Abstract

Familial dysautonomia (Riley–Day syndrome, hereditary sensory and autonomic neuropathy type III) is a rare autosomal recessive characterized by impaired development of primary sensory and autonomic neurons resulting in a severe neurological phenotype, which includes arterial baroreflex and chemoreflex failure with high frequency of sleep-disordered breathing and sudden death during sleep. Although a rare disease, familial dysautonomia represents a unique template to study the interactions between sleep-disordered breathing and abnormal chemo- and baroreflex function. In patients with familial dysautonomia, ventilatory responses to hypercapnia are reduced, and to hypoxia are almost absent. In response to hypoxia, thee patients develop paradoxical hypoventilation, hypotension, bradycardia, and potentially, death. Impaired ventilatory control due to chemoreflex failure acquires special relevance during sleep when conscious control of respiration withdraws. Overall, almost all adult (85%) and pediatric (95%) patients have some degree of sleep-disordered breathing. Obstructive apnea events are more frequent in adults, whereas central apnea events are more severe and frequent in children. The annual incidence rate of sudden death during sleep in patients with familial dysautonomia is 3.4 per 1000 person-year, compared to 0.5–1 per 1000 person-year of sudden unexpected death in epilepsy. This review summarizes recent developments in the understanding of sleep-disordered breathing in patients with familial dysautonomia, the risk factors for sudden death during sleep, and the specific interventions that could prevent it.

INTRODUCTION

Familial dysautonomia (FD, Riley–Day syndrome, hereditary sensory and autonomic neuropathy type III) is a rare autosomal recessive disease first described in 1949 in children of Jewish Ashkenazi ancestry (Norcliffe-Kaufmann et al., 2017; Riley et al., 1949). The disease is caused by a founder mutation in the IkB kinase-associated protein gene (*IKBKAP*) resulting in increased levels of mutant, defective, ELP-1 (IKAP) protein, mostly in central and peripheral nervous systems. Lack of functional ELP-1 causes impaired development of primary sensory and autonomic neurons (Blumenfeld et al., 1993; Hunnicutt et al., 2012; Mezey et al., 2003; Slaugenhaupt et al., 2001) resulting in a severe neurological phenotype, which includes arterial baroreflex and chemoreflex failure with high frequency of sleep-disordered breathing and sudden death during sleep (Bernardi et al., 2003; Edelman et al., 1970; Filler et al., 1965; Guilleminault et al., 1984; McNicholas et al., 1983; Palma et al., 2017). Although a rare disease with no more than 700 identified cases, FD represents a unique template to study the interactions between sleep-disordered breathing and abnormal chemo- and baroreflex function. Here, we review recent developments in the understanding of sleep-disordered breathing in patients with FD, the risk factors for sudden death during sleep, and the specific interventions that could prevent it.

THE PHENOTYPE OF FD IS A CONSEQUENCE OF DEAFFERENTATION

ELP-1 deficiency in FD affects the development of primary sensory (afferent) neurons, resulting in a complex neurological phenotype. Impaired development of primary sensory nerves results in reduced pain and temperature sensation, absent deep tendon reflexes and gait ataxia (Macefield et al., 2011), optic neuropathy (Mendoza-Santiesteban et al., 2017), and neurogenic dysphagia contributing to chronic lung disease (Kazachkov et al., 2018; Palma et al., 2018). In addition, abnormal development of mechano- and chemosensory neurons results in baro- and chemoreflex failure with orthostatic hypotension, paroxysmal hypertension, and abnormal control of heart rate and ventilatory responses to hypoxia and hypercapnia (Norcliffe-Kaufmann et al., 2010; Norcliffe-Kaufmann et al., 2016). These contribute to early-onset target organ damage (Goldberg et al., 2018; Norcliffe-Kaufmann et al., 2017; Palma et al., 2014), and chronic respiratory disease.

