Abstract

In general, a moderate drying trend is observed in mid-latitude arid Central Asia since the Mid-Holocene, attributed to the progressively weakening influence of the mid-latitude Westerlies on regional climate. However, as the spatio-temporal pattern of this development and the underlying climatic mechanisms are yet not fully understood, new high-resolution paleoclimate records from this region are needed. Within this study, a sediment core from Lake Son Kol (Central Kyrgyzstan) was investigated using sedimentological, (bio)geochemical, isotopic, and palynological analyses, aiming at reconstructing regional climate development during the last 6000 years. Biogeochemical data, mainly reflecting summer moisture conditions, indicate predominantly wet conditions until 4950 cal. yr BP, succeeded by a pronounced dry interval between 4950 and 3900 cal. yr BP. In the following, a return to wet conditions and a subsequent moderate drying trend until present times are observed. This is consistent with other regional paleoclimate records and likely reflects the gradual Late Holocene diminishment of the amount of summer moisture provided by the mid-latitude Westerlies. However, climate impact of the Westerlies was apparently not only restricted to the summer season but also significant during winter as indicated by recurrent episodes of enhanced allochthonous input through snowmelt, occurring before 6000 cal. yr BP and at 5100–4350, 3450–2850, and 1900–1500 cal. yr BP. The distinct ~1500-year periodicity of these episodes of increased winter precipitation in Central Kyrgyzstan resembles similar cyclicities observed in paleoclimate records around the North Atlantic, likely indicating a hemispheric-scale climatic teleconnection and an impact of North Atlantic Oscillation (NAO) variability in Central Asia.

Introduction

Reliably assessing the ecosystem impact of future human-induced climate change requires a profound understanding of past natural climate variability. This is especially crucial in climatologically extreme areas, for example, at high altitudes, where the consequences of future global warming are expected to be most severe (Solomon et al., 2007). In this context, the Tian Shan in Central Asia is of particular interest, as it represents the headwaters for several large rivers (e.g. Syr Darya, Tarim), and future climate-induced water shortage there may affect human subsistence across large parts of western Central Asia. Furthermore, being located at the intercept between the influences of the mid-latitude Westerlies, the Siberian Anticyclone, and partly also the Asian monsoon system (Cheng et al., 2012), the region holds information about hemispheric-scale climatic teleconnections, necessary to understand the global climate system. However, although the Tian Shan is thus of key importance for climate studies and various types of natural archives, for example, speleothems (Cheng et al., 2012), tree-rings (Esper et al., 2003), or loess sequences (Machalett

Figure 1. Location of Son Kol with bathymetric map of the lake (isobaths with corresponding water depths in meters below lake level) and relief of the surrounding area (elevations in meters a.s.l.). The coring sites D/E and F are indicated by white points (at site F, a mooring with water temperature loggers was installed) and the position of the air temperature logger is marked by a white star. The relief map of Kyrgyzstan is based on the CGIAR-CSI SRTM 90 m (3 arcsec) digital elevation data (Version 4) of the NASA Shuttle Radar Topography Mission (Jarvis et al., 2008).

et al., 2008) have been analyzed in this respect so far, knowledge about Holocene climate development and particularly hydrological changes in this region is still limited. For example, a moderate drying trend due to the gradual decline of moisture supplied by the Westerlies has been inferred for mid-latitude arid Central Asia since the Mid-Holocene from lake sediment records (Chen et al., 2008). Nevertheless, this might be spatially more complex as there were apparently significant differences in past climate development between the western and eastern parts of Central Asia (Kleinen et al., 2011; Rudaya et al., 2009) owed to the interplay of different climatic systems in the region. In order to provide more detailed insights into Holocene climate development in the western part of arid Central Asia, several lake sediment records (which are particularly valuable paleoclimate archives because of the robust age control, the high temporal resolution and the variety of climate-related proxy parameters to be investigated) from NW China (An et al., 2012; Li et al., 2011; Mischke and Wünnemann, 2006; Wünnemann et al., 2006), Tajikistan (Mischke et al., 2010), Kazakhstan (Boomer et al., 2000; Huang et al., 2011; Sorrel et al., 2006), and Kyrgyzstan (Beer et al., 2007; Mathis et al., 2014; Ricketts et al., 2001) have been studied so far, but further investigations are necessary to fully disentangle the complex climatic history and interfering interplays between the different climatic systems in this region.

As a part of the project CADY (*Central Asian Climate Dynamics*), aiming at reconstructing Holocene climate development in Central Asia, a sediment core from Son Kol, a lake in the Central Kyrgyz Tian Shan, was investigated within this study. The potential of this lake for regional paleoclimate reconstructions has recently been demonstrated by Huang et al. (2012) and Mathis et al. (2014). However, as the sediment core investigated in these studies missed the last 2000 years because of coring problems, we opted for a new, more complete core and applied additional high-resolution analyses. The new sediment core, covering the last *c.*

6000 years, was investigated using sediment microfacies analysis, high-resolution μXRF element scanning and stable isotope, (bio) geochemical and pollen analyses in order to provide new, more detailed information on regional climate development since the Mid-Holocene and to shed light on climatic teleconnections, particularly the regional influence of the mid-latitude Westerlies.

Study site

Lake Son Kol (also transcribed Son Kul, Sonkul, Song-Kul) is located at 3016 m a.s.l. (above sea level) in the Central Tian Shan of Kyrgyzstan, about 80 km northwest of the town Naryn (Figure 1). The lake is at maximum ~29 km long and ~18 km wide (surface area ~273 km^2, maximum depth ~13 m) and occupies the central part of an about 60 × 30 km large high-alpine valley (catchment area ~1130 km^2), which is surrounded by the mountains of the Son Kol Too and Baidula Ranges in the north and the Boor Albas Range in the south, reaching elevations of 3800–4000 m a.s.l. (Shnitnikov, 1980). These mountain ranges are composed of Cambro-Ordovician, Carboniferous and Permian granitoids, gabbros, metamorphites, and sedimentary rocks (De Grave et al., 2011), while the extensive pasture-covered plains around the lake mainly consist of Quaternary erosion material from the mountains. Besides receiving water from groundwater inflow and precipitation on its surface, the lake is predominantly fed by rainfall and snowmelt runoff, provided by several mostly perennial tributaries. The lake is drained by a single outlet at its eastern end, which discharges into the Naryn River and finally into the Syr Darya.

