ABSTRACT A new discovery of lawsonite eclogite is presented from the Lancône glaucophanites within the Schistes Lustrés nappe at Défilé du Lancône in Alpine Corsica. The fine-grained eclogitized pillow lava and inter-pillow matrix are extremely fresh, showing very little evidence of retrograde alteration. Peak assemblages in both the massive pillows and weakly foliated inter-pillow matrix consist of zoned idiomorphic Mg-poor (<0.8 wt% MgO) garnet + omphacite + lawsonite + chlorite + titanite. A local overprint by the lower grade assemblage glaucophane + albite with partial resorption of omphacite and garnet is locally observed. Garnet porphyroblasts in the massive pillows are Mn rich, and show a regular prograde growth-type zoning with a Mn-rich core. In the inter-pillow matrix garnet is less manganiferous, and shows a mutual variation in Ca and Fe with Fe enrichment toward the rim. Some garnet from this rock type shows complex zoning patterns indicating a coalescence of several smaller crystallites. Matrix omphacite in both rock types is zoned with a rimward increase in X_{Jd} , locally with cores of relict augite. Numerous inclusions of clinopyroxene, lawsonite, chlorite and titanite are encapsulated within garnet in both rock types, and albite, quartz and hornblende are also found included in garnet from the inter-pillow matrix. Inclusions of clinopyroxene commonly have augitic cores and omphacitic rims. The inter-pillow matrix contains cross-cutting omphacite-rich veinlets with zoned omphacite, Si-rich phengite (Si = 3.54 apfu), ferroglaucophane, actinolite and hematite. These veinlets are seen fracturing idiomorphic garnet, apparently without any secondary effects. Pseudosections of matrix compositions for the massive pillows, the inter-pillow matrix and the cross-cutting veinlets indicate similar P – T conditions with maximum pressures of 1.9–2.6 GPa at temperatures of 335–420 °C. The inclusion suite found in garnet from the inter-pillow matrix apparently formed at pressures below 0.6–0.7 GPa. Retrogression during initial decompression of the studied rocks is only very local. Late veinlets of albite + glaucophane, without breakdown of lawsonite, indicate that the rocks remained in a cold environment during exhumation, resulting in a hairpin-shaped P – T path.

Key words: Alpine orogeny; cold subduction; Corsica; lawsonite eclogite.

INTRODUCTION

Lawsonite eclogite and blueschist are expected to be the dominant lithologies forming during subduction of oceanic crust and should therefore be fairly abundant within the Earth's crust and particularly common in exhumed subduction complexes. However, lawsonite eclogite is rare and has been described only from a few localities worldwide (e.g. McBirney *et al.*, 1967; Watson & Morton, 1969; Krogh, 1982; Caron & Péquignot, 1986; Oh *et al.*, 1991; Ghent *et al.*, 1993, 2009; Shibakusa & Maekawa, 1997; Parkinson *et al.*, 1998; Carswell *et al.*, 2003; Och *et al.*, 2003; Usui *et al.*, 2003, 2006; Altherr *et al.*, 2004; Harlow *et al.*, 2004; Mattinson *et al.*, 2004; Tsujimori *et al.*, 2005, 2006a,b; Davis & Whitney, 2006; Zhang & Meng, 2006; Zhang *et al.*, 2007). Altherr *et al.* (2004) and

Zack *et al.* (2004) discussed the paucity of known lawsonite eclogite complexes, which they related to the following two factors: (i) in 'normal' subduction settings lawsonite eclogite enters the subduction factory and hence is usually not exhumed (Agard *et al.*, 2002), and (ii) in accretionary wedges where the P – T path leaves the stability field of lawsonite eclogite due to heating, lawsonite eclogite is only preserved if the exhumation path is constrained to a narrow window where the terminal stability of lawsonite is not crossed. Whitney & Davis (2006) suggested, based on observations from Sivrihisar, Turkey, that pristine lawsonite eclogite pods may represent rocks that were not deformed during exhumation. Tsujimori *et al.* (2006c) have used changes in inclusion mineralogy within garnet to distinguish between two types of lawsonite eclogite: L-type and E-type. L-type lawsonite eclogite

contains garnet porphyroblasts that grew only within the lawsonite stability field, whereas the E-type lawsonite eclogite records maximum temperatures in the epidote stability field (Tsujimori *et al.*, 2006c).

This paper presents data on eclogitized pillow lava and inter-pillow matrix from a new lawsonite eclogite locality in Corsica – Défilé du Lancône – showing evidence of very cold subduction-related prograde metamorphism.

GEOLOGICAL SETTING

The island of Corsica was isolated from the main European continent and from Italy during the opening of the Liguro-Provençal basin and the northern Tyr-

renian Sea, two back-arc basins of the central Mediterranean (Rehault *et al.*, 1984; Sartori *et al.*, 1987; Jolivet *et al.*, 1998). Despite significant deformation during this Oligocene extensional episode (Jolivet *et al.*, 1991), evidence for early Alpine evolution that started in the Late Cretaceous and ended in the Early Oligocene is well preserved (Mattaueur *et al.*, 1981; Durand Delga, 1984; Fournier *et al.*, 1991; Caron, 1994; Brunet *et al.*, 2000). The north-eastern part of Corsica (Figs 1 & 2) is mainly made up of “Schistes Lustrés”, which have undergone an Alpine HPLT metamorphism of glaucophane–lawsonite type (Caron & Péquignot, 1986). The Schistes Lustrés nappe complex consists of several thrust sheets folded and faulted in the late Cap Corse–Castagniccia antiform (Figs 1 & 2). Eclogite and