CHEMOREFLEX FAILURE IN FD

Physiology of respiration and the chemoreflex

The chemoreceptor reflex is a negative feedback mechanism that regulates ventilatory drive to maintain arterial pressures of oxygen (O_2) and carbon dioxide (CO_2) and pH within a narrow range. The *afferent* part of the chemoreflex includes *peripheral* multimodal chemoreceptor cells in the carotid body, and *central* CO_2 -H^+ -sensing chemoreceptor neurons in the brainstem. Peripheral chemoreceptor cells in the carotid bodies, which derive from the neural crest, monitor the partial pressure of oxygen (pO_2), the pCO_2, and pH in arterial blood. They synapse with nerve terminals of chemoreceptor neurons, with cell bodies in the petrosal ganglia of the glossopharyngeal nerve, which transmit chemosensory information to neurons in the nucleus of the solitary tract (NTS) in the medulla. These NTS neurons project to the pre-Bötzinger complex, a group of neurons that generates the

rhythmic signals underlying the periodic drive for inspiration (Del Negro et al., 2018). Neurons in the pre-Bötzinger complex project to neurons in the dorsal and ventral respiratory groups in the medulla, which control spinal motoneurons innervating respiratory muscles (diaphragm, intercostal and abdominal), as well as premotoneurons projecting to vagal (cranial nerve X) and hypoglossal (cranial nerve XII) motor neurons that control the tongue and upper airway muscles (Revill et al., 2015; Yang et al., 2018).

Central breathing networks are also modulated by input from *mechanoreceptors* sensing the stretch of the respiratory muscles (e.g., diaphragm) and lungs. Stretch receptors (mechano-sensors) in smooth muscle of bronchi and bronchioles send information via the vagus nerve to the pre-Bötzinger complex and other areas in the brainstem. Lung stretch-receptor afferents conveying signals to brainstem interneurons rhythmically inhibit the pre-Bötzinger complex and activate the lateral parafacial nucleus when lungs are inflated (inspiratory termination reflex) and conversely excite the pre-Bötzinger complex and inhibit the lateral parafacial nucleus when lungs are deflated. This feedback underlies the Breuer-Hering reflexes, essential in controlling inflation and deflation of the lungs.

In normal individuals, most of the respiratory control is exerted by brainstem neurons - *central* chemosensory neurons and glia located in the ventral parafacial nucleus and other regions respond to changes in partial pressure of CO_2 (pCO_2) and pH in the cerebrospinal fluid. These neurons project to the pre-Bötzinger complex -the primary neurons generating the essential periodic drive for inspiration- and other sites to coordinate the breathing cycle (Del Negro et al., 2018).

Breathing in humans is extremely sensitive to changes in the levels of pCO_2 in arterial blood, as they directly affect acid-base balance. For instance, in healthy subjects, an increase in arterial pCO_2 from 40 to 41 mmHg (~2.5%) stimulates central and peripheral chemoreceptors and increase minute ventilation from 5 to 7 liters (~40%). In contrast, under normal conditions, breathing is relatively insensitive to changes in levels of pO_2 in arterial blood. However, when oxygen levels decrease and arterial pO_2 is less than ~60 mmHg (e.g., high altitude or intense exercise) hypoxia becomes a powerful stimulus increasing ventilation at any given pCO_2 level (Hoiland et al., 2018). Decreases in pH (i.e., increases in H^+ concentration) stimulate central and peripheral chemoreceptors resulting in hyperventilation. In healthy subjects, reductions in pO_2 cause tachycardia and moderate increases in blood pressure, and both hypoxia and hypercapnia increase ventilatory drive and central sympathetic outflow. Baroreflex activation normally abolishes the increase in sympathetic activity induced by hypoxia, but not by hypercapnia (Somers et al., 1991; Somers et al., 1989a; Somers et al., 1989b).

Cardiorespiratory consequences of chemo- and baroreflex failure

Neurological disorders affecting central or peripheral chemoreceptor neurons can manifest with hypoxia and hypercapnia due to hypoventilation and most disturbingly episodes of apnea. In patients with FD, ventilatory responses to hypercapnia are reduced, and to hypoxia are almost absent. In response to hypoxia, thee patients develop paradoxical hypoventilation, hypotension, bradycardia, and potentially, death (Bernardi et al., 2003; Edelman et al., 1970; Filler et al., 1965; Guilleminault et al., 1984; McNicholas et al., 1983). Impaired ventilatory

control due to chemoreflex failure acquires special relevance during sleep when conscious control of respiration withdraws. Virtually all patients with FD have some degree of sleep-disordered breathing (Gadoth et al., 1983; McNicholas et al., 1983; Singh et al., 2018; Weese-Mayer et al., 2008), which is a risk factor for sudden unexpected death during sleep (Palma et al., 2017).

