This experiment was conducted two
205 weeks after experiment 1 and the mantids were fed a cricket diet in the meantime. We
206 expected C- with mantids to have reduced survival than sawflies in the other treatments.
207 Moreover, we expected more C+ sawflies to be consumed by the mantids with time, which
208 could be either due to a decreasing concentration of the clerodanoids or to prolonged
209 starvation of the mantids.

210 **(d) Experiment 3: Predation on C- conspecifics in mixed groups of C+ and C- sawflies in**
211 **microcosm**

212 We aimed to test whether presence of C+ sawflies led to defense against predation also for C-
213 sawflies. Therefore, we set up four group-composition treatments, consisting of varying
214 relative abundance of C+ and C- sawflies, keeping the total abundance of sawflies fixed at
215 six. We chose six as the total abundance as we knew from experiment 2 that mantids can
216 consume up to 5 C- *A. rosae* adults over a period of 1-3 half-days. The first group-
217 composition treatment consisted of six C- sawflies (6C-), and the other three mixed group-

218 compositions treatments were: two C+ and four C- sawflies (2C+4C-), three C+ and three C-
219 sawflies (3C+3C-), and four C+ and two C- sawflies (4C+2C-). For each replicate, we joined
220 the sawflies together in one petri dish according to the assigned group treatment two hours
221 prior to adding them to the microcosm, to allow the sawflies to interact (e.g., mate or nibble).
222 We used eighteen mantids for the experiment, and a microcosm cage set-up identical to
223 experiment 2. Each mantid was exposed to all group treatments in random order over multiple
224 trials (four trials per mantid), with each trial lasting two days. Each mantid was fed a small
225 cricket prior to each trial. For the mixed group-compositions treatments containing both C+
226 and C- individuals, we used only females as C- and males as C+. Using the different sexes
227 allowed us to distinguish between C- and C+ individuals in each replicate. From experiment
228 2, we know that both male and female sawflies are consumed by mantids (see Results). In
229 *A. rosae* adults, males are usually smaller than females (Sawa *et al.*, 1989; Travers-Martin &
230 Müller, 2008), making it potentially easier for C- females to nibble and gain access to
231 clerodanoids from C+ males. At the end of each trial, we counted the number of alive or ‘dead
232 but not consumed’ C+ and C- sawflies for each replicate. We calculated the number of
233 consumed C- sawflies as the difference between initial number of C- sawflies and number of
234 C- sawflies alive or ‘dead but not consumed’. Similarly, we calculated the number of
235 consumed C+ sawflies. We hypothesized that the presence and increasing abundance of C+
236 sawflies should lead to protection from predation for C- sawflies.

237 **(e) Chemical analysis of sawflies from experiment 3**

238 To test whether C- sawflies in mixed group-composition treatments acquired clerodanoids
239 compared to 6C- replicates, we collected C- sawflies from different group-composition
240 treatments and analysed them chemically. We also collected C+ sawflies to confirm their
241 clerodanoid acquisition. Lastly, we examined if C+ sawflies differed from C- sawflies of
242 mixed group-composition treatment in the amount of clerodanoid acquired, i.e. if there is a

