Background. The efficacy of ceftazidime-avibactam—a cephalosporin–β-lactamase inhibitor combination with in vitro activity against *Klebsiella pneumoniae* carbapenemase–producing carbapenem-resistant Enterobacteriaceae (CRE)—compared with colistin remains unknown.

Methods. Patients initially treated with either ceftazidime-avibactam or colistin for CRE infections were selected from the Consortium on Resistance Against Carbapenems in *Klebsiella* and other Enterobacteriaceae (CRACKLE), a prospective, multicenter, observational study. Efficacy, safety, and benefit-risk analyses were performed using intent-to-treat analyses with partial credit and the desirability of outcome ranking approaches. The ordinal efficacy outcome was based on disposition at day 30 after starting treatment (home vs not home but not observed to die in the hospital vs hospital death). All analyses were adjusted for confounding using inverse probability of treatment weighting (IPTW).

Results. Thirty-eight patients were treated first with ceftazidime-avibactam and 99 with colistin. Most patients received additional anti-CRE agents as part of their treatment. Bloodstream (n = 63; 46%) and respiratory (n = 30; 22%) infections were most common. In patients treated with ceftazidime-avibactam versus colistin, IPTW-adjusted all-cause hospital mortality 30 days after starting treatment was 9% versus 32%, respectively (difference, 23%; 95% bootstrap confidence interval, 9%–35%; *P* = .001). In an analysis of disposition at 30 days, patients treated with ceftazidime-avibactam, compared with those treated within colistin, had an IPTW-adjusted probability of a better outcome of 64% (95% confidence interval, 57%-71%). Partial credit analyses indicated uniform superiority of ceftazidime-avibactam to colistin.

Conclusions. Ceftazidime-avibactam may be a reasonable alternative to colistin in the treatment of *K. pneumoniae* carbapenemase–producing CRE infections. These findings require confirmation in a randomized controlled trial.

Keywords. carbapenem-resistant Enterobacteriaceae; *Klebsiella pneumoniae*; colistin; ceftazidime-avibactam; benefit-risk.

The global spread of carbapenem-resistant Enterobacteriaceae (CRE) is an important threat to vulnerable patient populations worldwide [1–5]. Treatment options for CRE infections include polymyxins such as colistin and polymyxin B [6]. Concerns about polymyxins include toxicity, limited efficacy, dosing uncertainties and resistance, including worrisome *mcr-1*–mediated resistance [7–9]. Recently, ceftazidime-avibactam

was approved for use by the Food and Drug Administration [10]. Avibactam is a non–β-lactam β-lactamase inhibitor that has activity against Ambler class A and class D serine carbapenemases, including *Klebsiella pneumoniae* carbapenemase (KPC) and OXA-48–like carbapenemases. In contrast, avibactam does not inhibit metallo-β-lactamase enzymes. Uncontrolled case series have shown variable outcomes in patients with CRE infections treated with ceftazidime-avibactam [11, 12]. Data comparing the use of ceftazidime-avibactam versus polymyxins in the treatment of CRE infections are limited.

The importance of patient-centered outcomes that go beyond mortality rates is increasingly recognized. Recently, several states of health were deemed by patients to be even worse than death, suggesting that patient-centered quality-of-life outcomes are important to measure [13]. Furthermore, when selecting an antibiotic strategy, issues of efficacy and safety should both

be considered. In the current study, we analyzed the outcomes in patients initially treated with ceftazidime-avibactam versus colistin for CRE infections. We evaluated combined benefits and risks to estimate patient-level differences between ceftazidime-avibactam and colistin. The Consortium on Resistance Against Carbapenems in *Klebsiella* and Other Enterobacteriaceae (CRACKLE) study offered a unique opportunity to address these questions, because ceftazidime-avibactam was introduced into clinical practice while the study was ongoing.

METHODS

CRACKLE Study

CRACKLE is a prospective, observational study involving 18 hospitals that are a part of 8 healthcare systems predominantly located in the Great Lakes region of the United States, as described elsewhere (see Supplementary Table S1 for relative contributions of each hospital) [14–16]. All hospitalized patients who have a culture from which CRE is isolated are included. From 24 December 2011 until 1 January 2015, only data on patients with carbapenem-resistant *Klebsiella pneumoniae* were collected. From 1 January 2015 onward, all patients with any CRE were included. Clinical data on these patients were entered into a central, standardized database. Data collection methods did not change during the study period.