The local high-alpine climate is characterized by short temperate summers and severely cold winters with snow cover between November and April. The long-term average annual air temperature is about −3.5°C, with January and July means
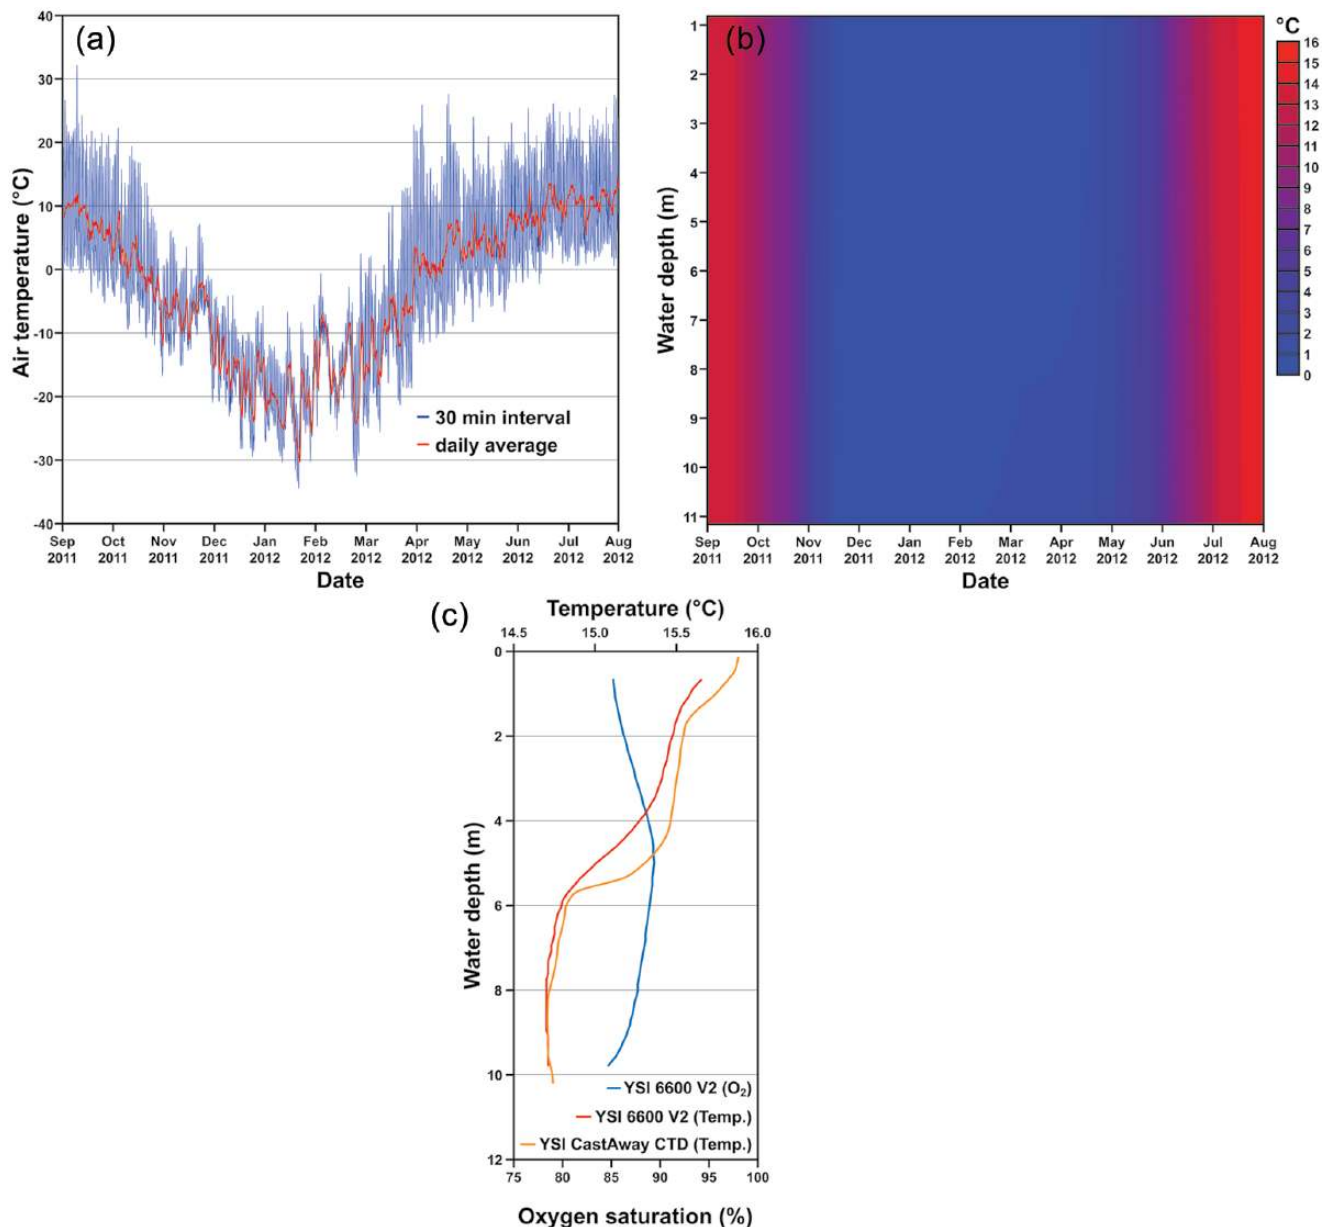

Figure 2. Results of air (a) and water temperature (b) measurements in 30-min intervals, carried out with HOBO Water Temperature Pro v2 data loggers between 1 September 2011 and 31 July 2012. Air temperature measurements were carried out 2 m above ground surface at a sun-shielded, north-facing site (Figure 1). Water temperature loggers were installed on a mooring at coring site F (Figure 1) in 1-m increments between 2 and 10 m water depth. The acquired water temperature data are displayed as a contour plot gridded with Grapher 7. Point measurements of water oxygen saturation and temperature (c) were carried out at 31 July 2012 at coring site D across the water column by using YSI 6600 V2 and YSI CastAway CTD multi-parameter water probes.

of about −20°C and 10°C, respectively (Academy of Science of the Kyrgyz SSR, 1987; Shnitnikov, 1980), which is mainly confirmed by own measurements (Figure 2a). Lake water temperature ranges between ~16°C in summer and 0–2°C in winter (ice cover usually between October and late April) with almost no vertical variations (<2°C) throughout the water column (Figure 2b and c). The precipitation regime in the Kyrgyz Tian Shan is presently mainly controlled by the interaction between the Siberian Anticyclone and the mid-latitude Westerlies (Aizen et al., 1997), the latter bringing moisture from the Aral-Caspian Basin, the Mediterranean, the Black Sea, and the North Atlantic (Aizen et al., 2006). In contrast, the Asian summer monsoon does not directly influence the region at present and most likely had only negligible impact since the Mid-Holocene (Cheng et al., 2012). Owed to orographic effects, the spatial distribution of precipitation in the region is strongly heterogeneous

(Academy of Science of the Kyrgyz SSR, 1987; Böhner, 2006) as clearly displayed by recent data: while at the Dolon Pass (41°50′24″N, 75°44′30″E, 3030 m a.s.l.), about 50 km east of Son Kol, the average annual precipitation amounts to ~400 mm (Williams and Konovalov, 2008), it is clearly higher at the lake itself (500–600 mm; Academy of Science of the Kyrgyz SSR, 1987). Most of the precipitation in the area occurs as convective rainfall during summer, driven by moist westerly air masses (Aizen et al., 2001), whereas only about 20% fall between November and March (Academy of Science of the Kyrgyz SSR, 1987) because of the blocking of the Westerlies by the Siberian Anticyclone in winter.

Owing to the high altitude and the associated extreme climate conditions, the local vegetation is characterized by montane steppe and meadow communities, dominated by Poaceae (e.g. *Festuca*), *Artemisia*, and alpine elements (e.g. *Gentiana*).
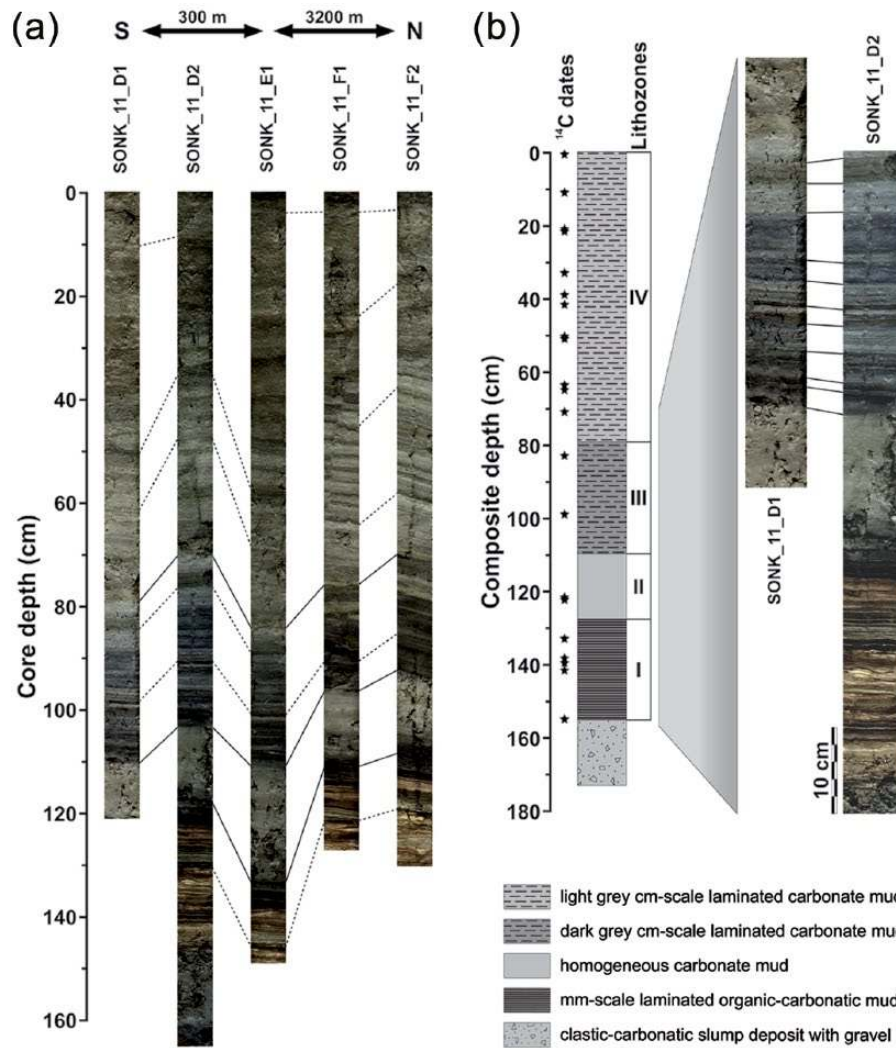

Figure 3. (a) General correlation between the five sediment cores obtained from Son Kol. Solid lines indicate boundaries of major lithostratigraphical units, dashed lines further correlation layers. For details concerning the location of the cores, see Figure 1. (b) Schematic lithological profile and corresponding lithostratigraphical units of the composite profile SONK_11_D1/2. Detail photographs of the two sediment cores SONK_11_D1 and SONK_11_D2 illustrate the close agreement between both cores and the correlation through distinct lithological marker layers.