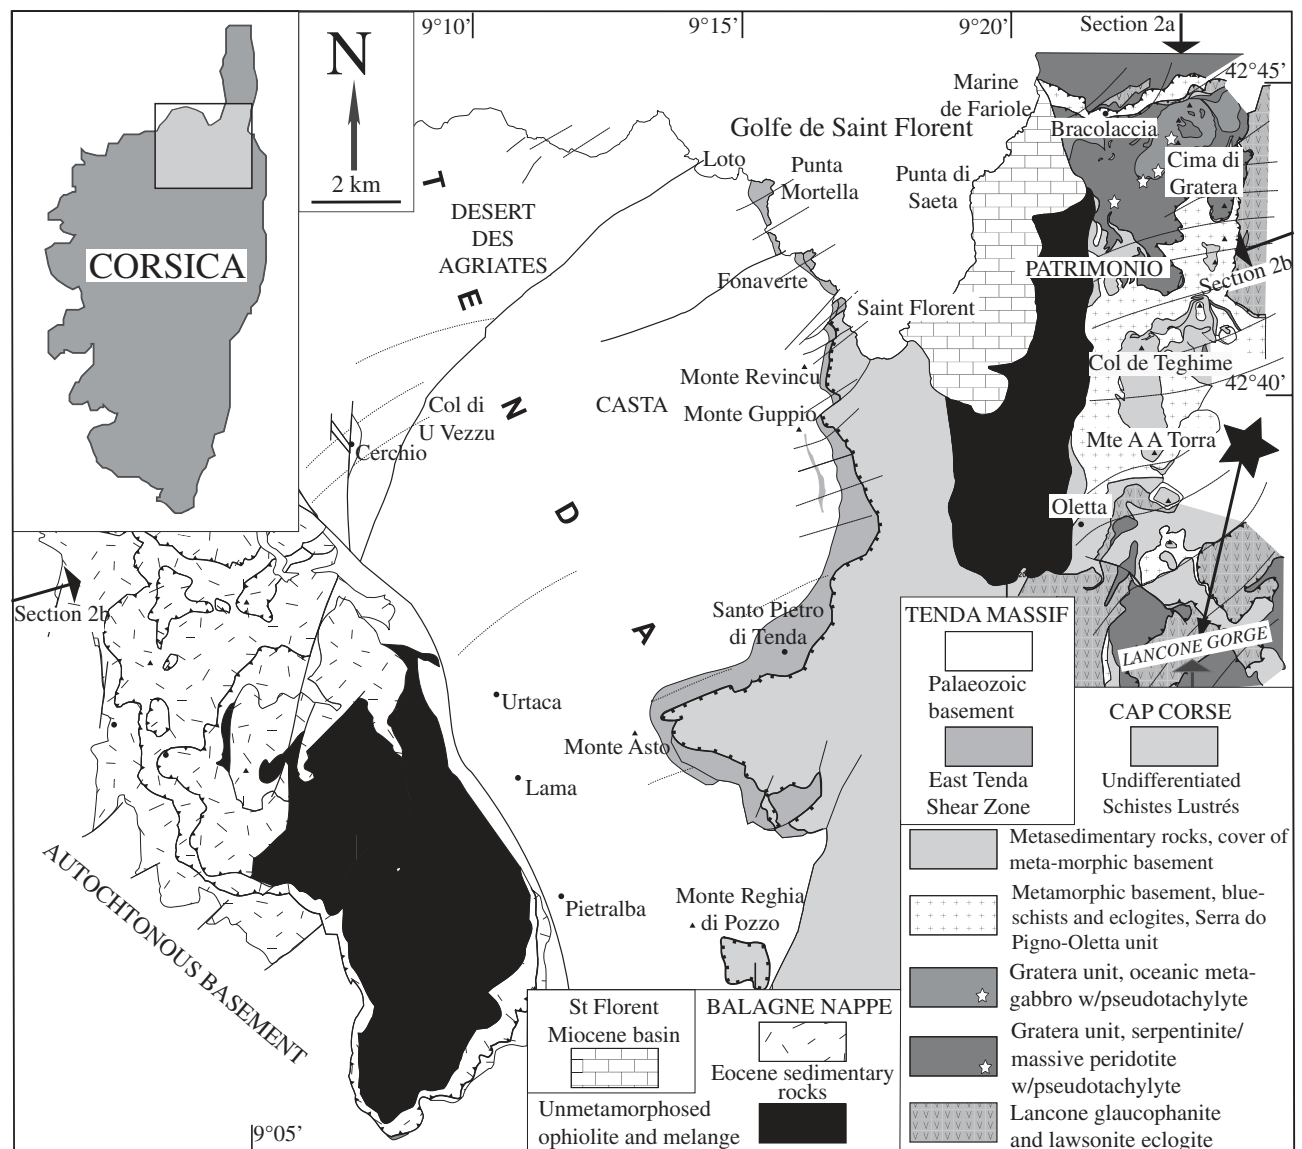

Fig. 1. Geological map of northern Corsica (see inset map for location) showing the main Alpine tectonic units and location of the new lawsonite eclogite locality in Défilé du Lancône (marked with star). Notice the location of subduction-related pseudotachylytes north of Patrimonio.

Fig. 2. N–S (a) and E–W (b) cross-sections of northern Corsica (modified from Jolivet *et al.*, 1998) showing the main tectonic units and the locations of blueschist to eclogite facies pseudotachylytes and the eclogite facies rocks in the area. Notice that the Défilé du Lancône lawsonite eclogite locality is positioned at a low structural level.

blueschist occur within both the lower ophiolitic unit and within nappes originating from the Hercynian continental basement (Lahondere, 1988). The Schistes Lustrés nappe is thrust on a large sheet of metamorphosed continental basement, the Tenda massif, where intermediate pressure blueschist parageneses have been described (Tribuzio & Giacomini, 2002; Molli *et al.*, 2006). All syn-high-pressure kinematic indicators show a top-to-the-west shear sense compatible with the underthrusting of the European basement below the oceanic nappes (Mattauer *et al.*, 1981; Fournier *et al.*, 1991). The age of the HPLT metamorphism is controversial, but $^{40}\text{Ar}/^{39}\text{Ar}$ dating of phengite indicates *c.* 65 Ma for the eclogitic stage and a subsequent major blueschist event from ~ 45 Ma until 37–35 Ma in the Cap Corse and Tenda massif (Brunet *et al.*, 2000). Older ages, between 80 and 60 Ma, are associated with the eclogitic stage (Brunet *et al.*, 2000). The overall history of HPLT metamorphism in Corsica is thus quite similar to that of the Alps both in terms of *P–T* conditions and timing (Agard *et al.*, 2002).