Patients and Clinical Data

In the study period from 24 December 2011 to 1 May 2016, all patients who started ceftazidime-avibactam or colistin treatment for a documented CRE infection were included (see Supplementary Table S2 for colistin dosing recommendations in place during the study period). Seven patients who started both colistin and ceftazidime-avibactam within a 24-hour window were excluded (See Supplementary Table S3). Standardized a priori definitions of infections were used, as described elsewhere [14]. Patients whose culture episode did not meet criteria for infection were excluded.

Patients with bacteremia were analyzed as such regardless of the primary source. Each patient was included once at the time of the most recent treated CRE infection. The Pitt bacteremia score based on the day of the index culture was calculated, and patients with a score ≥4 were considered critically ill [17]. The Charlson comorbidity index was determined at admission [18]. Renal failure was defined as a serum creatinine level ≥2 mg/dL and/or the use of renal replacement therapy. The study was approved by the institutional review boards of all study sites. Because CRACKLE is an observational study, treatment of CRE infections was at the discretion of the treating physician. Only patients who were treated with colistin or ceftazidime-avibactam were included in the study. Before the approval date of ceftazidime-avibactam, 81 patients (82% of the total colistin-first cohort) were included in the colistin-first group. After the approval date, an additional 18 patients (18% of the total colistin-first cohort) were included

in the colistin-first group. Of note, no significant difference in unadjusted 30-day mortality was observed between these 2 groups (25 of 81 [31%] vs 8 of 18 [44%]; *P* = .28).

Microbiology

Guidelines from the Clinical and Laboratory Standards Institute were used to define CRE [19]. Bacterial identification and routine antimicrobial susceptibility testing was performed with MicroScan (Siemens Healthcare Diagnostics) or Vitek2 (bioMerieux), supplemented by GN4F Sensititre tray (Thermo Fisher) or Etest (bioMerieux), as indicated. On available isolates, detection of carbapenemase genes and repetitive extragenic palindromic (rep)–polymerase chain reaction (PCR) strain typing was performed as described elsewhere [14]. Briefly, PCR amplification of bla_{KPC}, bla_{NDM}, bla_{VIM}, bla_{IMP}, and bla_{OXA-48} genes was conducted using established primers and methods; amplicons were sequenced at a commercial sequencing facility (MCLAB), and analyzed [20, 21]. rep-PCR was performed using the DiversiLab Strain typing system (Bacterial BarCodes; bioMerieux). Isolates with ≥ 95% similarity were considered of the same rep-PCR type.

Statistical Methods

Intention-to-treat analyses were used to compare strategies of initiating ceftazidime-avibactam versus colistin for the initial treatment of CRE infection, in the presence of routine additional clinical care and consequential downstream adjustments to therapy. There were 3 analysis foci: efficacy, safety, and benefit-risk. Efficacy analyses were conducted using the efficacy analysis set (n = 137). Safety and benefit-risk analyses were conducted using the safety/benefit-risk analysis set consisting of the patients in the efficacy analysis without renal failure at treatment initiation (n = 72), because patients with renal failure at treatment initiation were not at risk for the major safety outcome of incident renal failure.

Analyses focused on ordinal outcomes (Table 1) constructed from benefits and harms experienced during the "patient journey" that have an important impact on patients. Ordinal

Table 1. Ordinal Outcomes for Efficacy, Safety, and Benefit-Risk Analyses With Categories in Ascending Order of Desirability

Analysis	Outcomes
Efficacy	1. Hospital death 2. Alive in hospital or discharged not to home 3. Discharged home
Safety	1. Hospital death 2. Not observed to die, with incident renal failure 3. Not observed to die, without incident renal failure
Benefit-risk	1. Hospital death 2. Alive in hospital or discharged not to home, incident renal failure 3. Alive in hospital or discharged not to home, no incident renal failure 4. Discharged home

outcomes have pragmatic advantages compared with separate analyses of the different outcomes [22]. Adjustment for confounding by indication was performed using inverse probability of treatment weighting (IPTW) [23, 24]. Covariates included in the model for the decision between ceftazidime-avibactam and colistin were Pitt score (dichotomized as <4 or ≥4), type of infection (bloodstream infection vs urinary tract infection vs other), and (in the main sensitivity analysis) creatinine level ≥2 mg/dL at the time of first positive culture.