Resulting from high grazing pressure, dwarfed individuals of most taxa and grazing-resistant species (e.g. *Leontopodium*) dominate. Local tree-stands (mainly *Picea schrenkiana*) occur only beyond the surrounding mountain ranges up to altitudes of ~3000 m a.s.l. Most of the shore areas are covered by sedge marsh (mainly *Carex* and *Kobresia*), and large parts of the lake bottom down to water depths of at least 7–8 m are covered by submerged macrophytes (e.g. *Myriophyllum*) and algae (e.g. *Chara*).

Methods

Fieldwork and sampling

Five gravity cores of about 120–165 cm length were obtained in August 2011 from three different sites in the eastern part of Son Kol (D: 41°47′38″N, 75°11′49″E, 10.5 m water depth; E: 41°47′48″N, 75°11′47″E, 11.5 m water depth; F: 41°49′31″N, 75°12′03″E, 12.5 m water depth; Figure 1) by using a 90-mm UWITEC gravity corer with additional hammer weight. Despite the large distances between the sites and likely associated spatial differences in sediment distribution within the lake basin, all cores reveal a generally similar sediment composition (Figure 3a, Supplementary Figure S1 and Table S1, available online). As the two cores from site D (SONK_11_D1 and SONK_11_D2), which is located ~2 km off a large fluvial fan at the southern lake shore (Figure 1), contained the

longest sediment sequence, a ~175-cm-long composite profile (SONK_11_D1/2) was constructed from these cores by correlating them via distinct lithological marker layers (Figure 3b). Following core opening, photographing, and lithostratigraphical description, one half of the composite profile was kept for non-destructive core-scanning analyses, while the second was subsampled for sedimentological, isotopic, (bio)geochemical, and micropaleontological analyses as well as for radiocarbon dating.

To identify the imprint of different types of organic matter (OM) in the lake sediments, several samples of terrestrial and aquatic plants, algae, and dung from different herbivores, representing the digested residue of terrestrial plant material (Supplementary Table S2, available online), were collected from the lake and its catchment during field campaigns in summer 2011 and 2012. In addition, several samples of catchment soils were taken from different depth intervals (Supplementary Table S2, available online). All samples were air-dried in the field, and soil samples were additionally sieved at 2 mm mesh size.

Sediment microfacies and geochemical/isotopic analyses

Sediment microfacies analysis was carried out on large-scale petrographic thin sections, prepared according to Brauer et al.

(1999), by using a ZEISS Axiophot polarization microscope at 25–400× magnification. High-resolution major element scanning was performed on the foil-covered fresh surface of the split sediment cores by using a vacuum-operating Itrax micro x-ray fluorescence (μXRF) core scanner (Croudace et al., 2006) equipped with a Cr x-ray tube (tube voltage 30 kV, tube current 30 mA, 200 μm resolution, 10 s exposure time, single scan line). Measured element intensities for Ti and K are reported as counts per 10 s, semi-quantitatively representing relative changes in element concentration. To further characterize the composition of the lake sediments, selected freeze-dried and homogenized samples were analyzed by x-ray diffractometry using a PANalytical Empyrean diffractometer with a Cu Kα x-ray tube operating at 40 kV and 40 mA. Diffraction data were recorded from 5° to 85° (2θ) with a continuous step width of 0.013° (60 s scan time per step) and analyzed with the Rietveld algorithm Autoquan/BGMN (Bergmann et al., 1998).

For geochemical/isotopic analyses, 0.5-cm-thick sediment slices were taken continuously from the composite profile, followed by freeze-drying and homogenization. For analysis of the total organic carbon (TOC) content and the stable carbon isotope ratio of the organic fraction ($\delta^{13}C_{org}$), 1–3 mg sediment were placed in Ag capsules, treated with 20% HCl at 75°C, and subsequently processed in a Carlo Erba NC 2500 elemental analyzer coupled to a Finnigan DELTA^{plus}XL isotope ratio mass spectrometer (IRMS). Total nitrogen (TN) content and stable nitrogen isotope ratio ($\delta^{15}N$) measurements were carried out with the same analytical facility (15–50 mg sediment in Sn capsules, no acid treatment). Geochemical and isotopic analyses of plant, soil, and dung samples were carried out in a similar manner as for the lake sediments with 10–15 mg sample material for TOC, TN, and $\delta^{15}N$ analyses and ~0.5 mg for $\delta^{13}C_{org}$ analyses being used. For all analyzed samples, the TOC and TN contents were used to calculate the atomic C/N ratio. Results of the TOC and TN analyses are expressed as percent of dry weight, while those of the $\delta^{13}C_{org}$ and $\delta^{15}N$ measurements are expressed in the conventional δ-notation relative to the Vienna PeeDee Belemnite (VPDB) and atmospheric nitrogen (AIR) standards, respectively. Based on repeated measurements of international reference standards (IAEA CH-7, N-1, N-2, USGS24), the precision of the elemental and isotopic analyses is <0.2% and <0.2‰, respectively.

Biogeochemical analyses

To determine the *n*-alkane composition of the lake sediments, 0.3–1.3 g dried and homogenized sediment (average sample increment 1–2 cm) were processed in a DIONEX ASE 200 accelerated solvent extractor, operating at 100°C and 137 bar for 15 min in two cycles and using a 9:1 (v/v) CH_2Cl_2/CH_3OH solvent mixture. HCl-activated copper was added to remove elemental sulfur. The total lipid extract was separated using solid phase extraction on silica gel (0.040–0.063 mm mesh) according to Sachse et al. (2006), and the *n*-alkane fraction was eluted with 80 mL *n*-hexane. Identification and quantification of the *n*-alkanes were accomplished using a ThermoQuest TRACE GC 2000 gas chromatograph (GC), equipped with a flame ionization detector (FID) and an Agilent Technologies DB-1MS column (30 m length, 0.25 mm ID, 0.25 μm film thickness), and comparing results with an external *n*-alkane standard mixture (*n*-C$_{10}$ to *n*-C$_{34}$). The PTV injector was operated in splitless mode with an initial temperature of 45°C for 0.1 min, then heated up with 14.5°C/s to 300°C and held there for 3 min. The GC oven was held at 90°C for 1 min, raised with 10°C/min to 300°C, held there for 9 min, and finally heated with 30°C/min to 335°C and held there for 3 min. The He carrier gas flow was held constant

at 2 mL/min. The FID was operated at 300°C and with gas flows of 40, 45, and 450 mL/min for synthetic air, H$_2$ and N$_2$, respectively.

Stable hydrogen isotope ratios of the *n*-alkane *n*-C$_{29}$ ($\delta D_{n\text{-}C29}$) were analyzed using a coupled GC-IRMS system. Samples were injected into an Agilent Technologies HP5890 Series II GC system equipped with a SGE BP1 column (60 m, 0.32 mm ID, 0.50 μm film thickness). The injector was operated at 280°C in splitless mode. The oven was maintained for 1 min at 60°C, heated with 10°C/min to 300°C, and held there for 28.5 min. The final ramp heated with 20°C/min to 340°C, where it was held for 3 min. The column flow was constant at 2 mL/min; 5% of the gas flow were transferred to a ThermoElectron GCQ ion trap mass spectrometer for identifying mass fragments and 95% went to a Finnigan DELTA^{plus}XL IRMS. $\delta D_{n\text{-}C29}$ was determined in triplicate measurements and is reported in the conventional δ-notation relative to the Vienna Standard Mean Ocean Water (VSMOW) standard. An offset calculation was accomplished using H$_2$ reference gas of known isotopic composition and correcting measured δD values ($n = 7$) of a standard mixture (*n*-C$_{10}$ to *n*-C$_{34}$). When necessary, a drift correction was applied, determined by measuring standards every third sample (Werner and Brand, 2001). The H$_{3+}$ factor was determined daily and stayed constant within the analytical error at 10.78 (SD = 1.61, $n = 19$) during the measurement period.

Pollen analyses

For pollen analyses, 1 cm^3 sediment samples were taken from the composite profile (average increment 5 cm) and prepared with HCl, KOH, HF, and hot acetolysis mixture, following standard methods (Berglund and Ralska-Jasiewiczowa, 1986). A defined quantity of *Lycopodium* spores was added to each sample to calculate the pollen concentration as pollen grains per cm^3 dry sediment (Stockmarr, 1971). Sample residues were stained with safranine and mounted in glycerine, and on average 1000 terrestrial pollen grains per sample were counted and identified using the reference collection of the Senckenberg Research Station of Quaternary Palaeontology and pollen atlases of Reille (1992) and Beug (2004). Pollen percentages were calculated based on the sum of trees/shrubs (AP) and herbs (NAP), excluding aquatics and non-pollen palynomorphs. Local pollen assemblage zones (LPAZ) were defined by constrained incremental sum of squares cluster analysis (CONISS) with the software PAST (Hammer et al., 2001).