The Balagne nappe is the uppermost tectonic unit of the metamorphic complex and also overlies the autochthonous Hercynian basement and its cover (Fig. 1). The nappe, which occurs as two klippen, comprises a large sheet of pillow lavas in the west (Balagne ophiolite) and a mélange correlated with the Ligurian domain south of St Florent. Both of these klippen lack HPLT metamorphic rocks. The Balagne nappe was emplaced during the Eocene as attested by the presence of olistoliths in the Eocene foreland basin occurring just below the basalts (Egal, 1992).

Lawsonite eclogite has previously been described from Corsica in the Monte San Petrone Complex, further south in the Castagniccia antiform, within a meta-ophiolitic thrust-sheet consisting of serpentized peridotite, Fe–Ti-rich and Mg–Cr-rich metagabbro, tholeiitic metabasalt and metasedimentary rocks including manganiferous metachert (Lardeaux *et al.*, 1986). In the field, the Monte San Petrone eclogite

occurs as lenses within a glaucophane schist matrix (Péquignot *et al.*, 1984). The eclogite consists of almandine-rich garnet + omphacite + phengite + glaucophane + lawsonite + quartz + titanite + opaques (Caron *et al.*, 1981; Caron & Péquignot, 1986; Lardeaux *et al.*, 1986), and a temperature of 400–450 °C at 1.0 GPa was estimated by Lardeaux *et al.* (1986). However, a recalculation of the garnet–clinopyroxene–phengite data of Caron & Péquignot (1986) using the garnet–clinopyroxene thermometer (Ravna, 2000) and the garnet–clinopyroxene–phengite barometer (Ravna & Terry, 2004) gives ~ 390 °C at 2.05 GPa.

In Défilé du Lancône (Fig. 1) blueschist of the Lower Ophiolitic unit outcrops (Fournier *et al.*, 1991). This is the best-exposed section through the lower glaucophanite unit, which is composed of several sheets of massive basalt, pillow breccia and pillow lava. The main foliation is folded in a broad antiform, and a NE–SW-stretching lineation defined by the elongation of pillows and pillow fragments is observed throughout the section. Syn-high-pressure kinematic indicators consistently indicate top-to-the-SW shear during the formation of the blueschist foliation that, until the discovery of the lawsonite eclogite, was thought to represent peak pressure conditions (Jolivet *et al.*, 1991). At this locality, variably deformed pillow lava and hyaloclastite breccia consisting of glaucophane + epidote + titanite \pm garnet \pm lawsonite is common within a late foliation of chlorite + albite \pm actinolite \pm quartz (Fournier *et al.*, 1991), who estimated a minimum *P–T* of 1.1 GPa and 400 °C for the glaucophane assemblage.

Well-preserved pillow breccia and pillow lava, the latter locally with preserved drain-out cavities, occur along the riverbed in Défilé du Lancône, immediately downstream from the water reservoir (Fig. 3a). Massive green-coloured fine-grained cores of the pillows are metamorphosed to low-temperature eclogite. The longest dimension of the eclogitized pillows ranges from 10 to 40 cm (Fig. 3a), and they consist of a green,

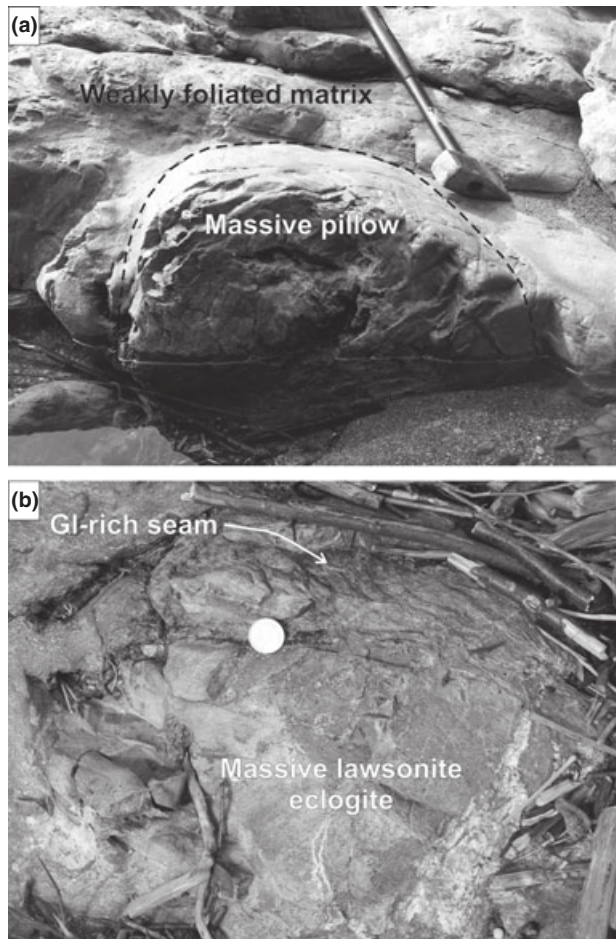

Fig. 3. Eclogitized pillow lava along the riverbed of Défilé du Lancône. (a) A well-preserved pillow with internal drain-out, convex upward cavity. Notice that the pillows have blue outer margins due to the superimposed blueschist facies metamorphism. (b) Details of a massive eclogitized pillow with a thin seam of glaucophanite.

very fine-grained massive rock with tiny euhedral garnet evenly distributed throughout. Locally, somewhat coarser grained, weakly foliated zones with aggregates of white mica form matrix material between pillows and pillow fragments. Seams of glaucophane-rich material are locally present, especially in the deformed pillows and meta-hyaloclastite, the latter occurring between the pillows and fragmented pillows and along pillow margins (Fig. 3b).