In patients with FD cardiorespiratory responses to hypoxia and hypercapnia are markedly abnormal, likely due to impaired afferent chemo- and baroreflex neurons. Several investigations have consistently reported these responses (Bernardi et al., 2003; Edelman et al., 1970; Filler et al., 1965; Guilleminault et al., 1984; McNicholas et al., 1983). Specifically, in patients with FD (Table 1):

a. Hypercapnia decreases the ventilatory response to progressive hypercapnia instead of increasing it, as it occurs in normal subjects.

b. Hypoxia results in little or no increase in ventilatory response, rather than the marked increase seen in normal subjects.

c. During hypoxia and hypercapnia patients with FD experience bradycardia and hypotension, with some patients experiencing convulsive syncope (frequently misdiagnosed as "grand mal seizures"), instead of tachycardia and a moderate increase in blood pressure as in normal subjects.

Studying 6 subjects with FD, Edelman and colleagues (Edelman et al., 1970) described that sudden relief of hypoxemia (e.g., with the administration of intranasal 100% O_2) was followed by complete apnea of variable duration (10–56 seconds) in 4 of the subjects, instead of only a mild decrease in ventilation (−40% in tidal volume) as in normal subjects. The apnea following the abrupt relief of hypoxia in some subjects with FD might be a consequence of cessation of the hypoxic drive from the peripheral chemoreceptors, suggesting that, at least in some patients, residual peripheral chemoreceptor function might remain.

One dramatic clinical consequence of these cardiorespiratory abnormalities is breath-holding episodes. These are relatively frequent in children with FD after crying or laughing and can result in severe hypotension, hypoxia, and decerebrate posturing before breathing resumes (Maayan et al., 2015). In addition, during respiratory infections, patients with FD have no compensatory tachypnea, and can suffer hypotension and syncope in low oxygen environments, such as high altitude, airplane travel, and underwater swimming (Kazachkov et al., 2018).

SLEEP-DISORDERED BREATHING IS ALMOST UNIVERSAL IN FD

Several studies, some performed decades ago, suggested high prevalence of sleep-disordered breathing in patients with FD (Gadoth et al., 1983; Guilleminault et al., 1984; McNicholas et al., 1983; Weese-Mayer et al., 2008). All studies had important limitations, including small sample size, inclusion of subjects before genetic confirmation of the disease was available, lack of end-tidal CO_2 (EtCO$_2$) measurements, selection bias due to inclusion of only symptomatic patients, and inclusion of either adult or pediatric patients only. To overcome

these limitations we conducted a large comprehensive study reporting the results of in-hospital polysomnography from 75 consecutive adult and pediatric patients with genetic confirmation of the *IKBKAP* mutation, performed regardless of the presence of sleep-related symptoms (Singh et al., 2018).

Overall, almost all adult (85%) and pediatric (95%) patients had some degree of sleep-disordered breathing (Singh et al., 2018). Obstructive apnea events were more frequent in adults, whereas central apnea events were more severe and frequent in children. While the number of central events decreased with advancing age, the severity of hypoventilation (average and maximum EtCO$_2$ levels) progressively worsened with age, suggesting that the mechanisms driving central events tended to have less influence as the brain matured. The amygdala and the hippocampal head are specifically involved in breathing control and the pathophysiology of central apneas (Lacuey et al., 2017). Because ELP-1 is required for the normal CNS development and is highly expressed in amygdala and hippocampus (Chaverra et al., 2017), it is possible that abnormal development and maturation of these regions may underlie the high frequency of central events during the pediatric years in FD. As these regions mature with age, central events become less frequent.

Not surprisingly, a higher apnea hypopnea index was associated with increased severity of hypoxia and hypoventilation. Importantly, in 46% of patients hypoventilation and hypercapnia occurred with no accompanying apnea (Singh et al., 2018). This finding has key clinical implications: episodes of hypercapnia not associated with apneas might be missed in polysomnography studies that do not include EtCO$_2$ monitoring. Expert consensus guidelines now recommend EtCO$_2$ monitoring in all sleep studies performed in patients with FD (Kazachkov et al., 2018).

In addition to chemoreflex failure, additional factors contribute to sleep apnea and the rapid development of hypoxemia in patients with FD. Patients have craniofacial abnormalities with large tonsils and adenoids that predispose to upper airway obstruction, and a smaller thorax and vital capacity due to a physically smaller body habitus and limited chest wall expansion caused by kyphoscoliosis. Also, if anemia is present, oxygen carrying capacity is decreased. Finally, gastro-esophageal reflux, frequently present in FD, can cause reflex laryngeal closure resulting in apnea. This laryngeal closure reflex has been implicated in the pathogenesis of sudden-infant death syndrome (Cummings, 2016; Horne, 2018), and could potentially play a role in sleep-disordered breathing in FD. These factors may contribute to prolonged apnea, as well as poor tolerance of environments with low partial pressure of oxygen, such as pressurized airplane cabins and high altitude (Kazachkov et al., 2018).