Radiometric dating

In order to establish a chronology for the composite profile, 28 samples of organic material (plant macrofossils, shells, bulk sediment) collected from the sediments as well as a recent algae (Table 1) were dated by accelerator mass spectrometry (AMS) ^{14}C dating at the Poznań Radiocarbon Laboratory. The resulting conventional radiocarbon ages were calibrated using OxCal 4.1 (Ramsey, 1995, 2001, 2009) with the IntCal09 calibration data set (Reimer et al., 2009). To further constrain the chronology, activity measurements for the short-lived radionuclides ^{137}Cs and [241]Am were carried out on dried and homogenized sediment samples, taken continuously at 0.5-cm-steps from the uppermost 10 cm of the sediment core. Measurements were conducted by gamma spectrometry using a high-efficiency, low-background well-type germanium detector (Canberra Industries GWC 2522-7500 SL) and processed with the software GENIE 2000 3.0. Counting statistics were better than 5% for [137]Cs (661 keV) and better than 20% for [241]Am (59.5 keV), except for samples with very low activities (<0.002 Bq/g [241]Am). The measurement accuracy was validated using the standard reference materials IAEA-384 and

Table 1. AMS ^{14}C dates obtained from macrofossils and bulk sediment OM from composite profile SONK_11_D1/2. Conventional ^{14}C ages were calibrated using OxCal 4.1 (Ramsey, 1995, 2001, 2009) with the IntCal09 calibration data set (Reimer et al., 2009). Conventional ^{14}C ages obtained from aquatic material and bulk sediment OM were corrected by −150 years before calibration to consider the hardwater effect. Italicized samples were not considered for age modeling (for explanations see the results chapter).

Results

Sediment core chronology

Because of the limited number of terrestrial organic macros within the lake sediments, also several samples of aquatic material (shells, water plants, bulk sediment with unknown proportion of aquatic OM) were selected for AMS ^{14}C dating. As such material is commonly regarded to give too old radiocarbon ages because of the incorporation of dissolved, ^{14}C-depleted carbon, for example, from catchment rocks (Deevey et al., 1954; Olsson, 1986), a living deep-water algae (Poz-47591) from coring site D was dated to assess the recent hardwater effect and its possible impact on ^{14}C dates obtained from lacustrine materials. The obtained conventional radiocarbon age of 155 ± 30 ^{14}C yr BP (Table 1) shows that the recent hardwater effect is rather small, but as this might have changed through time, several cross-datings on terrestrial and aquatic samples from the same stratigraphic level in the composite profile were carried out. As a result, conventional ages obtained from aquatic material are consistently only slightly older than those from terrestrial remains with partly overlapping 2σ ranges after calibration, indicating a temporally relatively stable hardwater effect. Thus, a reservoir

correction of −150 years, inferred from the age of the recent algae, was applied prior to calibration to all conventional ages derived from samples containing aquatic material (Table 1).

According to the presence of ^{137}Cs and [241]Am within the topmost sediments, which are exclusively of anthropogenic origin and occur in the environment only since the mid-20th century onset of atmospheric nuclear weapon testing, it is clear that the composite profile SONK_11_D1/2 is, in contrast to the sediment core investigated by Mathis et al. (2014), complete even for modern times. However, further pinning down the chronology using ^{137}Cs was impossible as the record revealed the constant occurrence of ^{137}Cs down to a sediment depth of 9 cm (Figure 4) without distinct peaks attributable to the maximum of thermonuclear weapon testing in 1963 or the Chernobyl reactor accident in 1986 (Appleby, 2001), likely owed to post-sedimentary diffusion of ^{137}Cs within the soft and water-saturated surface sediments (Davis et al., 1984; Klaminder et al., 2012). Instead, precise chronological information can be gained from [241]Am, which is less mobile than ^{137}Cs and has a longer half life, making activity peaks easier detectable (Appleby et al., 1991). Accordingly, the strong [241]Am activity increase at 5.5 cm can be likely attributed to the onset of atmospheric nuclear weapon testing in 1950 at the former USSR test site Semipalatinsk, ~1000 km north of Son Kol. Alternatively, it could represent the maximum in global atmospheric nuclear weapon testing in 1958–1962, but
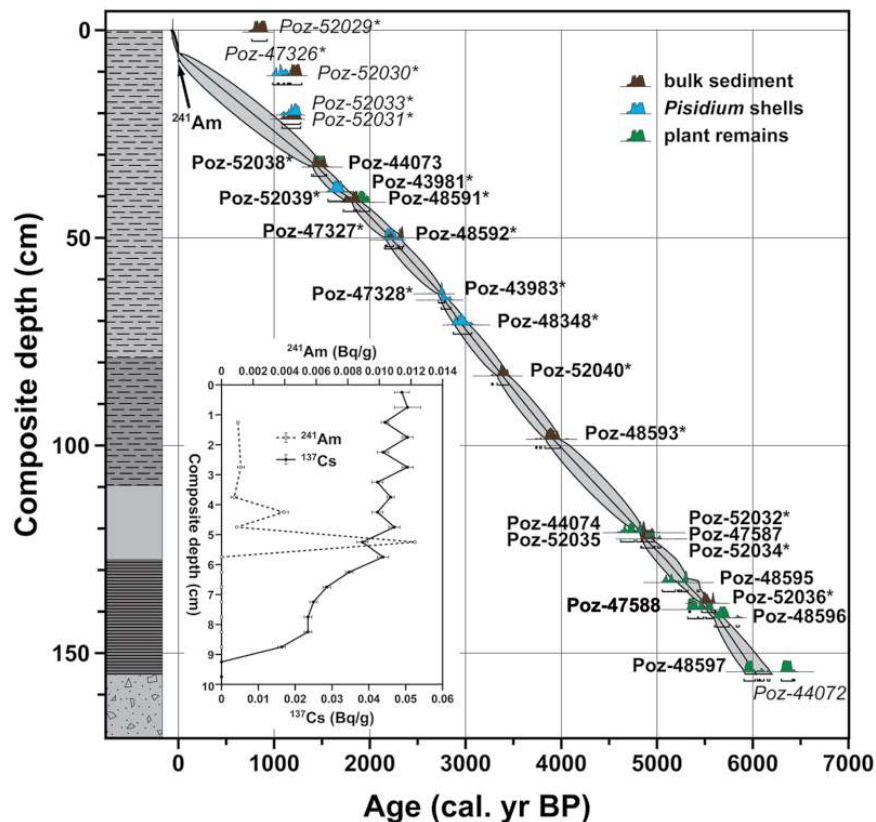

Figure 4. Age model of composite profile SONK_11_D1/2, derived from the *P_Sequence* depositional model (model parameter *k* = 2) implemented in OxCal 4.1 (Ramsey, 1995, 2001, 2008). The solid line between individual radiocarbon dates represents the age model and the gray shading represents the 2σ probability range. Individual AMS ^{14}C dates obtained from bulk sediment OM, *Pisidium nitidum* shells and terrestrial plant remains are displayed as calibrated 2σ probability functions. Aquatic samples with asterisks were corrected for the hardwater effect prior to calibration and italicized samples were omitted from the age modeling procedure (for further details see the text). The inset shows results of ^{137}Cs and ^{241}Am activity measurements on the uppermost 10 cm of the composite profile.

such detailed age information cannot be reliably inferred from ^{241}Am because of the low sedimentation rate and comparatively large sampling interval (0.5 cm).

As the five radiocarbon ages obtained from the uppermost *c.* 20 cm of the composite profile (Poz-53029, Poz-47326, Poz-53030, Poz-52033, and Poz-53031) contradict for inexplicable reasons the reliable results of ^{241}Am dating (e.g. the sediment surface dates to *c.* 750–900 cal. yr BP) and the inferred sedimentation rate development, they were rejected from age modeling. Also, one radiocarbon age from the base of the sediment sequence (Poz-44072) was rejected as it turned out to be *c.* 300 years older than that of another sample (Poz-48597) from the same stratigraphic level, most likely owed to re-deposition of the dated material. In consequence, the age model for composite profile SONK_11_D1/2 (Figure 4) was finally established using the remaining 22 corrected conventional radiocarbon ages (Table 1) as well as the chronological fix points at 5.5 cm sediment depth (first occurrence of ^{241}Am: AD 1950) and at the sediment–water interface (date of the coring campaign: AD 2011) as input parameters for a *P_Sequence* deposition model implemented in OxCal 4.1 (Ramsey, 2008). The high agreement index A_{model} of 94.2% proves the robustness of the chronology (Ramsey, 1995, 2001), which is furthermore independently constrained by pollen analyses, revealing the first appearance of (most likely long-distance-transported) *Juglans* pollen at 44.5 cm composite depth, i.e. at *c.* 2000 cal. yr BP, which is in good agreement with the reported maximum age for the Kyrgyz walnut forests (Beer et al., 2008). According to the established age model, the geochemical/isotopic and biogeochemical data are multi-decadally resolved, while the

resolution of the μXRF and pollen data is sub-annually and multi-centennially, respectively.