The primary efficacy analysis was an IPTW-adjusted disposition plot displaying the probability of disposition outcomes over time. The probability of hospital mortality in the first 30 days was compared between treatment groups adjusting for potential confounding by indication through IPTW. This analysis relies on correct specification of the treatment initiation model. In a sensitivity analysis, the primary outcome was evaluated by using the standardized risks, conditioning on the same confounders using a logistic regression model for the probabilities of the different outcome categories. This sensitivity analysis relies on correct specification of the logistic regression models for the outcomes in both treatment groups. In another sensitivity analysis for the primary outcome, we added Charlson score, age, and race to the list of confounders in the treatment initiation model.

Efficacy, safety, and benefit-risk were also analyzed using the desirability of outcome ranking (DOOR), resulting in estimates of the probability that a randomly selected patient initially treated with ceftazidime-avibactam would have a better overall outcome than a randomly selected patient initially treated with colistin (with half credit given for tied ranks) [22, 25]. Estimates were adjusted using IPTW.

The ordinal outcomes for safety and benefit-risk were also analyzed using the partial credit strategy, which provides a score of 1 (100%) to the most desirable category of the ordinal outcome, 0 (0%) to the least desirable, and partial credit to the intermediate categories [26]. For safety, the following scoring was implemented: the category "not observed to die, no renal failure" was scored as 1, the category "not observed to die, with renal failure" was given a partial credit of x, and the category "died in the hospital" was scored as 0. Analyses display the contrast between ceftazidime-avibactam and colistin as x varies, allowing for personalized patient-clinician team decision making.

For the benefit-risk analysis, the following scoring was implemented: the category "died in the hospital" was scored as 0; the category "alive in the hospital or discharged not to home with renal failure" was given a partial credit of x_1, with $0 \leq x_1 \leq 1$; the category "alive in the hospital or discharged not to home without renal failure" was given a partial credit of x_2 with $x_1 \leq x_2 \leq 1$; and the category "discharged home" was scored as 1. Analyses display the contrast between ceftazidime-avibactam and colistin as x_1 and x_2 vary. Estimates were adjusted using IPTW. The nonparametric bootstrap with 5000 replicates was implemented to obtain all confidence intervals (CIs) using Efron's percentile method, and CIs were inverted to obtain P values.

RESULTS

Baseline Characteristics

During the study period, 137 patients within the CRACKLE study met criteria for CRE infection and started on treatment with ceftazidime-avibactam or colistin. Of the 137 patients, 38 (28%) received ceftazidime-avibactam first, and 99 (72%) colistin first. The baseline characteristics are summarized in Table 2 (IPTW-adjusted characteristics are in Supplementary Table S4). Patients tended to be both chronically and acutely ill, with a median Charlson comorbidity score of 3 (interquartile range [IQR], 1–5) and a median Pitt bacteremia score of 4 (2–6).

Almost half of patients (n = 63; 46%) presented with CRE bloodstream infection (sources are summarized in Supplementary Table S5). Other common infection types included respiratory tract infections in 30 patient (22%) and urinary tract infection in 19 (14%) (Table 2). Almost all patients (n = 133; 97%) were infected with *K. pneumoniae*; the other 4 (3%) were infected with *Enterobacter* spp. A total of 98 CRE isolates were tested to determine colistin susceptibility. Patients treated first with ceftazidime-avibactam were less likely to have colistin-susceptible isolates (23 of 30; 77% of tested) than patients treated with colistin first (63 of 68; 93% of tested; $P = .04$). Of the 24 isolates on which ceftazidime-avibactam susceptibility testing was performed, 23 (96%) were reported as susceptible. The single isolate that tested resistant was in the ceftazidime-avibactam–first treatment group. In 54 carbapenem-resistant *K. pneumoniae* isolates, the presence or absence of carbapenemase genes was tested; 28 (52%) and 24 (44%) were positive for bla_{KPC-2} and bla_{KPC-3}, respectively. In 2 of 54 isolates (4%), no carbapenemase genes were found. None of the tested isolates was positive for bla_{NDM}, bla_{VIM}, bla_{IMP}, or bla_{OXA-48}. ST258A (18 of 54; 33%) and ST258B (23 of 54; 43%) were the most commonly encountered clades of carbapenem-resistant *K. pneumoniae*.