243 difference between amount acquired directly from plant leaves or indirectly from
244 conspecifics. We only collected individuals from replicates that had intact sawflies left at the
245 end of the trial and stored them at -80 °C until further analysis. The final sample size for C-
246 sawflies chemically analysed was six, five, seven, and five samples each of 6C-, 2C+4C-,
247 3C+3C- and 4C+2C- group-composition treatments, respectively. The final sample size for
248 C+ sawflies was one, four and five from 2C+4C-, 3C+3C- and 4C+2C- group treatments,
249 respectively. To extract putative clerodanoids from the sawflies, the individuals were freeze-
250 dried and then homogenized using glass beads in a ball mill. Each individual was extracted
251 twice by shaking for seven minutes at room temperature in ethyl acetate (LC-MS grade,
252 VWR, Leuven, Belgium), and the supernatants were pooled to a final volume of 400 µl. The
253 extracts were dried in a vacuum centrifuge at 35 °C. Dried extracts were suspended in 125 µl
254 100% methanol (LC-MS grade, Fisher Scientific, Loughborough, UK) in an ultrasonic bath
255 for 15 minutes, after which they were filtered using syringe filters (polytetrafluoroethylene
256 membrane, 0.2 µm pore size, Phenomenex, Torrance, CA, USA). The samples were analyzed
257 using ultra high performance liquid chromatography (UHPLC; Dionex UltiMate 3000,
258 Thermo Fisher Scientific, San José, CA, USA) with a Kinetex XB-C18 column (1.7 µm, 150
259 × 2.1 mm, with guard column, Phenomenex), and coupled to a quadrupole time of flight mass
260 spectrometer (QTOF-MS; compact, Bruker Daltonics, Bremen, Germany), see SI 2 for
261 details. The resulting chromatograms were processed with the software Compass Data
262 Analysis 4.4 (Bruker Daltonics). The putative clerodanoids 482.22 m/z (C₂₄H₃₄O₁₀) and
263 484.23 m/z (C₂₄H₃₆O₁₀) occur in the chromatograms as [M+HCOOH-H]⁻ adducts resulting in
264 features with 527.21 m/z and 529.23 m/z, respectively (Paul *et al.*, 2021a). We manually
265 integrated the peak areas of these two features from the extracted ion chromatograms,
266 extracted with 0.02 m/z accuracy.

267 We expected C- sawflies from mixed group-composition treatments to acquire clerodanoids,
268 but to have lower amounts of clerodanoid compounds compared to C+ sawflies.

269 **(f) Statistical analyses**

270 In experiment 1, we examined whether treatment had an effect on number of attacks, sawfly
271 being discarded after mouth contact, and sawfly being consumed using a binomial generalized
272 linear mixed-effects model (GLMM), with mantid identity as random effect. As there was
273 quasi-complete separation in our data for two variables (sawfly being discarded after mouth
274 contact and sawfly being consumed), i.e. the predictor variable could perfectly predict the
275 response variable for a subset of our data, we fitted a Bayesian binomial GLMM using ‘blme’
276 package (version 1.0-5, Chung *et al.*, 2013) for all variables. We evaluated if the order in
277 which the mantid was presented the treatments influenced the mantid response variables by
278 incorporating the trial round of a treatment as a fixed effect (due to only three levels) in each
279 model, and this gave qualitatively similar results (not shown).

280 In experiment 2, we examined the effect of treatment, time and their two-way interaction on
281 number of alive sawflies using a Poisson GLMM (‘lme4’ package version 1.1-27.1, Bates *et*
282 *al.*, 2015) with replicate ID as random effect. We also examined if there was a significant
283 difference in number of consumed and ‘dead but not consumed’ sawflies between C- and C+
284 treatments with mantids (C-M+ and C+M+) using a Kruskal-Wallis test.

285 In experiment 3, we calculated the proportion of consumed, alive and ‘dead but not
286 consumed’ C- with respect to the initial abundance of C- sawflies in that replicate. We
287 examined whether the proportion of consumed, alive, and ‘dead but not consumed’ C-
288 individuals differed significantly among the group-composition treatments using a binomial
289 GLMM (‘lme4’ package), with mantid identity and trial number as random effects. We
290 considered the number of C- individuals consumed/alive/‘dead but not consumed’ as

291 successes and initial number of C- present as the number of trials. Similarly, we calculated the
292 proportion of consumed, alive, and ‘dead but not consumed’ C+ with respect to the initial
293 abundance of C+ sawflies in that replicate. Finally, we examined if there was a significant
294 difference in the amount (quantified based on peak area) of the two putative clerodanoid
295 compounds between C- and C+ sawflies of mixed group-composition treatments using a
296 Kruskal-Wallis test.