Microfacies and geochemical/isotopic composition of the lake sediments

The basal deposits (below 155.0 cm) in composite profile SONK_11_D1/2 are older than *c.* 6000 cal. yr BP. They consist of light gray, clay-sized endogenic carbonate mud with abundant, mostly angular sand- to gravel-sized allochthonous minerogenic detritus (quartz, feldspars, carbonates, micas) randomly scattered within the carbonate matrix, but also contain allochthonous organics, ostracod valves, and lumps of reworked micritic lake marl. Because of the chaotic sediment microfacies, this unit is interpreted as a debris flow layer. Although it was impossible to penetrate this deposit, in situ lake sediments most likely occur below (Mathis et al., 2014). Above a sharp transition at the top of this deposit, the regular pelagic sediments of composite profile SONK_11_D1/2 can be subdivided into four lithostratigraphical units (Figure 3b).

Unit I (155.0–127.5 cm/6000–5100 cal. yr BP) consists of irregularly laminated (sub-cm- to mm-scale) sediments with yellowish to light gray layers of micritic idiomorphic aragonite and calcite and brownish layers containing amorphous OM, algal material, ostracod valves, and diatom frustules. Minerogenic detritus (quartz, feldspars, micas) is abundant and randomly scattered within the sediments, reflected by strongly variable but generally high Ti and K μXRF counts (Figure 5). C/N ratios fluctuate between 8 and 10 and $\delta^{13}C_{org}$ ranges between −19‰ and −25‰, while $\delta^{15}N$ is fairly stable (3–5‰). Higher detrital contents at

**Figure 5.** Results of stable isotope and (bio)geochemical ($\delta^{13}C_{org}$, $\delta^{15}N$, C/N, Ti and K µXRF counts, total amount of n-alkanes n-C$_{17\text{-}31}$, $\delta D_{n\text{-}C29}$) analyses on the sediments of composite profile SONK_11_D1/2 from Son Kol. The black lines in the Ti and K µXRF records represent 25-point running means. Gray bars highlight intervals of increased terrestrial input after enhanced spring snowmelt.

5500–5300 cal. yr BP are paralleled by more negative $\delta^{13}C_{org}$ values (below −27‰) and positive peaks in $\delta^{15}N$ (>6‰) and C/N ratios (11–13).

Overlying unit II (127.5–109.5 cm/5100–4350 cal. yr BP) is characterized by homogenous, clay-sized light gray lake marl composed of endogenic calcite/aragonite with abundant ostracod valves but only very few amorphous OM and diatom frustules. The increased abundance of finely dispersed, silt-sized (~50 µm) minerogenic detritus is reflected by strongly elevated Ti and K µXRF counts (Figure 5). $\delta^{15}N$ values are the highest of the entire record, and two prominent peaks (up to 8–9‰) are paralleled by distinct negative $\delta^{13}C_{org}$ spikes (below −26‰). C/N ratios gradually increase from 8 to 13 within this unit.

The sediment composition of unit III (109.5–79.0 cm/4350–3250 cal. yr BP) is almost similar to unit II, but ostracod valves are less abundant and the rather dark gray lake marl reveals a gradually upward-fading sub-cm-scale light-dark lamination, owed to fluctuations in OM and carbonate contents. Although the content of finely dispersed, silt-sized minerogenic detritus is generally rather low, two short-term increases, mirrored by slightly elevated Ti and K µXRF counts, are observed at 3900–3850 and 3450–3300 cal. yr BP. C/N ratios and $\delta^{15}N$ values are in general fairly stable, but also show prominent peaks (16–20 and 6–7‰, respectively) parallel to the increases in minerogenic detritus. $\delta^{13}C_{org}$ is also rather stable, but shows distinct negative excursions (up to −31‰) synchronous to the increases in the C/N ratio, $\delta^{15}N$ values and detrital matter content.

The uppermost unit IV (79.0–0.0 cm/3250 cal. yr BP to present) consists of faintly cm-scale layered yellowish gray lake marl (aragonite and calcite) with abundant amorphous OM and frequent *Pisidium nitidum* shells. The amount of silt-sized minerogenic detritus is generally reduced, except for increases at 3250–3050, 3000–2900, 2200–2150, and 1900–1500 cal. yr BP, reflected by elevated Ti and K µXRF counts (Figure 5). Apart from two distinct peaks at 3250–3150 and 3000–2900 cal. yr BP, C/N ratios are rather stable (11–15). $\delta^{13}C_{org}$ fluctuates between −21‰ and −25‰, but shows negative spikes concomitant to the positive C/N peaks and also at 2100 cal. yr BP. $\delta^{15}N$ also reveals distinct peaks (>7‰) around 3250–3050, 3000–2850, 2250–2150, and 1900–1500 cal. yr BP.

Geochemical/isotopic composition of the catchment samples

Geochemical and isotopic compositions of modern OM samples from the lake and its catchment allow to characterize the predominant sources of lake sediment OM (Figure 6 and Supplementary Table S2, available online). Soils reveal a characteristic geochemical/isotopic signature, relatively close to that of the lake sediments. While soil $\delta^{15}N$ is slightly higher (between 5.8‰ and 12.3‰) than the average of the lake sediments, $\delta^{13}C_{org}$ (−25.4 to −23.0‰) and C/N ratios (9–14) plot in a similar range. In contrast, modern terrestrial plants show comparatively low $\delta^{15}N$ (−3.3‰ to 6.1‰) and $\delta^{13}C_{org}$ values (−21.7‰ to −29.6‰), but clearly higher C/N ratios (23–75). Animal dung is characterized by relatively narrow ranges of $\delta^{15}N$ (2.9–4.2‰) and $\delta^{13}C_{org}$ (−27.5‰ to −27.9‰) as well as C/N ratios (25–28). $\delta^{15}N$ (3.2–4.2‰) and $\delta^{13}C_{org}$ values (−24.9‰ to −28.7‰) of emerged aquatic macrophytes are on average fairly similar to those of the terrestrial vegetation, while C/N ratios are distinctly lower (15–30). Submerged aquatic macrophytes and algae reveal $\delta^{15}N$ values of −0.3‰ to 8.5‰ and relatively low C/N ratios (11–26). Overall, higher $\delta^{13}C_{org}$ values (−10.0‰ to −19.0‰) clearly separate them from other materials.

Biogeochemistry of the lake sediments

Sediments of the composite profile SONK_11_D1/2 contain n-alkanes of variable chain length (n-C$_{15}$ to n-C$_{33}$) with a clearly bimodal distribution, maximizing at n-C$_{29}$ (6.9 ± 2.8 µg/g) and n-C$_{31}$ (7.49 ± 3 µg/g). High fluctuations in the total amount of odd-numbered n-alkanes n-C$_{17\text{-}31}$ characterize lithostratigraphical unit I, while $\delta D_{n\text{-}C29}$ is strongly depleted with minimum values of about −225‰ (Figure 5). Within unit II, the total amount of n-alkanes n-C$_{17\text{-}31}$ reaches a minimum after 4950 cal. yr BP and $\delta D_{n\text{-}C29}$ shows a strong enrichment (more than −150‰). Unit III is characterized by intermediate and relatively stable amounts of n-alkanes n-C$_{17\text{-}31}$. $\delta D_{n\text{-}C29}$ is still enriched until about 3900 cal. yr BP, but reveals clearly depleted values (around −200‰) afterwards. Within unit IV, the total amount of n-alkanes n-C$_{17\text{-}31}$ shows an overall increasing trend with clear fluctuations. $\delta D_{n\text{-}C29}$ reveals a slight increase towards the top of the record from the uppermost part of unit III, superimposed by a short-term enrichment at 1650–950 cal. yr BP.
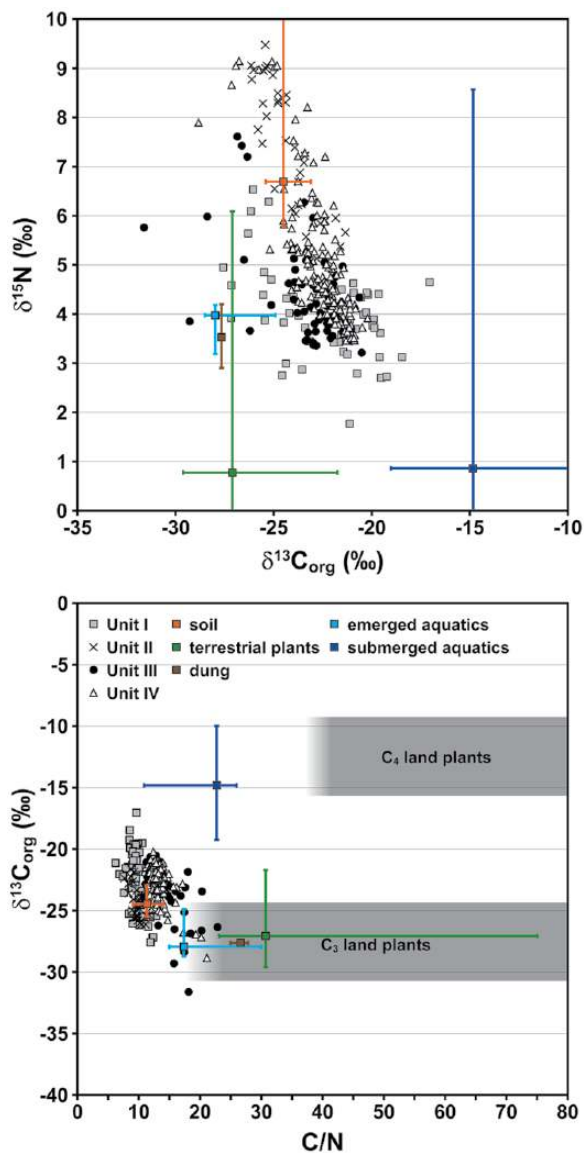