Efficacy, Safety, and Benefit-Risk
Efficacy
Efficacy was evaluated using the efficacy analysis set (n = 137). All-cause in-hospital mortality 30 days after the start of treatment was 3 of 38 (8%) in the ceftazidime-avibactam group versus 33 of 99 (33%) in the colistin group. After IPTW adjustment, the estimated adjusted percentages were 9% and 32%, respectively, resulting in a difference of 23% (95% CI, 9%–35%; $P = .001$; Table 3). Figure 1 displays the IPTW-adjusted disposition over time for patients initially treated with ceftazidime-avibactam (Figure 1A) versus those initially treated with colistin (Figure 1B). Patients treated with ceftazidime-avibactam were less likely to die and more likely to be discharged home during the first 30 days after starting treatment. DOOR

analyses indicated that the IPTW-adjusted probability of a better outcome on ceftazidime-avibactam compared with colistin is 64% (95% CI, 57%–71%; Table 3).

Safety

Safety was evaluated using the safety/benefit-risk analysis set (n = 72; 26 initially treated with ceftazidime-avibactam and 46 initially treated with colistin; see Supplementary Table S6 for IPTW-adjusted characteristics), which excludes the patients with renal failure at treatment initiation, that is, those not at risk for incident renal failure. Figure 2 displays the IPTW-adjusted safety outcome over time for patients initially treated with ceftazidime-avibactam (Figure 2A) versus those initially treated with colistin (Figure 2B). The IPTW-adjusted estimates for (1) hospital death, (2) not observed to die with incident renal failure, and (3) not observed to die without incident renal failure were 9%, 5%, and 86% for ceftazidime-avibactam, respectively, and 25%, 13%, and 62% for colistin (Table 3). DOOR analyses indicated that the IPTW-adjusted

Abbreviations: CI, confidence interval; DOOR, desirability of outcome ranking; IPTW, inverse probability of treatment weighting.

[a]The DOOR estimates represent the probability that a randomly chosen patient from the study population has a more desirable outcome when starting ceftazidime-avibactam treatment than when starting colistin treatment.

probability of a better outcome with ceftazidime-avibactam than with colistin is 62% (95% CI, 52%– 72%; Table 3).

The estimated IPTW-adjusted between-treatment difference (ceftazidime-avibactam minus colistin) in mean scores (and associated 95% CIs) is displayed as a function of the partial credit assigned to those not observed to die with renal failure in Figure 3A. Analyses are based on patients without renal failure at treatment initiation. Being not observed to die without renal failure is assigned a credit of 1 and hospital death a credit of 0. Partial credit for being not observed to die with renal failure is assigned x (on the horizontal axis), with $0 \leq x \leq 1$. Results are plotted as the partial credit x varies to allow visualization of the impact on the estimated treatment effect.

Positive differences indicate favorable results for ceftazidime-avibactam. For example, point A assigns a partial credit of 1 to patients not observed to die with renal failure, implying that renal failure is irrelevant and only survival matters, resulting in an estimated difference of 0.16 (95% CI, −.02 to .32), equivalent to a binary end point of hospital death. As another extreme example, point B assigns a partial credit of 0 to patients not observed to die with renal failure implying that incident renal failure is as poor an outcome as death, resulting in an estimated difference of 0.24 (95% CI, .04–.43). This is equivalent to a binary end point of not observed to die without renal failure. Point C assigns a

partial credit of 0.8 (selected by the authors) to patients not observed to die with renal failure, resulting in an estimated difference of 0.18 (95% CI, 0–.34).

Benefit-Risk Analysis

Benefit-risk was evaluated using the safety/benefit-risk analysis set (n = 72). The IPTW-adjusted estimates for (1) hospital death, (2) alive in the hospital or discharged not to home with incident renal failure, (3) alive in the hospital or discharged not to home without incident renal failure, and (4) discharged home were 9%, 5%, 65%, and 20% for ceftazidime-avibactam respectively, and 25%, 11%, 56%, and 8% for colistin (Table 3). DOOR analyses indicated that the IPTW-adjusted probability of a better outcome with ceftazidime-avibactam than with colistin is 64% (95% CI, 53%–75%; Table 3).