297 All data was analyzed using R 4.0.5 (2021-03-31) (R Core Team, 2021). We checked and
298 tested model assumptions statistically and visually. Posthoc-tests were conducted using
299 ‘multcomp’ package (version 1.4-17, Hothorn *et al.*, 2008).

300 **3. Results**

301 **(a) Experiment 1. Clerodanoid access protects against consumption by predator**

302 All sawflies irrespective of treatment were attacked at least once with no significant effect of
303 treatment on number of attacks ($\chi^2 = 5.92$, d.f. = 2, $p = 0.052$; figure 1*b*). In contrast, the
304 treatments differed significantly in whether a sawfly was discarded after mouth contact by a
305 mantid ($\chi^2 = 21.15$, d.f. = 2, $p < 0.001$; figure 1*c*, SI 3*a*), with C+ individuals dropped
306 significantly more often compared to C- (posthoc test: $p < 0.001$) and AC+ (posthoc test: $p <$
307 0.001). Likewise, treatment had a significant effect on whether an individual was consumed
308 ($\chi^2 = 21.28$, d.f. = 2, $p < 0.001$; figure 1*d*, SI 3*b*), with C+ individuals (0% consumed) being
309 significantly less likely to be consumed compared to C- (100% consumed) (posthoc test: $p <$
310 0.001) and AC+ (70% consumed) (posthoc test: $p = 0.001$).

311 **(b) Experiment 2. C+ individuals are not consumed by predator even after prolonged** 312 **exposure**

313 There was a significant interactive effect of treatment and time on number of sawflies alive
314 ($\chi^2 = 36.76$, d.f. = 3, $p < 0.001$). In the treatment with no mantids, all C- and all but one C+

315 individual survived across all replicates (figure 2*b*). In C- treatments with mantids, no
316 individual was alive after three-half days. In contrast, for C+ treatments with mantids, all
317 individuals were alive in two replicates. In the other six C+M+ replicates the number of alive
318 individuals decreased with time, although in no replicate all individuals were killed. There
319 was a significant difference in number of consumed sawflies ($\chi^2 = 15.63$, d.f. = 1, $p < 0.001$,
320 figure 2*c*) with all sawflies consumed in the C-M+ treatment, while only few sawflies were
321 consumed across three replicates in the C+M+ treatment. Similarly, the number of ‘dead but
322 not consumed’ individuals significantly differed between C-M+ and C+M+ treatments ($\chi^2 =$
323 5.95, d.f. = 1, $p = 0.014$, figure 2*d*). In four C+ replicates but zero C- replicates, we collected
324 ‘dead but not consumed’ individuals, suggesting that while the mantids attacked C+
325 individuals, they were not always consumed.

326 **(c) Experiment 3. Less C- individuals consumed by predator, if C+ individuals are**
327 **present**

328 Group-composition treatment had a significant effect on the proportion of consumed C-
329 sawflies ($\chi^2 = 41.87$, d.f. = 3, $p < 0.001$; figure 3*a*), with significantly more C- consumed in
330 the 6C- treatment compared to the 2C+4C- (posthoc test: $p < 0.001$), 3C+3C- (posthoc test: p
331 < 0.001), and 4C+2C- (posthoc test: $p < 0.001$) treatments. There was no significant
332 difference between the other treatments (SI 4*a*). The proportion of alive C- sawflies differed
333 between the treatments ($\chi^2 = 27.23$, d.f. = 3, $p < 0.001$; figure 3*b*), with significantly less C-
334 alive in the 6C- compared to the 2C+4C- (posthoc test: $p = 0.005$) and 3C+3C- (posthoc test:
335 $p < 0.001$) treatment, while other treatments were not significantly different (SI 4*b*).
336 Similarly, the proportion of ‘dead but not consumed’ C- sawflies differed between the
337 treatments ($\chi^2 = 8.77$, d.f. = 3, $p = 0.032$; figure 3*c*), with significantly more C- sawflies being
338 ‘dead but not consumed’ in the 4C+2C- compared to the 6C- treatment (posthoc test: $p =$
339 0.029), and no other significant differences between treatments (SI 4*c*). Similarly, to

340 experiment 2, C+ sawflies were consumed rarely, although in many replicates there were
341 ‘dead but not consumed’ C+ individuals (SI 5a-c).