ANALYTICAL PROCEDURES

Mineral analyses were performed by electron microprobe (Cameca SX-100) at Dionýz Štúr Institute of Geology in Bratislava. Analytical conditions for the EMPA were 15 kV accelerating voltage and 20 nA beam current, with a peak counting time of 20 s and a beam diameter of 2–10 μm . Raw counts were corrected using a PAP routine. Mineral standards (Si, Ca: wollastonite; Na: albite; K: orthoclase; Fe: fayalite, Mn:

rhodonite), pure element oxides (TiO₂, Al₂O₃, Cr₂O₃ and MgO) were used for calibration. Supplementary analyses were performed using a JEOL-840 Scanning Electron Microscope with an EDAX unit at the Department of Medical Biology, University of Tromsø. The ZAF matrix correction and optimized SEC factors using various natural standards were used. Counting time was 200 s with an accelerating voltage of 20 kV and a sample current of 6 nA. Totals of anhydrous minerals are normalized to 100.0 wt%, amphibole to 98.0% and chlorite to 86.0 wt%.

Garnet formulae are normalized to 12 oxygen and clinopyroxene to four cations, with Fe³⁺ calculated by charge balance (Droop, 1987). Phengite is normalized to 11 oxygen, chlorite to 28 oxygen, and lawsonite and titanite to eight and five oxygen respectively. Amphibole analyses were normalized according to the scheme recommended by the IMA (Leake *et al.*, 1997), using the spreadsheet AMPH-CLASS (Esawi, 2004). Selected mineral analyses are given in Tables 1–3.

PETROGRAPHY AND MINERAL CHEMISTRY

The massive pillows generally consist of very fine-grained eclogite (Fig. 3). Of 10 samples, three representative samples were chosen for our investigation. Samples from massive pillows and the weakly foliated phengite-bearing layers are described, and mineral analyses of principal minerals from three samples are presented. Samples COR-1 and COR-1' are from a massive pillow fragment, whereas samples COR-4 are from the weakly foliated variety. Sample COR-1 is from the core and COR-1' from the faint bluish margin of the same pillow fragment.

Both the massive eclogite (Fig. 4a) and the foliated variety (Fig. 4b) have small idiomorphic garnet (5 modal %; up to 200 μm across) set in a matrix of omphacite (55–60 modal %; up to $70 \times 200 \mu\text{m}$ across), lathlike lawsonite (20–30 modal %; up to $20 \times 300 \mu\text{m}^2$ across), chlorite (7–15%) and titanite (3–5%). Calcite occurs in tiny veinlets. In the foliated inter-pillow matrix, cross-cutting veinlets consisting of omphacite (80%), phengite (15%) with minor glaucophane (< 5%) and hematite is common (Fig. 4d–g). Locally, these veinlets also cross-cut fractured garnet (Fig. 4f), but there does not seem to be any resorption of garnet in contact with the veins. Garnet commonly contains numerous solid inclusions. Inclusions of lawsonite, chlorite, titanite and clinopyroxene are present in all samples (Fig. 4a–c). In addition, inclusions of albite, hornblende and quartz are found in garnet in the foliated rock. Glaucophane has been found as a secondary matrix phase in the marginal part of the massive pillow fragment (sample COR-1') where it occurs together with albite against slightly resorbed garnet (Fig. 4g). In the massive eclogite, omphacite and lawsonite are randomly oriented (Fig. 4a). In foliated eclogite matrix omphacite and lawsonite show a weak preferred orientation.

Garnet

Garnet is rich in almandine, grossular and spessartine, and low in pyrope (Table 1), similar to that described by Caron *et al.* (1981). It is chemically zoned, in sample COR-1 ranging from $\text{Gr}_{29}\text{Sp}_{27}\text{Alm}_{42}\text{Py}_2$ (core) to $\text{Gr}_{33}\text{Sp}_{15}\text{Alm}_{49}\text{Py}_3$ (rim). Garnet in sample COR-4 is more Ca- and Fe-rich and lower in Mn, ranging from $\text{Gr}_{44}\text{Sp}_6\text{Alm}_{49}\text{Py}_2$ (core) to $\text{Gr}_{32}\text{Sp}_8\text{Alm}_{59}\text{Py}_2$ (rim). Zoning profiles appear to be continuous in both samples (Fig. 5a,b), except for some irregularly zoned garnet from COR-4 (Fig. 4b).

Clinopyroxene

Clinopyroxene analyses are recalculated to four cations and six oxygen with estimation of Fe^{3+} by charge balance (Droop, 1987). Clinopyroxene in the studied samples shows a large compositional variation (Table 2; Fig. 6). Generally, clinopyroxene inclusions in garnet are less sodic than the matrix omphacite in all samples. Low-Na and Al–Ti-rich clinopyroxene (augite) with up to 4.6 wt% Al_2O_3 and 3.95 wt% TiO_2 occurs as cores of inclusions in all samples, commonly

mantled and rimmed by successively more jadeite-rich omphacite (Fig. 4c; Table 2). Matrix clinopyroxene is also zoned with augitic cores and increasing jadeite content toward the rim. Omphacite in the cross-cutting veinlets in sample COR-4 have distinctly lower Mg # (46.7–55.4) than those in the matrix (63.2–70.8). They also show an opposite rimward zoning from $\text{Jd}_{23}\text{Aeg}_{21}$ (Mg# = 55) to $\text{Jd}_{11}\text{Aeg}_{14}$ (Mg# = 47).