Figure 6. Geochemical and isotopic signatures ($\delta^{15}N$ vs $\delta^{13}C_{org}$ and $\delta^{13}C_{org}$ vs C/N) of the Son Kol sediments compared with those of modern organic materials collected from the lake and its catchment. The latter are given as medians (squares) with total ranges (bars). Submerged aquatics include macrophytes and algae. For detailed values, see Supplementary Table S2 (available online).

Pollen analyses

The pollen record of composite profile SONK_11_D1/2 (Figure 7) is mainly dominated by steppe communities. Local sedge marshes and alpine meadows as well as the forest stands outside the valley are clearly underrepresented; arboreal pollen (mainly *Picea, Juniperus, Betula*), which most likely derives from long-distance eolian transport, is generally below 7%. Throughout the record, pollen spectra show only small-scale changes, revealing a relatively stable ecosystem and timber line during the last 6000 years and confirming the vegetation development inferred for Son Kol by Mathis et al. (2014). The most notable feature of the record, separating LPAZ1 and LPAZ2, is the increase of *Artemisia* from about 40% to 60% at about 5000 cal. yr BP with a stable steppe community prevailing afterwards. Although the catchment is nowadays strongly influenced by livestock grazing and the presence of herding nomads in the Central Tian Shan is documented at least since the 1st millennium BC (Yablonsky, 1995), there is no indication for human impact throughout the pollen record.

Discussion

Summer moisture conditions in Central Kyrgyzstan since the Mid-Holocene

As recently shown, the δD of odd-numbered long-chain *n*-alkanes (e.g. *n*-C$_{27}$, *n*-C$_{29}$, and *n*-C$_{31}$), which are major constituents of the epicuticular waxes of higher terrestrial plants (Eglinton and Hamilton, 1967; Maffei, 1996), reflects the δD composition of precipitation during the vegetation period at a respective site, modified by changes in evapotranspiration, relative humidity, and soil moisture (Sachse et al., 2004, 2006; Smith and Freeman, 2006). As high δD values are in this respect generally considered to reflect high leaf/soil evapotranspiration and thus low humidity, whereas low values correspond to relatively wet climate conditions (e.g. Liu and Huang, 2005), the δD$_{n-C29}$ record of the Son Kol sediments can be used to infer information about past summer moisture conditions.

In general, the δD$_{n-C29}$ record confirms the previously proposed prevalence of humid conditions in mid-latitude arid Central Asia during the Mid-Holocene (at least between *c.* 6000 and 5000 cal. yr BP) and the subsequent moderate drying trend until present times, which is thought to be caused by the gradual reduction of the intensity of the mid-latitude Westerlies and thus the amount of moisture provided during summer (Chen et al., 2008). However, as there were apparently significant differences in Holocene climate development between the western (e.g. Kyrgyzstan, Kazakhstan, Tajikistan, NW China) and eastern parts (e.g. Mongolia, NE China) of Central Asia (Kleinen et al., 2011; Rudaya et al., 2009), the Son Kol record is in the following mainly compared with other records from the same climatic domain.

Depleted δD$_{n-C29}$ values between 6000 and 4950 cal. yr BP (Figure 5) reflect an episode of predominantly humid summers at Son Kol. This coincides with indication for relatively wet climate conditions until about 5000 cal. yr BP in NW China (An et al., 2012; Li et al., 2011; Mischke and Wünnemann, 2006), Kazakhstan (Boomer et al., 2000), and Kyrgyzstan (Beer et al., 2007; Mathis et al., 2014). The humid Mid-Holocene at Son Kol was followed by a pronounced dry episode between 4950 and 3900 cal. yr BP (Figure 5). This observation is in line with dry phases documented in NW China (An et al., 2012; Li et al., 2011; Mischke and Wünnemann, 2006; Wünnemann et al., 2006) and a phase of lowered lake-levels in SE Kyrgyzstan at about the same time (Beer et al., 2007), together proving the regional significance of this dry episode. Interestingly, it is not reflected in the Son Kol pollen record (this study and Mathis et al., 2014), which could be explained by the relative stability and climatic insensitivity of the local montane steppe ecosystem, indicating that critical precipitation thresholds for significant vegetation changes might not have been crossed during this interval. This interpretation is confirmed by the missing indication for this dry episode in other regional records (e.g. Boomer et al., 2000; Ricketts et al., 2001), showing that site-specific hydrological conditions, internal thresholds of the respective ecosystems, the sensitivity of the investigated climate proxies, and the temporal resolution and dating accuracy of the individual records are of crucial importance for identifying such climate fluctuations. Subsequent to the pronounced dry interval, a return to again more humid summers is observed around 3900 cal. yr BP at Son Kol, followed by a gradual but moderate drying trend until present. This broadly coincides with similar observations in NW China (Mischke and Wünnemann, 2006; Wünnemann et al., 2006), Kazakhstan (Boomer et al., 2000), Tajikistan (Mischke et al., 2010), and Kyrgyzstan (Beer et al., 2007; Mathis et al., 2014; Ricketts et al., 2001), although the timing of the onset of the drying trend and its severity at the individual sites slightly differs, which might be owed to dating uncertainties and site characteristics. However, there is also local evidence for prevailing wet or rather fluctuating climate
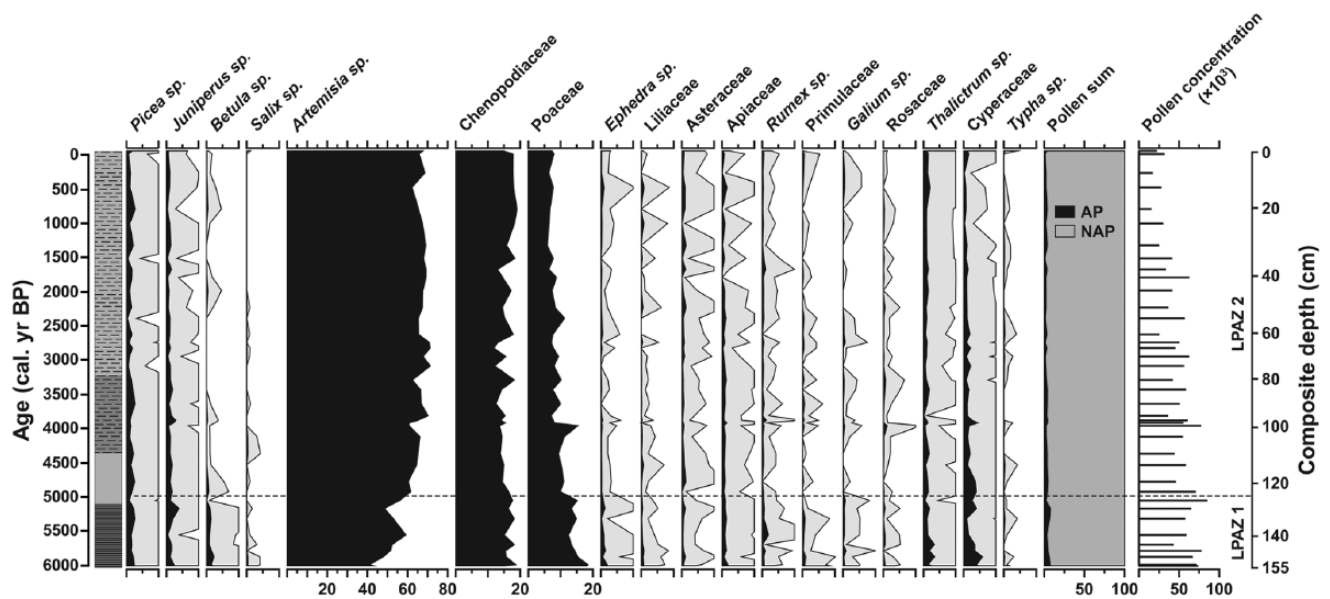