342 The chemical analysis revealed that the putative clerodanoids 482.22 m/z and 484.23 m/z
343 could be detected in sixteen (~94%) and fourteen (~82%), respectively, of the seventeen
344 sampled C- sawflies from mixed group-composition treatments (figure 4a,b). All ten (100%)
345 C+ sawflies had acquired both putative clerodanoids (figure 4). There was intraspecific
346 variation in the amount of clerodanoids acquired for both C+ and C- sawflies of mixed
347 groups. Two out of six replicates of the 6C- group-treatment also had small amounts of
348 clerodanoids (figure 4), possibly resulting from contamination as these replicates were placed
349 in the microcosms where previously mixed group-composition treatments were housed. This
350 contamination could also potentially explain why these C- sawflies were not consumed by the
351 mantids. C+ sawflies had significantly higher amounts of both clerodanoids, 482.22 m/z ($\chi^2 =$
352 10.98, d.f. = 1, $p < 0.001$, figure 4a) and 484.23 m/z ($\chi^2 = 15.75$, d.f. = 1, $p < 0.001$, figure
353 4b), than C- sawflies for mixed group-composition treatments.

354 **4. Discussion**

355 Chemical defense as an anti-predator strategy is widespread and well-documented in animals
356 (Speed *et al.*, 2012). However, it is less clear if such chemical defense can be intraspecifically
357 transmitted and whether presence of chemically defended individuals can confer protection
358 onto undefended conspecifics. In some species, such defensive chemicals can be taken up
359 independently of the nutrient-delivering food source, as in the case of our study organism,
360 *A. rosae*, that takes up clerodanoids (and potentially also other chemicals)
361 pharmacophagously from *A. reptans* plants and likely metabolized them (Paul *et al.*, 2021b).
362 Here, we showed that direct access to *A. reptans* leaves serves as defense against predation by
363 making the sawflies unpalatable to the predator. We also demonstrated that clerodanoid

364 access provides protection not only to focal individuals but also to conspecifics in mixed
365 groups of C+ and C- individuals.

366 While most sawflies without access to clerodanoids were lethally attacked and consumed by
367 the mantids, only very few sawflies that had taken up clerodanoids from leaves were
368 consumed, as we had predicted. Nevertheless, many sawflies with clerodanoid access were
369 also attacked but then readily rejected by the mantids, as shown by the ‘discarding after
370 mouth contact’ behavior in experiment 1 and by the higher number of ‘dead but not
371 consumed’ sawflies in experiment 2. This rejection is likely induced by the bitter taste of the
372 clerodanoids that may be deposited on the cuticle and in body tissue of the adult sawfly
373 (Nishida & Fukami, 1990). When tested directly, two clerodanoids (clerodendrin B and D)
374 had a deterrent effect on Japanese tree sparrows, who consumed fewer rice grains that had
375 been treated with the clerodanoids compared to untreated grains (Nishida & Fukami, 1990). A
376 taste-rejection behavior, in which predators taste but do not ingest a prey item, as found by
377 the mantids in the present experiment, has been shown to be elicited by distasteful prey and
378 can lead to an increased survivorship of the prey (Halpin & Rowe, 2017). Although we did
379 not quantify the long term survivorship of sawflies after mantid attack in experiment 1, visual
380 inspection showed that the damage spectrum ranged from nearly unharmed to dead sawflies
381 (SI 1a,b), indicating that clerodanoid uptake could lead to survivorship advantages.