Other minerals

Phengite in the cross-cutting veins of sample COR-4 is virtually unzoned, with a Si-content of 3.56 apfu based on 11 oxygen and Mg# = 66 assuming all Fe as Fe^{2+} (Table 3). Lawsonite has Fe_2O_3 content in the range 0.50–1.18%, inclusions in garnet having the lower values. Chlorite is present as inclusions in garnet and as a matrix phase, with Mg# ranging from 65 (inclusion in garnet) to 68 (matrix) in COR-1, and Mg# = 50 in COR-4. Titanite is relatively Al-poor ($X_{\text{Al}} = 0.04$). Albite included in garnet in sample COR-4 and as a secondary matrix phase in sample COR-1' is relatively pure (Ab_{97} and Ab_{100} respectively). Small inclusions of edenitic hornblende with $\text{Ca}_B = 1.70$, $(\text{Na} + \text{K})_A = 0.51$, $\text{Fe}^{3+}/(\text{Fe}^{3+} + \text{Al}) = 0.24$ and Mg# = 60 were identified in the core of a garnet in sample COR-4. Blue amphibole occurring in the omphacite-rich veins in sample COR-4 has $\text{Fe}^{3+}/(\text{Fe}^{3+} + \text{Al}) = 0.21$ and Mg# = 48, and is classified as ferroglaucophane. Secondary blue amphibole associated with albite in sample COR-1' is glaucophane with $\text{Fe}^{3+}/(\text{Fe}^{3+} + \text{Al}) = 0.00$ and Mg# = 62.

METAMORPHIC EVOLUTION AND CONDITIONS

Pre-metamorphic relics (0)

Ca–Al–Ti-rich cores (augite) of clinopyroxene inclusions in garnet and in the matrix most likely represent relict magmatic pyroxene crystallized from the basaltic precursor. Similar compositions are reported from relict magmatic cores of porphyroblastic Na-pyroxene in eclogitic metabasites from Sivrihisar in the Tavsanlı Zone, Turkey (Çetinkaplan *et al.*, 2008).

Pre-eclogitic metamorphic stages (I)

The earliest metamorphic minerals recorded in the lawsonite eclogite from Défilé du Lancône are found as

Fig. 4. (a) Massive lawsonite eclogite with euhedral garnet in a matrix of randomly oriented omphacite and lawsonite (light grey laths). Sample COR-1. (b) BSE image of euhedral garnet showing complex compositional variation due to reciprocal concentrations of Fe and Ca. Areas with dark grey colour have lower Fe/Ca ratio. Dark inclusions are mainly omphacite and lawsonite. Sample COR-4. (c) BSE image of euhedral garnet with numerous inclusions of augite, omphacite, albite, chlorite and quartz. Matrix consists of omphacite, lawsonite and minor titanite. Sample COR-4. (d) BSE image of euhedral garnet with inclusions of lawsonite and augite overgrown by omphacite. Matrix consists of omphacite, lawsonite and minor titanite. Sample COR-1. (e) Veinlets of omphacite + phengite + minor glaucophane cross-cutting the weakly foliated matrix of sample COR-4. (f) Details of omphacite-rich veinlet with phengite and glaucophane. Sample COR-4. (g) Omphacite-rich veinlet cross-cutting a fractured garnet. Sample COR-4. (f) Incipient retrogression with secondary glaucophane and albite and partly resorption of garnet. Sample COR-1'.