The estimated between-treatment difference (ceftazidime-avibactam minus colistin) is displayed as a function of the partial credits assigned to (1) being alive in the hospital or discharged not to home with incident renal failure and (2) alive in the hospital or discharged not to home without incident renal failure, in Figure 3B. Estimates are adjusted using IPTW. Analyses are based on patients without renal failure at treatment initiation. Hospital death is assigned a credit of 0, and being discharged home a credit of 1. Partial credit is given for (1) being alive in the hospital or discharged not to home with
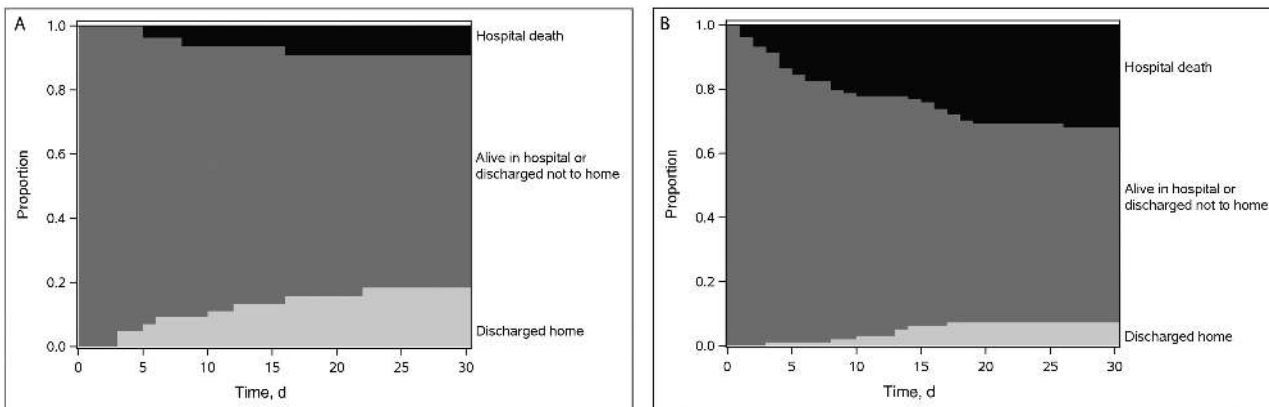

Figure 1. Inverse probability of treatment weighting (IPTW)–adjusted efficacy: disposition over time (n = 137; IPTW-adjusted probability estimates of hospital mortality and discharge status). *A*, Ceftazidime-avibactam group (n = 38). *B*, Colistin group (n = 99).

incident renal failure (x_1, with $0 \leq x_1 \leq 1$) and (2) being alive in the hospital or discharged not to home without incident renal failure (x_2, with $x_1 \leq x_2 \leq 1$). Results are plotted as partial credits vary to allow visualization of the impact on the estimated treatment effect.

Positive differences indicate favorable results for ceftazidime-avibactam. For example, point *A* in Figure 3B is the extreme example of both x_1 and x_2 being assigned a partial credit of 1. This is equivalent to analysis of a hospital death resulting in an estimated difference of 0.16 (95% CI, −.02 to .32). Point *B* is another extreme example of both x_1 and x_2 being assigned a partial credit of 0. This is equivalent to analysis of being discharged home resulting in an estimated difference of 0.13 (95% CI, −.04 to .31]). Point *C* is another extreme example where x_1 is assigned a partial credit of 0 and x_2 a partial credit of 1. This is equivalent to analysis of a binary end point (being discharged home or alive in hospital or discharged not to home without incident renal failure versus

other), resulting in an estimated difference of 0.22 (95% CI, .02–.41). As an example of a value judgment in which both disposition and development of renal failure are thought to be important, point *D* on the graph indicates assigned values of 0.6 for x_1 and 0.8 for x_2, resulting in an estimated difference of 0.17 (95% CI, .02–.30).