382 Adult *A. rosae* can acquire clerodanoids not only from plants but also from conspecifics *via*
383 nibbling on their body surface. However, acquiring clerodanoids indirectly from conspecifics
384 resulted in less protection than direct acquisition from the plants in *A. rosae* in our
385 experiments. Not all sawflies successfully acquire sufficient clerodanoid amounts from C+
386 conspecifics (Paul *et al.*, 2021a) and the concentrations could be much lower than after direct
387 uptake from the *A. reptans* leaves (figure 4). Such quantitative and potentially also qualitative
388 differences in clerodanoid acquisition may explain, why many AC+ sawflies (experiment 1)

389 and C- sawflies in mixed C+ C- group treatments (experiment 3) were consumed by mantids.
390 The effectiveness of defense chemicals sequestered from host plants against predators has
391 been shown to be concentration-dependent in a glucosinolate-sequestering leaf beetle species,
392 with individuals having lower levels of sequestered glucosinolates being more susceptible to
393 predation (Sporer *et al.*, 2020). In *A. rosae*, transfer of clerodanoids can occur both within and
394 between sexes (Paul *et al.*, 2021a), which seems rather exceptional. In other insect species,
395 usually chemicals are transferred from the male to the female during mating. For example, in
396 some arctiid moth species, pyrrolizidine alkaloids are sexually transmitted from males to
397 females, and these chemicals render protection against predation to the recipient female
398 (Gonzalez *et al.*, 1999; Conner *et al.*, 2000). Moreover, such defensive chemicals acquired by
399 the female from the male can also be incorporated into the offspring (Eisner *et al.*, 2002;
400 Camarano *et al.*, 2009; Sternberg *et al.*, 2015) providing it with benefits. Evidence for such
401 benefits of parental clerodanoid access to offspring in *A. rosae* is currently lacking (Paul *et*
402 *al.*, 2021b).

403 Our data from the predation microcosm experiment (experiment 2) demonstrated that the
404 mantids attacked C+ sawflies, with number of alive sawflies decreasing over time, but this
405 decline was less rapid than that of C- sawflies in presence of mantids. This suggests that the
406 mantids may learn to avoid C+ sawflies after first encounters, leading to a longer survival
407 period of the sawflies. Learned aversion has been found in the mantid *Tenodera aridifolia*,
408 where the mantids reduced attacks on certain prey items when these prey items were made
409 bitter (Carle *et al.*, 2018). Similarly, repeated exposure to unpalatable milkweed bugs that had
410 sequestered cardenolides from their host plants led to avoidance by *T. aridifolia* of both
411 palatable and unpalatable milkweed bugs altogether (Berenbaum & Miliczky, 1984).
412 Interestingly, the mantid *H. patellifera* attacked sawflies in both experiment 2 and 3 despite
413 having been exposed to the C+ sawflies previously, suggesting that such avoidance learning

414 may not last long, as also seen in *T. aridifolia* (Prudic *et al.*, 2007). Moreover, such avoidance
415 learning can be more effective if the distasteful prey is conspicuously colored (Roper &
416 Redston, 1987; Raška *et al.*, 2017). Indeed, organisms that use chemical defenses are usually,
417 but not always, brightly colored and conspicuous, i.e. aposematic, to advertise their
418 distastefulness to predators (Poulton, 1890; Kikuchi *et al.*, 2021). The sawfly *A. rosae*, used
419 in our study, is aposematically colored, with a bright orange body (SI 1), which might
420 facilitate temporary avoidance learning by mantids.