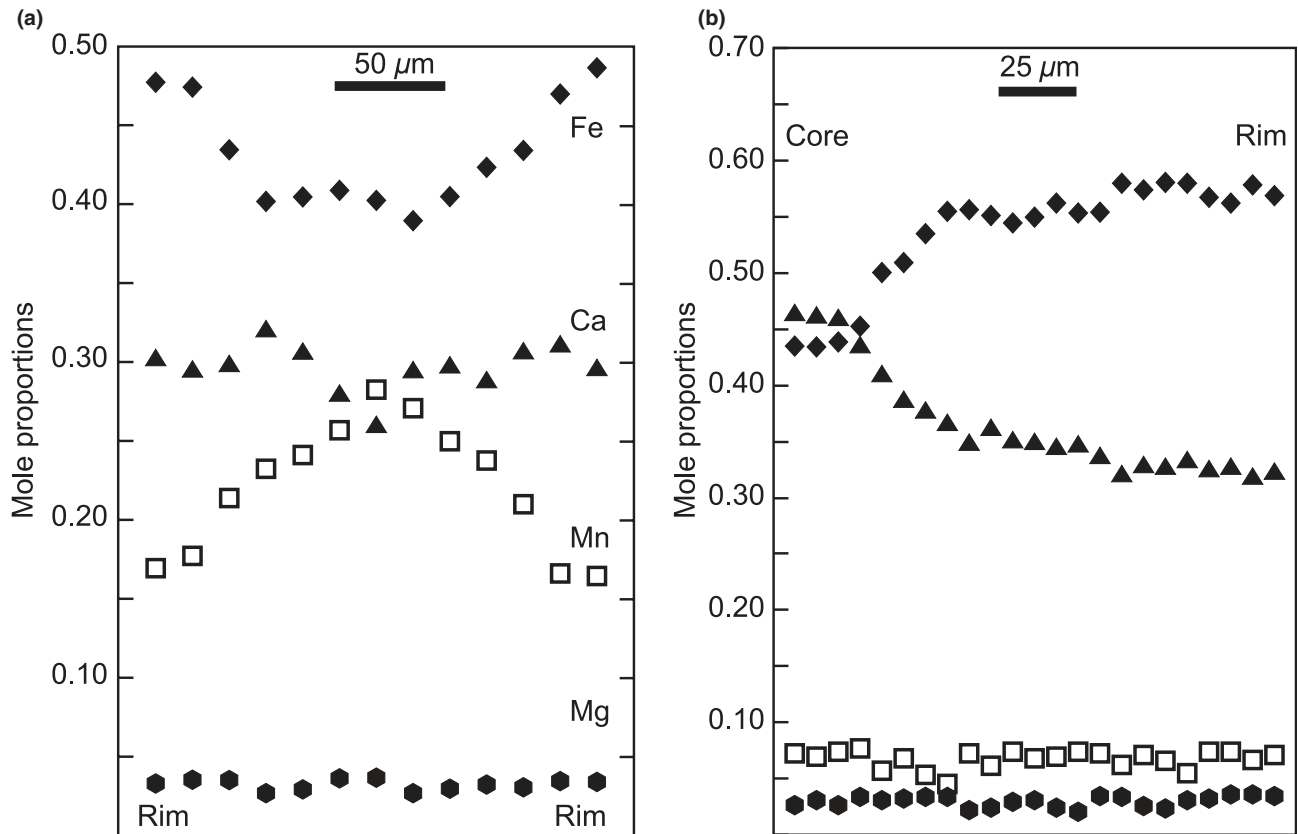

Fig. 5. Zoning profile across euhedral garnet in sample COR-1 (a) and COR-4 (b). The garnet from the latter sample did not show any evidence of coalescence of several smaller garnet as that shown in Fig. 4c.

Fig. 6. Compositional variations of clinopyroxene from sample COR-4. Quad = quadrilateral components (Ca, Mg and Fe) in clinopyroxene. Stippled and solid arrows indicate compositional evolution of matrix and vein clinopyroxenes respectively.

inclusions within garnet and as low-jadeite cores of matrix clinopyroxene. Inclusions of Ca-rich and TiO₂-poor clinopyroxene, hornblende, chlorite, albite and

titanite probably represent early (low-*P*) metamorphic phases. Overgrowths of successively more sodic pyroxene on Na-poor pyroxene indicate that the continuous reaction

produced more omphacitic pyroxene by consumption of albite during increasing pressure. The observed zoning in matrix omphacite in the same sample supports this interpretation. The zoning patterns of garnet from the two different lithologies studied here, with cores strongly enriched in Mn (COR-1) or Ca (COR-4) are also consistent with initial growth at low *P-T* conditions. Thus, the observed inclusion suite of albite, quartz, hornblende and low- to high-Na clinopyroxene in garnet in sample COR-4 apparently represents different transient *P-T* conditions during early subduction. A true equilibrium assemblage among these phases is therefore difficult to suggest. The irregular zoning pattern observed in some garnet in sample COR-4 apparently indicates that they formed by coalescence and overgrowth of several smaller garnet during increasing *P-T*.

A precise estimate of *P-T* for these early stages of subduction is not straight forward. Reaction (1) is likely to have proceeded during this time until albite was entirely consumed. The low modal content and

Mn- and Ca-rich and Mg-poor composition of garnet points to very low temperatures.

Lawsonite eclogite stage (II)

The Fe–Mg distribution among garnet and omphacite is commonly used as a temperature monitor, and the garnet–clinopyroxene Fe–Mg exchange thermometer (Ravna, 2000) gives temperatures in the range of 350–400 °C at a nominal pressure of 2.0 GPa, using rim compositions of garnet and matrix omphacite.

The cross-cutting omphacite-rich veinlets with phengite, ferroglaucophane and hematite in sample COR-4 were obviously emplaced as a result of influx of Na-rich fluids along fractures after the growth of garnet (Fig. 4f), but at still high-*P* conditions as evidenced by high jadeite content of omphacite, stability of ferro-glaucophane and the high Si-content of phengite. The zoning of vein omphacite with decreasing jadeite content from core to rim suggests that the fluid influx continued at decreasing pressure conditions or, alternatively, at changing composition of the fluid. The significantly lower Mg number of the vein clinopyroxene compared with the matrix pyroxene clearly indicates different origins.

Lawsonite blueschist stage (III)

The assemblage glaucophane + albite, observed very locally in sample COR-1', post-dates the lawsonite eclogite stage and constrains the metamorphic conditions to <450 °C and <1.5 GPa according to the metamorphic facies grid of Bousquet *et al.* (1997).

Post-blueschist stages

As no greenschist overprint was observed in the samples reference is made to Miller & Cartwright (2006) who presented data on greenschist facies metamorphism and almost monomineralic albite veins from the same locality at Défilé du Lancône. They estimated that the greenschist assemblages formed at 510 °C and 0.6 GPa, whereas they concluded that the albite veins were formed at 478 ± 31 °C and 0.37 ± 0.14 GPa after the regional greenschist facies retrogression.

P–T estimates from isochemical phase diagrams

To further constrain the metamorphic evolution and *P–T* conditions for the Défilé du Lancône lawsonite eclogites isochemical *P–T* phase diagrams were constructed for three bulk compositions. The bulk compositions (Figs 7–9) were obtained by EDS area scans of the matrix of samples COR-1 and COR-4, respectively, as well as of the omphacite-rich veinlets in sample COR-4.

For the first two compositions the system SiO₂–TiO₂–Al₂O₃–FeO–MgO–CaO–Na₂O and for the veinlets the system SiO₂–Al₂O₃–FeO–MgO–CaO–

Na₂O–K₂O–O₂, all with excess H₂O were investigated. Clarke *et al.* (2006) pointed out that unusually high water contents are demanded by lawsonite assemblages. The program Theriak–Domino (de Capitani & Brown, 1987) with the Berman database JUN92.bs and the activity models therein were used. The modelling does not include Mn, which principally will be partitioned into garnet and thus increase the stability field of garnet to lower temperatures and pressures.