Antimicrobial Treatment

Anti-CRE directed treatment characteristics are outlined in Table 4 and Supplementary Table S7. The median time from collection of the index culture until starting ceftazidime-avibactam or colistin was similar in the 2 groups: 3 (IQR, 2–4) versus 2 (1–4) days, respectively, in the ceftazidime-avibactam and colistin groups (*P* = .22). The median durations of treatment were also similar: 10 (IQR, 5–26) versus 10 (4–18) days, respectively. The use of other antibiotics directed against CRE was common and included tigecycline (n = 72; 53%), aminoglycosides (n = 60; 44%), and carbapenems (n = 70; 51%), among
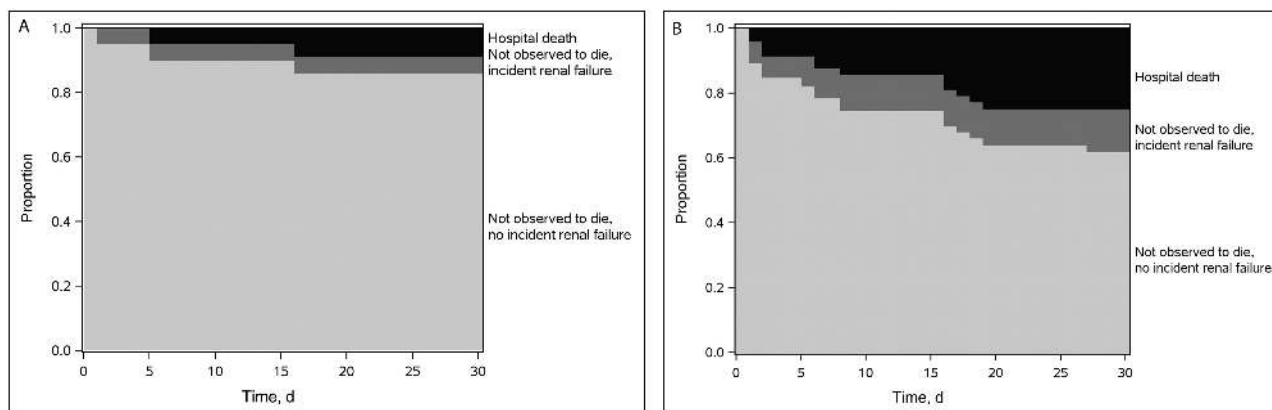

Figure 2. Inverse probability of treatment weighting (IPTW)–adjusted safety over time: renal failure (n = 72; restricted to patients at risk for incident renal failure, without renal failure at treatment initiation). *A*, Ceftazidime-avibactam group (n = 26). *B*, Colistin group (n = 46).
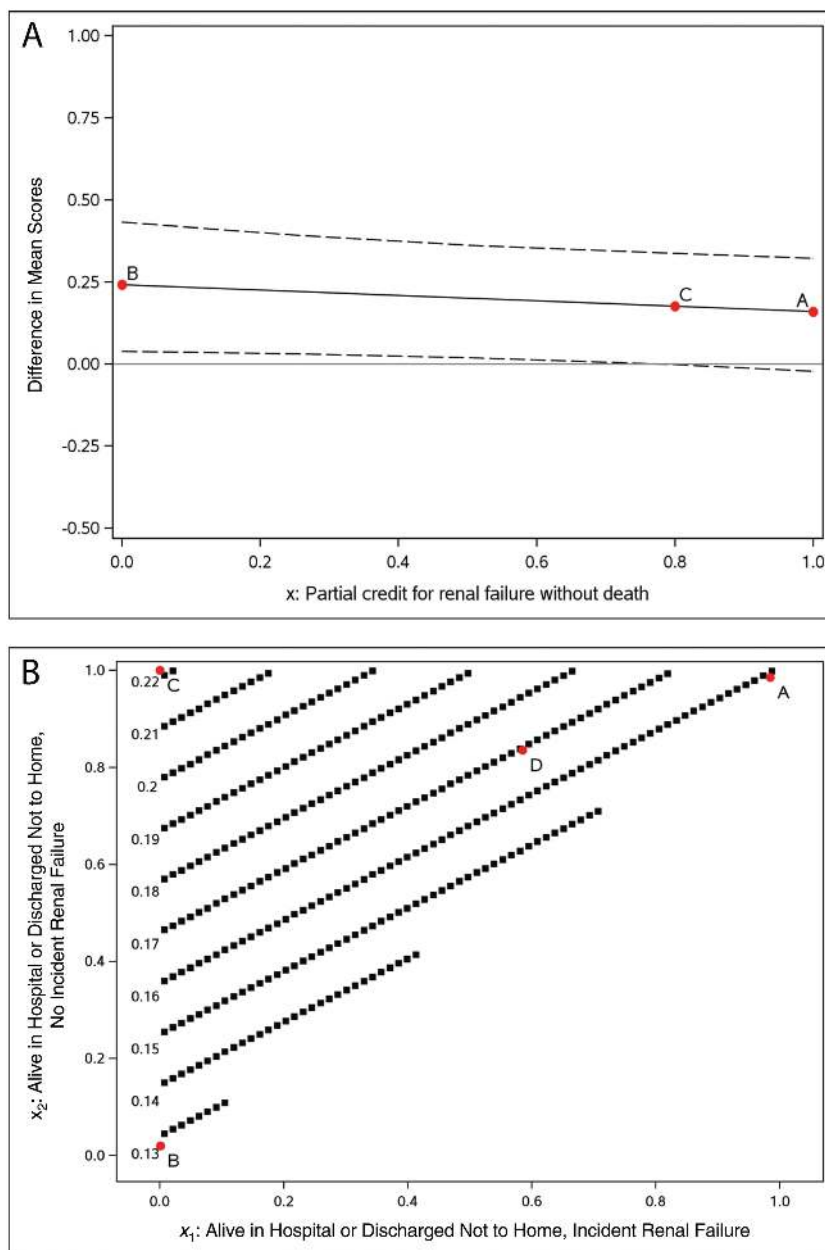