421 In line with our prediction, the presence of C+ sawflies was beneficial for C- sawflies with a
422 smaller proportion of C- sawflies consumed in group-composition treatments that had C+
423 individuals present compared to groups of C- sawflies only. This suggests that presence of
424 chemically defended sawflies can lead to ‘herd protection’ of conspecifics. Such protection
425 may result from the C- individuals acquiring clerodanoids, or temporary learned avoidance of
426 C- by mantids after encountering C+ sawflies. Our chemical analysis showed that most, but
427 not all, sawflies had acquired detectable amounts of clerodanoids, suggesting that both of
428 these mechanisms could play a role in the ‘herd-protection’ of C- conspecifics. In our
429 experiment, there was no significant change in the expected direction in number of consumed
430 C- sawflies across the gradient of the C+ and C- mixed group-composition treatments. This
431 may have been due to the small number of sawflies used (six), and hence only small
432 differences between the mixed treatments. A study using the domestic chick, *Gallus gallus*
433 *domesticus*, as predator showed that the birds rejected the mimics (palatable prey items) less
434 frequently when the relative abundance of these mimics compared to the models (unpalatable
435 prey items) increased, but birds only discriminated between the models and mimics when the
436 frequency of mimics was above 25% (Skelhorn & Rowe, 2007). Moreover, density-
437 dependence of predation can also be influenced by other factors such as predator behavior,
438 e.g. learning, forgetting and memory (Speed & Turner, 1999), and the energetic and

439 informational state of the predator, leading to state-dependent decision-making (Aubier &
440 Sherratt, 2020).

441 In natural populations of *A. rosae*, intraspecific variation in clerodanoid uptake could be
442 expected if the distribution of pharmacophagy-suitable plants is patchy, if there in
443 intraspecific variation in the clerodanoid concentrations available from the plants, or if there
444 are associated costs of clerodanoid uptake. Indeed, *A. rosae* individuals that were exposed to
445 clerodanoids had a shorter lifespan than control individuals (Zanchi *et al.*, 2021). This
446 suggests that there might be costs to clerodanoid uptake, although clerodanoid access did not
447 immediately cause high mortality during our observed period in experiment 2 (figure 2*b*).
448 Similar costs of chemical defense have been revealed in swallowtail butterflies of the tribe
449 Troidini which showed reduced larval survivorship (Dimarco & Fordyce, 2017) or a reduction
450 in adult fat content (Fordyce & Nice, 2008) when sequestering toxic alkaloids. Our study
451 demonstrates that even if individuals do not take up clerodanoids, they could still benefit
452 indirectly from conspecifics that do. This could lead to emergence of cheaters that do not pay
453 the cost of chemical defense but enjoy the benefits (Lindstedt *et al.*, 2018). Future studies
454 should examine variation in clerodanoid contents in natural populations of *A. rosae*. In
455 conclusion, our study showed that clerodanoids serve as chemical defense for *A. rosae* that
456 can be intraspecifically transferred. Furthermore, chemically defended sawflies can confer
457 protection onto conspecifics that had no direct access to clerodanoids in a group, indicating a
458 ‘herd-protection’ effect.

636 **Figures**

637

638 Figure 1. (A) Experimental design illustration of no-choice feeding assay, where each mantid
639 was exposed to one *Athalia rosae* sawfly of different clerodanoid treatments (C- no access,
640 AC+ indirect access via conspecific that had contact with leaf of *Ajuga reptans*, C+ direct
641 access to *A. reptans*) over multiple trials performed in different orders. Effects of clerodanoid
642 treatment on percentage of sawflies that were (B) attacked twice (all other sawflies were
643 attacked once), (C) discarded after mouth contact, and (D) consumed, by mantid ($n = 20$
644 replicates per treatment). Different letters denote significantly different treatment effects
645 inferred from Tukey HSD post hoc tests.