SUDDEN UNEXPECTED DEATH DURING SLEEP IS FREQUENT IN FD

The two most common causes of death in FD are sudden unexpected death during sleep (SUDS) and respiratory disorders. SUDS is defined as a sudden, unexpected, witnessed or unwitnessed, nontraumatic, and non-drowning death occurring during sleep, with or without evidence of a seizure. Until recently, the risk factors for SUDS in FD remained unidentified. In a recent study we hypothesized that the high incidence of SUDS in patients with FD was linked to the presence of respiratory abnormalities during sleep. To test this hypothesis, we

analyzed the clinical features and polysomnography findings of patients with FD who died suddenly during sleep, and compared them to age- and sex-matched patients with FD who remained alive at the time of the study.

This study was based on the New York University (NYU) FD Patient Registry, an ongoing, prospective study of the natural history of patients with FD. The study began in 1970 and contains clinical and diagnostic data, including cause of death, on 670 patients at the time of the study. Of these, 327 (49%) remained alive at the time of the study. All patients have genetic confirmation of FD; more than 99% are homozygous for the same founder mutation (6T>C change) in the *IKBKAP* gene. The majority of patients included in the Registry (above 50%) are from the United States. Patients are followed closely and seen at least once a year (Norcliffe-Kaufmann et al., 2017).

We found that the annual incidence rate of SUDS in patients with FD is 3.4 per 1000 person-year, compared to 0.5–1 per 1000 person-year of sudden unexpected death in epilepsy (SUDEP) (Tomson et al., 2008). The Registry search specifically identified 32 (14 women) patients with FD and SUDS that had undergone polysomnography in the 18-month period before death. SUDS occurred most frequently during the 2nd and 3rd decades of life (mean age at death was 29.3 ± 12.4 years old). Autopsy was available in 6 cases. All of them showed brainstem, spinal cord, and dorsal root ganglia atrophy, which are neuropathological hallmarks of FD (Cohen et al., 1955; Pearson et al., 1978). These 6 cases showed no structural cardiac pathology and no structural brain lesions. Most of them had nonspecific pulmonary congestion or focal hemorrhage, typically seen as a consequence, rather than a cause, of asphyxia.

Multivariable analysis disclosed that treatment with fludrocortisone, plasma potassium levels below 4 mEq/L, and untreated sleep apnea were factors independently associated with increased risk of SUDS in patients with FD. Conversely, treatment with nocturnal noninvasive ventilation was associated with a reduced risk of SUDS.

Taken together, these findings indicate that in patients with FD, sleep-disordered breathing with chemoreflex failure results in episodes of severe hypoxia, hypercapnia, hypotension and bradycardia. In some patients, hypokalemia is an added factor, potentially contributing to fatal cardiac arrhythmias. Supporting this hypothesis, Figure 1 shows a polysomnography tracing of a 19-year-old male with FD and severe sleep-disordered breathing. It highlights two apnea episodes. During these, O_2 decreases and $EtCO_2$ increases, but in contrast to the expected tachycardia, the heart rate decreases (R-R interval increases). Note that the moderate hypercapnia (his highest EtCO2 was 51 mmHg) and mild hypoxia (his lowest O_2 was 94%) was associated with a marked decline in heart rate from 75 of 50 bpm.

THERAPEUTIC IMPLICATIONS

Non-invasive ventilation

The finding that untreated sleep apnea and fludrocortisone are independent risk factors for SUDS in patients with FD has important therapeutic implications. Early identification of sleep abnormalities with polysomnography and implementation of non-invasive ventilation

with CPAP or BiPAP when required are now encouraged in expert consensus guidelines for the diagnosis and management of respiratory disorders in FD (Kazachkov et al., 2018).

Treatment with non-invasive ventilation may not only decrease the risk of apneas, hypopneas and sudden death during sleep but also improve daytime ventilatory responses, as we recently showed (Kaufmann et al., 2019) (Figure 2). Indeed, treatment with nocturnal non-invasive ventilation in patients with FD resulted in a marked reduction in daytime arterial pCO_2 suggesting that nocturnal non-invasive ventilation might help maintain arterial pCO_2 levels during wakefulness by, perhaps, resetting the chemoreceptor to lower pCO_2 levels.