For sample COR-1 the calculated stability field of the matrix assemblage garnet–omphacite–lawsonite–chlorite–titanite within a wedge-shaped field occurs between ~1.9 and 2.75 GPa at 350 °C with a maximum thermal stability of ~470 °C at 2.3 GPa (Fig. 7). At lower pressures amphibole is stable, and at higher pressures ilmenite becomes an additional phase. Neither of these phases has been observed. Albite is stable in this composition only up to ~0.6 GPa, garnet (Ca-rich) appears at pressures slightly below 0.5 GPa and lawsonite appears at ~1.1 GPa, all at 400 °C.

Sample COR-4 has the same matrix assemblage, which is stable within a relatively large field ranging from ~340 °C and 1.3–2.6 GPa to a thermal maximum of 490–500 °C at 2.0–2.1 GPa (Fig. 8). In this composition garnet is stable over most of the diagram. Lawsonite appears at ~1.1 GPa and albite disappears at ~0.7 GPa at 400 °C. The assemblage albite + Ca-clinopyroxene + hornblende + titanite, which is included in garnet cores, is stable together with garnet and paragonite (not observed) at pressures below ~0.7 GPa at 400 °C.

The omphacite-rich veinlets consisting of omphacite + phengite + glaucophane + hematite + quartz are stable between 1.05–2.4 GPa at 330 °C and 1.9–2.5 GPa, 410–420 °C (Fig. 9). The assemblage omphacite + phengite + glaucophane + hematite may also coexist with coesite at pressures above 2.4–2.5 GPa. Quartz/coesite has not been observed, but the estimated content of free silica in our calculations is less than 2%.

To summarize, the results of the thermodynamic modelling of the three different bulk compositions indicate that the observed peak mineral assemblages were all stable within a wedge-shaped window ranging from ~340 °C and 1.9–2.6 GPa to 415 °C and 2.2 GPa.

DISCUSSION

The lawsonite eclogite from Défilé du Lancône shows evidence of extremely low temperatures, as exemplified by low modal content of garnet, typical low-*T* composition of garnet (low Mg, high Mn and Ca), large compositional variations of clinopyroxene and garnet. These features may also be indicative of rapid subduction. There is no evidence of breakdown of lawsonite during decompression, clearly indicating that the terminal stability limit of lawsonite was not crossed, and that the low *P/T* persisted during exhumation.

Fig. 7. Isochemical P - T phase diagram showing the stability fields for mineral assemblages in sample COR-1, calculated using Theriak-Domino. See text for discussion. Hatched area marks overlapping P - T conditions for peak assemblages in all three bulk compositions. Note that in the upper left corner are two small fields with two coexisting clinopyroxenes. A tentative P - T path of the Défilé du Lancône lawsonite eclogite based on textural observations and thermodynamic modelling is shown (solid hairpin arrow). Alternative retrograde P - T paths are taken from Fournier *et al.*, 1991 (Fea) and Jolivet *et al.*, 1998 (Jea).

The earliest observed phase occurring as inclusions in garnet and as cores of matrix clinopyroxene is Ti-Al-rich augite assumed to represent relicts of the magmatic stage. During the early stages of subduction Ca- and Mn-rich garnet, diopsidic clinopyroxene, Ca-amphibole, chlorite, albite, titanite and probably epidote and paragonite (not observed) became stable at pressures below ~ 0.7 GPa, probably at temperatures of ~ 350 °C. Continued subduction resulted in the consumption of the lower pressure assemblages, giving rise to the peak assemblage garnet-omphacite-lawsonite-chlorite-titanite, representing lawsonite eclogite facies. The thermodynamic modelling using Theriak-Domino constrains the peak P - T conditions to 340–415 °C and 1.9–2.6 GPa, which actually is in agreement with the garnet-clinopyroxene Fe-Mg thermometric estimates. These peak conditions are close to, and even enter, the coesite stability field and the so-called “forbidden zone” of Liou *et al.* (2000), which indicates a regime of rapid subduction. Rapid subduction and burial of the HPLT rocks in Corsica is further supported by the evidence of subduction-related seismic activity recorded by blueschist facies

pseudotachylites found in both gabbro and spinel-peridotite in the Cima di Gratera area (see Fig. 1; Austrheim & Andersen, 2004; Andersen & Austrheim, 2006). These rocks preserve evidence of high strength during subduction, another argument for the very cold geotherm (Andersen *et al.*, 2008).

It is, however, important to stress that the accuracy of the P - T estimates obtained here are hampered by large uncertainties. In the present samples the pyrope content of garnet is very low and far outside the range used for the calibration of the garnet-clinopyroxene Fe-Mg thermometer, and the obtained temperatures are at least 200 °C lower than the lowermost temperature (600 °C) used for this calibration (Ravna, 2000). Thus, these temperature estimates obtained here should only be regarded as indicative of very low temperatures. Likewise, in the thermodynamic modelling Mn as a major component in garnet has been omitted, and the results are also strongly dependent on the quality of the thermodynamic data at such low temperatures. In addition, the observed incomplete reactions of even pre-metamorphic phases will probably have some influence on the effective bulk

Fig. 8. Isochemical P – T phase diagram showing the stability fields for mineral assemblages in sample COR-4 matrix, calculated using Theriak–Domino. See text for discussion. Note that at 0.9–2.6 GPa and < 340 °C two coexisting clinopyroxenes can be stable.

composition, and thus the final output. Nevertheless, the obtained results are not unrealistic. More important than the ‘absolute’ P – T conditions is the sequential metamorphic evolution which clearly demonstrates a cold regime during subduction as well as initial exhumation. If these rocks ever entered the area defined as the ‘forbidden zone’, or were subjected to coesite stability conditions cannot be evaluated here.