646

647

648 Figure 2. (A) Experimental design illustration of clerodanoid treatment (C- no access, C+

649 access to leaf of *Ajuga reptans*) and predation microcosm experiment, where in each

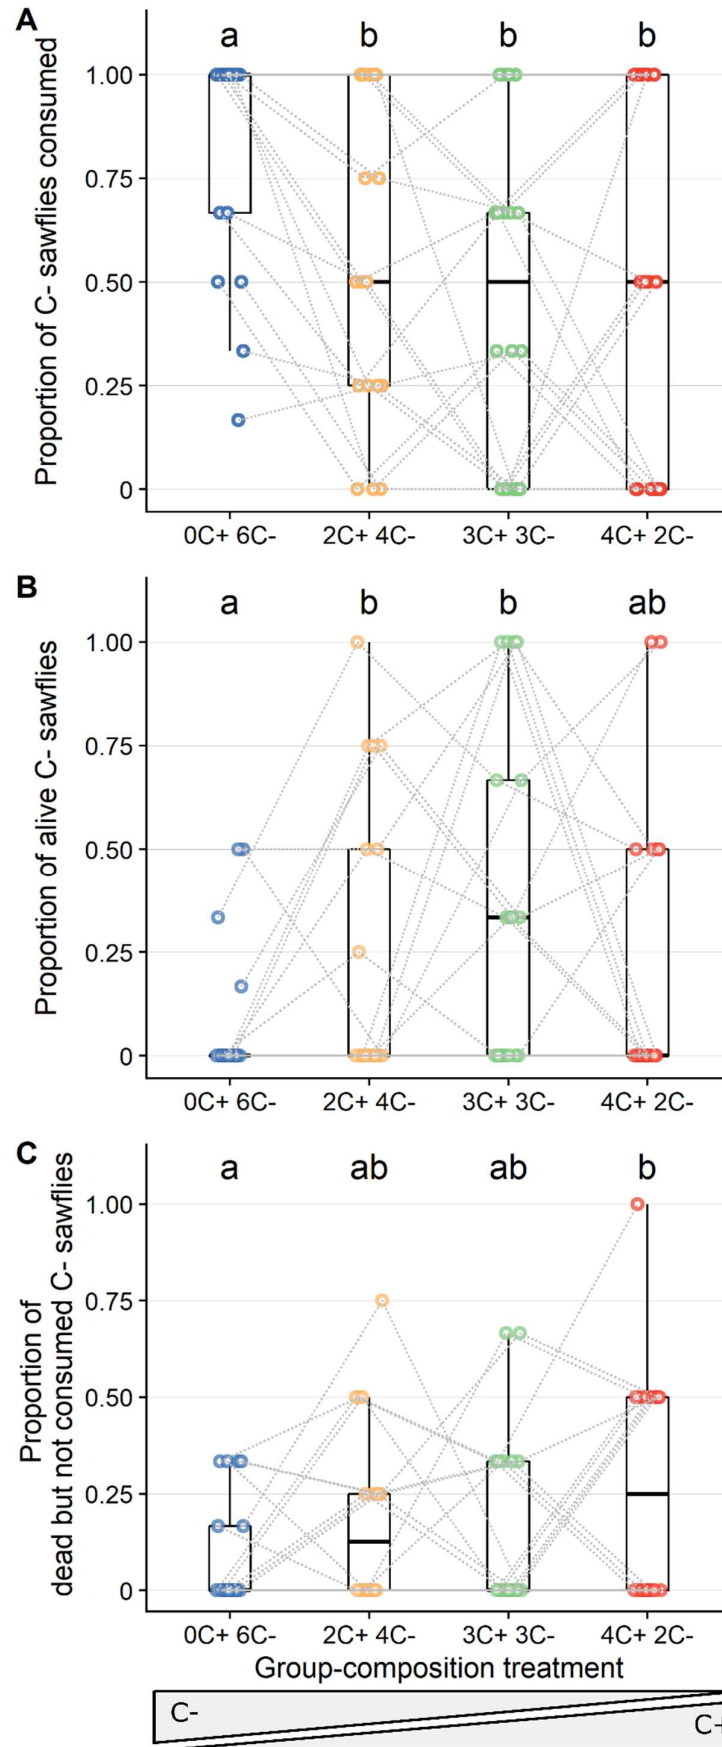

650 microcosm five *Athalia rosae* sawflies were added that were either C- or C+ and with-or-

651 without a mantid. B) Number of alive sawflies of different clerodanoid treatments over time.