Role of potassium

The finding that potassium levels in the low range of normality and treatment with fludrocortisone were associated with SUDS was somewhat unexpected. Fludrocortisone (9α-fluorocortisol) is a synthetic mineralocorticoid that increases renal sodium and water reabsorption, expands intravascular volume, and increases blood pressure. Fludrocortisone for the treatment of orthostatic hypotension in patients with FD became widespread in the 1990s, sometimes at very high dosages (up to 0.6 mg/day). Hypokalemia is a very frequent side effect of fludrocortisone therapy (Chobanian et al., 1979). Thus, it is likely that lower serum potassium levels in cases with SUDS were the result of fludrocortisone treatment. In the general population, hypokalemia and plasma potassium levels in the lower range of normality are independent risk factors for life-threatening arrhythmias and sudden cardiac death (Kjeldsen, 2010). Interestingly, all drugs proven to reduce mortality and morbidity rates in patients with cardiovascular disease increase plasma potassium concentration (Kjeldsen, 2010). Because specific potassium (TASK-1) channels are key components of the arterial chemoreceptors (Buckler, 2015; Trapp et al., 2008), it is tempting to hypothesize that, in patients with FD lower potassium levels may worsen chemoreceptor failure. Indeed, dysfunction of the TASK-1 receptor in mice results in attenuated cardiorespiratory responses to hypoxia (Trapp et al., 2008), a similar phenotype to that described in patients with FD.

Therefore, reduction or, when possible, discontinuation of fludrocortisone treatment are now recommended. Frequent monitoring of plasma potassium concentration during the first 2 weeks following discontinuation is recommended as some patients may develop hyperkalemia. Fludrocortisone discontinuation has other benefits, as long-term treatment with fludrocortisone is associated with target organ damage, including left ventricular hypertrophy and renal failure (Norcliffe-Kaufmann et al., 2013).

CONCLUSION

The interactions between sleep disorders and autonomic nervous system abnormalities inducing potentially fatal cardiovascular consequences are increasingly recognized in a variety of neurological disorders (Berteotti et al., 2018; Chiaro et al., 2018; Fink et al., 2018; Palma, 2018). In FD, discoveries in the last decade have defined the phenotype of the disease, characterized by deafferentation resulting in baroreflex and chemoreflex failure with a high frequency of sleep disordered breathing and SUDS (Norcliffe-Kaufmann et al., 2017; Palma et al., 2017; Singh et al., 2018). The recent identification of specific risk factors for SUDS has resulted in the widespread implementation of non-invasive ventilation and

reduction or discontinuation of fludrocortisone therapy (Palma et al., 2017). Non-invasive ventilation in FD may also have the potential of reversing daytime hypercapnia (Kaufmann et al., 2019).

A number of questions regarding the pathophysiology of sleep-disordered breathing in FD remain. Chemoreceptor failure should result in central sleep apnea, which is the phenotype in children, but not in adults with FD who have predominantly obstructive sleep apnea. Other factors, such as upper airway abnormalities or interactions between the chemoreceptor signals and upper airway regulation might be responsible and need to be studied. Airway stretch mechanosensing neurons are imprtant for maintaining normal breathing in adults. Functional ablation of mechanosensing neurons in mice abolishes Breuer-Hering reflexes, causes apnea, respiratory failure, and death (Goridis, 2017; Nonomura et al., 2017), not unlike the phenotype of FD. It is likely that mechanical signals from airway-innervating sensory neurons are also impaired in FD, but this has not been specifically studied neither in patients nor in animal models of FD (Heras-Garvin, 2017; Lefcort et al., 2017). Further investigation of the ventilatory responses during sleep in patients with FD and elucidation of the role of potassium in chemoreceptor function may prove valuable to identify novel therapeutic approaches.

Figure 1. Polysomnography of a 19-year-old patient with FD and severe sleep-disordered breathing.