The prograde metamorphic evolution of the Défilé du Lancône lawsonite eclogite bears similarities to lawsonite eclogite described from the Motagua fault zone, Guatemala (Harlow *et al.*, 2004; Tsujimori *et al.*, 2005, 2006b), where the basalt–eclogite transformation may have occurred at temperatures as low as ~ 300 °C in a cold subduction zone with the apparent direct formation of lawsonite eclogite without passing through the blueschist facies. These authors suggested that dehydration of chlorite + albite + lawsonite \pm pumpellyite to form garnet + omphacite within the lawsonite field may be more effective than the glaucophane-forming reaction during subduction. In our samples, however, the thermodynamic model-

ling indicates that glaucophane was not a stable phase at any P – T conditions due to bulk compositional constraints. Glaucophane was only stabilized in the extreme Na-rich composition of the omphacite-rich veinlets of sample COR-4, and in the very local domains of retrograde glaucophane + albite.

The preservation of lawsonite indicates that the low geothermal gradient prevailed during at least the initial stages of exhumation, following more or less the same path as during subduction, similar to the path proposed by Çetinkaplan *et al.* (2008) for the lawsonite eclogite in Sivrihisar, Tavşanlı Zone in Turkey. This suggests that material flowing up along the subduction channel was refrigerated by continued subduction of cold material. The estimated peak pressures of 1.9–2.6 GPa are much higher than those recorded for the main lawsonite blueschist facies (top-to-the-south-west shear) event, which is well developed elsewhere in the area and most probably related to retrogression during exhumation. The main thrusting phase was thus contemporaneous with the upward motion of the HP units within the subduction complex. This shows that

Fig. 9. Isochemical P - T phase diagram showing the stability fields for mineral assemblages in omphacite-rich veins, sample COR-4, using Theriak-Domino. Contours for jadeite content of clinopyroxene are shown as stippled lines. See text for discussion.

the Lancône ophiolitic material was not significantly deformed until after it reached its maximum depth and that the first deformation was associated with exhumation. Continued retrogression into greenschist facies conditions has been thoroughly studied (Fournier *et al.*, 1991; Jolivet *et al.*, 1998; Miller & Cartwright, 2006) and the suggested retrograde P - T paths from Fournier *et al.* (1991) and Jolivet *et al.* (1998) are shown in Fig. 10. The latter part of exhumation has been attributed to the post-orogenic extension that started at *c.* 33–32 Ma and led to the opening of the Liguro-Provençal Basin and the Tyrrhenian Sea (Jolivet *et al.*, 1991; Brunet *et al.*, 2000). Miller & Cartwright (2006) suggested estimates of 510 °C at 0.6 GPa for the greenschist facies overprint, which requires a late thermal pulse. However, their estimate may be too high for greenschist facies.

In the model presented here we assume, supported by the numerical modelling of P - T -depth conditions

in subduction channels (Gerya *et al.*, 2002; Yamato *et al.*, 2007), that pressure can be converted to depth according to $P \pm 10\% = \rho gh$ (ρ , density; g , gravitational acceleration; h , burial depth).

Finally, we propose a possible exhumation scenario (Fig. 10). The finding of very high pressure in Défilé du Lancône forces us to reconsider previously proposed schemes (Fournier *et al.*, 1991), that did not have to accommodate such large depths of burial. Our reconstruction starts in the latest Cretaceous when Ligurian oceanic crust and perhaps also the leading edge of the European continental margin (the youngest oceanic sediments date to late Cretaceous) had entered the subduction zone, and an accretionary complex had already developed above it at the expense of Ligurian oceanic domain. At this time a piece of partly eclogitized oceanic crust detached from the subducting lithosphere at ~ 80 km depth and began its exhumation path along the subduction channel. The

Fig. 10. Model of tectonic evolution of the Alpine LTHP metamorphic complexes Corsica (modified from Jolivet *et al.*, 1998), where the new P - T data from lawsonite eclogites in Défilé du Lancône have been incorporated. See text for discussion and details.

main top-to-the-west deformation recorded in the eclogite dates from the Palaeocene and Eocene when it had reached the blueschist domain. From the Eocene onward the Adria plate to the east started subducting and a progressive reorganization of the subduction polarity ensued orogen-parallel extension and arc bending forced by slab tearing and toroidal flow at the junction between the Alps and Apennines (Vignaroli *et al.*, 2008). This situation developed during the Eocene and culminated in the middle Eocene with the emplacement of superficial parts of the accretionary complex onto the foreland basin to the west. Units undergoing exhumation continued their way up in the subduction channel and eventually reached the accretionary complex, the last units to be involved in thrusting being the Tenda massif and Corte slices. At 33 Ma the regime of subduction changed in the Mediterranean region as a whole and slab retreat started (Jolivet & Faccenna, 2000), leading to the reactivation of major thrusts as extensional shear zones and normal faults that completed the exhumation of the metamorphic domain. Finally, the extensional deformation migrated eastward and Corsica became more or less stable.

ACKNOWLEDGEMENTS

Grants covering the analytical expenses of E. Krogh Ravna were received from the Norwegian Academy of Science and Letters through 'Nansenfondet og de dermed forbundne fond'. A Centre of Excellence grant from the Norwegian Research Council to the PGP financed T.B. Andersen. The technical support by T.I. Eilertsen at the Electron Microscopy Lab, Department of Medical Biology, University of Tromsø, and the staff at the Electron Microprobe Lab at Dionýz Štúr Institute of Geology in Bratislava are much appreciated. Thorough reviews by T. Rivers and J.X. Zhang greatly improved the paper.