Figure 7. Pollen percentage/concentration diagram for selected taxa for composite profile SONK_11_D1/2 from Son Kol. Pollen abundances are presented as percentages of the total pollen sum (AP + NAP), excluding aquatics and non-pollen palynomorphs. Local pollen assemblage zones (LPAZ) were determined using CONISS. The outline curves represent a 10× exaggeration.

conditions during the Late Holocene in NW China (An et al., 2012; Liu et al., 2008; Rhodes et al., 1996), highlighting the spatial complexity of Late Holocene climate development in the region and the need for further investigations. Nevertheless, in summary, the overall evolution of summer moisture conditions during the last 6000 years at Son Kol with a rather wet Mid-Holocene and a subsequent moderate drying during the Late Holocene is in quite good agreement with results from other paleoclimate records in the western part of mid-latitude arid Central Asia.

Phases of increased winter precipitation and hemispheric-scale climate teleconnections

In addition to the biogeochemical data, information about past environmental and climatic changes at Son Kol can also be gained from the $\delta^{13}C_{org}$, $\delta^{15}N$ and C/N composition of lake sediment OM. Facilitated by the characteristic geochemical/isotopic signatures of the different aquatic and terrestrial organic components involved in lake sediment formation, these parameters allow to track for instance changes in environmental conditions, productivity, nutrient availability, or the origin of OM (e.g. Hodell and Schelske, 1998; Hollander et al., 1992; Talbot, 2001; Talbot and Lærdal, 2000; Teranes and Bernasconi, 2000). While $\delta^{15}N$ is in this regard a partly ambiguous proxy because of the complexity of the nitrogen cycle and the various in-lake and catchment processes and nitrogen sources involved in lake sediment OM formation (Talbot, 2001), the $\delta^{13}C_{org}$ and C/N signatures of different organic materials are relatively well known. For example, freshwater phytoplankton is commonly characterized by low $\delta^{13}C_{org}$ values (−30 to −20‰) and C/N ratios (<10), whereas C_3 terrestrial plants and aquatic macrophytes reveal low $\delta^{13}C_{org}$ values but high C/N ratios (>20), and C_4 terrestrial plants are characterized by both high $\delta^{13}C_{org}$ values (more than −15‰) and C/N ratios (e.g. Meyers and Teranes, 2001).

In general, these values are confirmed by the geochemical/isotopic signatures of modern OM samples from Son Kol and its catchment (Figure 6 and Supplementary Table S2, available online). Accordingly, Son Kol sediment OM represents a complex mixture of different sources with temporally variable contributions. However, soil and terrestrial plant OM (and partly also emerged aquatics) apparently prevail as their $\delta^{15}N$, $\delta^{13}C_{org}$, and

C/N signatures are most similar to those of the lake sediments (Figure 6). This is corroborated by the predominance of the long-chain *n*-alkanes *n*-C_{29} and *n*-C_{31} within the sediments, which derive from higher terrestrial plants (Eglinton and Hamilton, 1967; Maffei, 1996) and thus indicate a significant contribution of terrestrial material to sediment OM. Concerning the general geochemical/isotopic composition of the Son Kol sediments, the most striking feature are three distinct, multi-centennial phases of high $\delta^{15}N$ values at 5100–4350, 3450–2850, and 1900–1500 cal. yr BP as well as three short-term enrichments at 5500–5300, 3900–3850 and 2250–2200 cal. yr BP (Figure 5), which are paralleled by lowered $\delta^{13}C_{org}$ values. High $\delta^{15}N$ values in the sediments could be attributed to (1) denitrification processes in an anoxic hypolimnion during periods of pronounced meromixis (Hodell and Schelske, 1998; Talbot and Lærdal, 2000), (2) increased aquatic productivity (Gu et al., 1996; Talbot and Lærdal, 2000; Teranes and Bernasconi, 2000), (3) evaporative loss of isotopically light ammonia during dry climate conditions (Talbot and Johannessen, 1992), or (4) increased input of terrestrial OM (Haberzettl et al., 2005; Mayr et al., 2009).

However, denitrification is unlikely to have caused elevated $\delta^{15}N$ values, as there is no sedimentological indication (e.g. varves and/or pyrite formation) for hypolimnetic anoxia within the respective intervals and sediment-dwelling ostracods (e.g. *Limnocythere inopinata, Candona neglecta*) and shells, which require well-oxygenized bottom waters, are also abundant. As evidence for a significantly deeper water body (e.g. abandoned shorelines) in the past is lacking, it is likely that the lake retained its present small depth-to-surface-area ratio at least since the Mid-Holocene and was, also in consequence of the large wind fetch, always well mixed as it is today, which is indicated by a high O_2 saturation throughout the water column and almost no temperature stratification throughout the year (Figure 2b and c). Furthermore, productivity changes can also be ruled out to have triggered high $\delta^{15}N$ values as $\delta^{15}N$ and $\delta^{13}C_{org}$ are clearly anti-correlated throughout the sediment record (Figure 6), whereas the opposite is commonly regarded to reflect in-lake productivity changes (Finlay and Kendall, 2007; Hodell and Schelske, 1998; Talbot and Lærdal, 2000). Finally, also evaporative loss of isotopically light ammonia during dry climate conditions is unlikely to have caused increases in $\delta^{15}N$, as there is no clear correspondence between

high-δ^{15}N-intervals and dry episodes reflected by the $\delta D_{n\text{-}C29}$ record (Figure 5).

Hence, the only reasonable explanation for elevated δ^{15}N values in the lake sediments is input of terrestrial OM, particularly soil material. This is endorsed by the high similarity between the isotopic/geochemical signatures of the soils and lake sediment OM during high-δ^{15}N-intervals and also the parallel increases of δ^{15}N and Ti and K μXRF counts, the latter reflecting terrestrial minerogenic input (Figure 5). A similar correlation observed in lake sediments from Chile has recently also been interpreted in terms of increased soil input from the catchment (Haberzettl et al., 2005). The mechanism primarily responsible for high δ^{15}N values in soils is the enrichment of ^{15}N during the mineralization/decomposition of terrestrial OM, which is influenced by several ecosystem variables, for example, climate, vegetation, soil composition, and depth as well as microbial processes (Amundson et al., 2003; Kendall, 1998). The ^{15}N-enriched soil OM is thereby mainly bound to minerogenic components (besides occurring as dissolved organic/inorganic nitrogen), which are easily transported to the lake basin by catchment erosion processes. In this context, it should be mentioned that C/N ratios are in the case of Son Kol a rather ambiguous proxy for soil input. Although the catchment soils are characterized by elevated δ^{15}N values and relatively low C/N ratios (Figure 6 and Supplementary Table S2, available online), lake sediment C/N ratios reveal a strongly heterogeneous response during the individual intervals of increased soil input (Figure 5). This might be owed to variable contributions of plant OM with considerably higher C/N ratios (Figure 6 and Supplementary Table S2, available online) during the individual intervals of increased allochthonous input.

Concerning the transport of soil material to the lake basin, eolian supply is rather unlikely as related deposits (loess) are generally restricted to lower altitudes, i.e. the piedmont regions of the Tian Shan (Machalett et al., 2006), and grain sizes of the detrital material within the high-δ^{15}N-intervals are relatively large. Hence, soil input should be mainly related to fluvial transport processes, namely precipitation (reflecting wetter climate conditions in summer) or meltwater runoff (reflecting increased winter snowfall). As intervals of intensified terrestrial input do not explicitly correlate with phases of pronounced summer humidity but rather occur randomly during both dry and humid summer periods (indicated by high and low $\delta D_{n\text{-}C29}$ values, respectively), they are consequently most likely not associated with summer precipitation but with increased winter snowfall and enhanced meltwater supply during subsequent spring thaw. This interpretation is corroborated by own field observations, revealing the perennial creeks around Son Kol almost completely desiccated during summer, although this is presently the season with the highest precipitation. Nevertheless, it should be mentioned that enhanced snowmelt and thus meltwater runoff might also be caused by increased temperatures, but since no explicitly temperature-related proxy data are available from the Son Kol sediments, this option remains speculative.