The tracing shows two apnea episodes (airflow tracing flattening). During these, O_2 saturation ($SatO_2$) decrease and $EtCO_2$ increase, as expected, but the R-R interval increases, i.e., heart rate decreases (see arrows). This is in contrast to the expected tachycardia that typically accompanies hypoxia in patients with typical sleep apnea. Note that the patient had relatively moderate hypercapnia (his highest EtCO2 was 51 mmHg) and mild hypoxia (his lowest O_2 was 94%) but his heart rate declined from 75 of 50 bpm during the apneas. It is conceivable that more pronounced hypoxia and/or hypercapnia episodes could result in more severe bradycardia, arrhythmias and cardiac arrest.
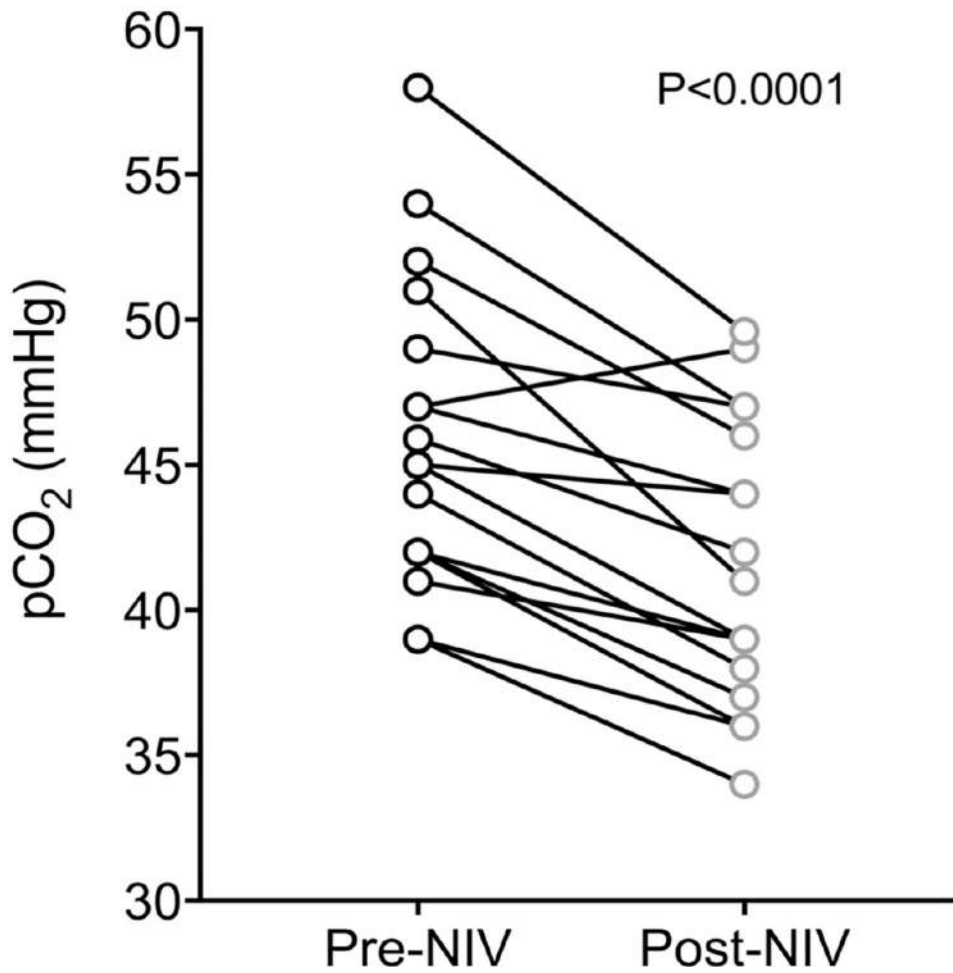

Figure 2. Arterial pCO2 concentration during wakefulness (daytime) before and during non-invasive ventilation.

Treatment with non-invasive ventilation in patients with familial dysautonomia resulted in reduced arterial pCO_2 concentration during daytime, suggesting that nocturnal use of non-invasive ventilation could reset the chemoreceptor, even during wakefulness time. Adapted from (Kaufmann et al., 2019).

Table 1.

Cardiorespiratory responses to different setups of hypoxia and hypercapnia in patients with familial dysautonomia compared to healthy subjects.

	Healthy subjects	Familial dysautonomia
Isocapnic hypoxia (Bernardi et al., 2003)	V: ↑↑ HR: ↑↑	V: = HR: =/↓
Hyperoxic hypercapnia (Bernardi et al., 2003; Edelman et al., 1970)	V: ↑↑ HR: ↑	V: ↑ HR: ↑
Hypoxic hypercapnia (Edelman et al., 1970)	V: ↑↑↑ HR: ↑↑	V: =/ ↑ HR: =

V: Ventilation; HR: heart rate; ↑: increase; ↓: decrease; =: no change.