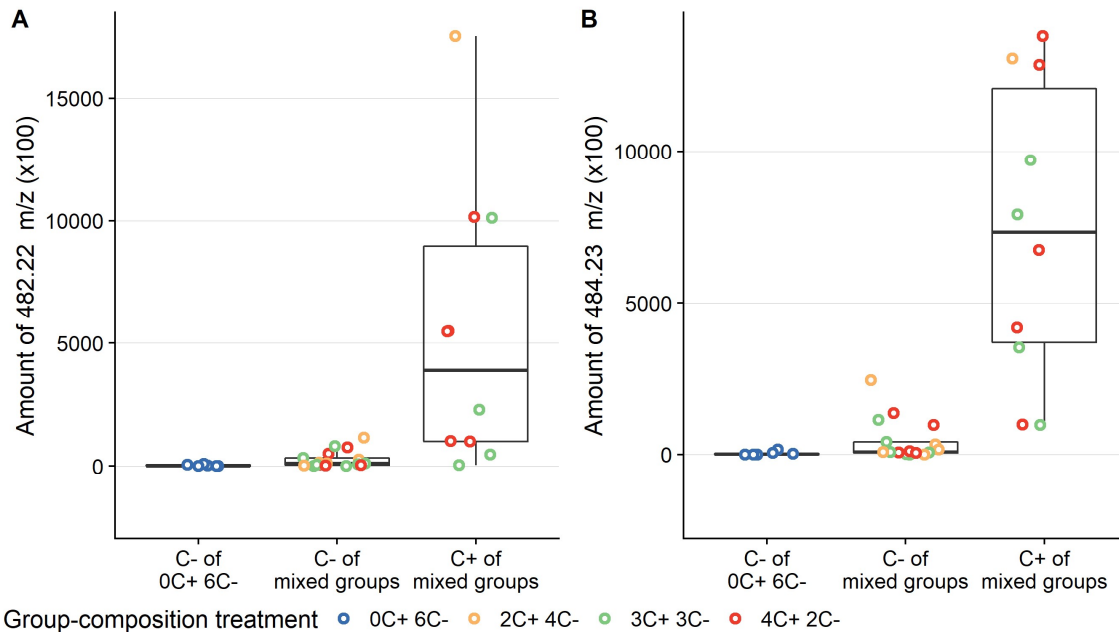

652 Lines are jittered to decrease overlapping. Number of C- and C+ individuals that were (C)

653 consumed or (D) ‘dead but not consumed’ in replicates of mantid present (M+) treatment.

654

656 Figure 3. Effects of different group-composition, i.e. varying relative abundance of *Athalia*
657 *rosae* sawflies with (C+) and without (C-) access to a leaf of *Ajuga reptans* and thus
658 clerodanoids, on proportions of (A) consumed, (B) alive, and (C) ‘dead but not consumed’ C-
659 sawflies in presence of a mantid. Data are presented as boxplots, medians and interquartile
660 with individual data points also plotted. Grey dotted lines connect data from each mantid ($n =$
661 18) across trials. Note that abundance of C- sawflies decreases and C+ increases from left to
662 right.

664 Figure 4. Amount (peak area) of candidate chemical features representing putative
665 clerodanoids, (A) 482.22 m/z ($C_{24}H_{34}O_{10}$) and (B) 484.23 m/z ($C_{24}H_{36}O_{10}$), respectively, from
666 the extracted ion chromatograms for C- (without access to a leaf of *Ajuga reptans*) and C+
667 (with access to a leaf of *A. reptans*) sawflies of different group-composition treatments.
668 Mixed groups represent groups that had both C+ and C- sawflies present in the microcosm,
669 while 0C+6C- had only C- sawflies present.