Considering also the basal debris flow in composite profile SONK_11_D1/2 as a meltwater-related deposit, distinct phases of enhanced winter precipitation in Central Kyrgyzstan occurred before *c.* 6000 and at 5100–4350, 3450–2850, and 1900–1500 cal. yr BP with an intriguing recurrence interval of ~1500 years. This closely matches a prominent low-frequency millennial-scale climate cyclicity of about 1500–1600 years observed in drift ice transport (Bond et al., 1997), ocean temperature conditions, and strength of the thermohaline circulation in the North Atlantic (Bianchi and McCave, 1999; Thornalley et al., 2009), but also in many other Northern Hemisphere paleoclimate records (Wanner et al., 2008). As recently shown, this cyclicity is not triggered by solar activity changes (Debret et al., 2007; Sorrel et al., 2012) but

rather related to an ocean-internal variability of conveyor strength (Bianchi and McCave, 1999). As processes in the ocean are closely coupled to changes in atmospheric conditions in the North Atlantic realm, namely, the intensity of the mid-latitude westerly jet stream, similar periodicities are also apparent in wind strength in Iceland (Jackson et al., 2005) and storm activity in northern France (Sorrel et al., 2009), as well as in the amount of winter precipitation in southwestern Norway (Bjune et al., 2005) and the western Mediterranean (Fletcher et al., 2012). Since moisture supply to Central Kyrgyzstan is mainly controlled by the strength of the mid-latitude Westerlies (Aizen et al., 1997; Böhner, 2006), changes in their intensity observed in the North Atlantic realm should consequently also influence climate conditions at Son Kol. Indeed, snow-rich episodes in Central Kyrgyzstan reveal a close correspondence with millennial-scale increases in wind strength in Iceland (Jackson et al., 2005) and winter precipitation in southwestern Norway (Bjune et al., 2005), reflecting episodic intensifications of westerly atmospheric flow at high northern latitudes (Figure 8), as well as with the occurrence of drier winters and thus reduced westerly flow at lower latitudes, for example, in the western Mediterranean (Fletcher et al., 2012). This latitudinal pattern is characteristic for the present-day positive mode of the North Atlantic Oscillation (NAO; Hurrell, 1995), and it thus appears that enhanced winter precipitation in the Central Tian Shan is closely coupled to a strengthening of the Westerlies during positive NAO phases. In this context, the apparent discrepancy of weakened Westerlies in the western Mediterranean but enhanced westerly flow at about the same latitude in Central Asia might be explained by a longitudinally contrasting precipitation pattern: as indicated by data reanalysis and modeling studies, the southeastern Mediterranean (Black, 2012; Dünkeloh and Jacobeit, 2003) and western Central Asia (Syed et al., 2006, 2010) experience increased winter precipitation during positive NAO phases, while the western Mediterranean remains rather dry at these times (Fletcher et al., 2012). Hence, the ~1500-year cyclicity observed in snowfall intensity at Son Kol provides strong evidence for a significant impact of millennial-scale North Atlantic climate variability and particularly the NAO on winter precipitation conditions in Central Asia since the Mid-Holocene, a relation so far not shown for western Central Asia on longer timescales. However, as the relation between increased winter precipitation in the Tian Shan and NAO variability is still controversially debated (Aizen et al., 2001) and since also other remote influences on regional winter precipitation variability may exist (e.g. Syed et al., 2010), further studies are necessary to test the results from Son Kol and to fully understand the teleconnections exerting influence on winter precipitation variability in the western part of Central Asia.

Conclusion

Multi-proxy analyses of lake sediments from Son Kol (Central Kyrgyzstan) provide evidence for a predominant influence of the mid-latitude Westerlies on Holocene moisture evolution in this region. Following a wet Mid-Holocene and a pronounced dry phase between 4950 and 3900 cal. yr BP, a progressive but only moderate reduction of summer precipitation is observed during the Late Holocene, being in accordance with results from other regional paleoclimate records and mainly attributable to the gradually weakening influence of the Westerlies in mid-latitude arid Central Asia throughout the Holocene. However, changes in the intensity of the Westerlies, which are directly related to climate variability in the North Atlantic realm, apparently did not only influence summer precipitation patterns but also had a substantial impact on winter climate conditions in mid-latitude arid Central Asia. This is indicated by periods of enhanced detrital input through snowmelt, reflecting increased winter snowfall brought by the Westerlies, which occurred with a distinct periodicity of ~1500
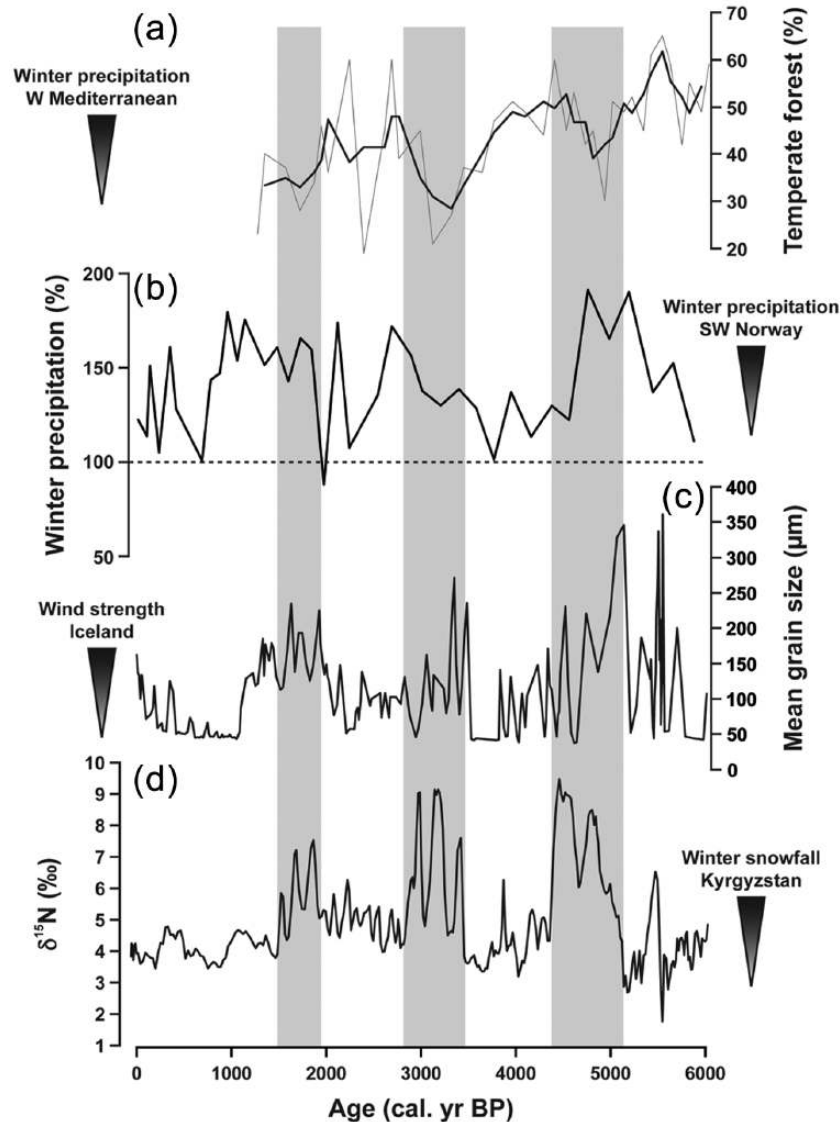

Figure 8. Hemispheric-scale comparison of climate records reflecting changes in the intensity of the wintertime Westerlies. (a) Changes in forest composition (percentage of temperate forest taxa) in the western Mediterranean as a proxy for winter precipitation (Fletcher et al., 2012). The gray line represents the original data, while the black line is a 3-point running mean. (b) Reconstructed amount of winter precipitation in southwestern Norway compared with the present-day level (100%; Bjune et al., 2005). (c) Mean grain size of loess as a proxy for wind strength on Iceland (Jackson et al., 2005). (d) $\delta^{15}N$ of Son Kol sediments as a proxy for meltwater-derived input of soil material and thus snowfall intensity in Central Kyrgyzstan.

years. Synchronous low-frequency millennial-scale climate oscillations, attributed to changes in the strength and position of the westerly jet stream, have also been observed in several paleoclimate records in the North Atlantic realm, revealing a significant hemispheric-scale teleconnection between the North Atlantic and the Central Asian climate system and a possible impact of NAO variability on winter precipitation in the Central Tian Shan. However, understanding the underlying climatic mechanisms in full detail requires further investigations and more high-resolution paleoclimate records from the climatically sensitive region of mid-latitude Central Asia.