Figure 3. Inverse probability of treatment weighting (IPTW)–adjusted partial credit analysis. *A,* Safety: estimated between-treatment difference (ceftazidime-avibactam minus colistin) in mean scores and associated 95% confidence bands, as a function of the partial credit assigned to those not observed to die with renal failure (more details in Section 5.25–5.45). *B,* Benefit-risk: estimated between-treatment difference (ceftazidime-avibactam minus colistin) in mean scores as a function of the partial credits assigned to those alive in the hospital or discharged not to home, with or without incident renal failure (more details in Section 5.85–6.45).

others (Table 4). Of note, fewer patients (n = 24; 63%) in the ceftazidime-avibactam–first group received additional CRE-active antibiotics than in the colistin-first group (n = 93; 94%), *P* < .001. One patient in the ceftazidime-avibactam–first group received colistin later and 5 patients in the colistin-first group received ceftazidime-avibactam later in their treatment course.

DISCUSSION

We compared the use of colistin versus ceftazidime-avibactam in the treatment of CRE infections. Clinical outcomes were better

in the patients who were treated first with ceftazidime-avibactam rather than colistin. Specifically, all-cause 30-day hospital mortality was substantially decreased in the ceftazidime-avibactam group. A previous recent report of 3 cases of CRE bloodstream infection treated with ceftazidime-avibactam similarly reported good outcomes in these patients [11]. A larger retrospective study of 37 patients with CRE infections reported a 30-day survival of 76%, and clinical success in 59% [12]. However, of concern was the observed resistance to ceftazidime-avibactam that occurred in 3 of 10 patients with microbiologic failure [12]. In addition to

Table 4. Treatment Characteristics

Characteristic	Patients, No. (%)[a]			
	Ceftazidime-Avibactam (n = 38)	Colistin (n = 99)	All (N = 137)	P Value
Time to treatment, median (IQR), d[b]	3 (2–4)	2 (1–4)	3 (1–4)	.22[c]
Duration of treatment, median (IQR), d	10 (5–26)	10 (4–18)	10 (5–19)	.52[d]
Additional antibiotics				
None	14 (37)	6 (6)	20 (15)	<.001[e]
Tigecycline	12 (32)	60 (61)	72 (53)	.002[e]
Amikacin	6 (16)	23 (23)	29 (21)	.34[e]
Gentamicin	12 (32)	14 (14)	26 (19)	.02[e]
TMP/SMX	4 (11)	12 (12)	16 (12)	.80[e]
Carbapenem	11 (29)	59 (60)	70 (51)	.001[e]
Fosfomycin	1 (3)	3 (3)	4 (3)	>.99[c]

Abbreviations: IQR, interquartile range; TMP/SMX, trimethoprim/sulfamethoxazole.

[a]Data represent No. (%) of patients, unless otherwise specified.

[b]Days from index culture until first dose of colistin or ceftazidime-avibactam.

treatment-emergent resistance, another important unanswered question is the impact of combination therapy in CRE infections when ceftazidime-avibactam is used. In the INCREMENT study, which did not include any patients treated with ceftazidime-avibactam, combination therapy tended to have the most benefit in more severely ill patients [27]. However, whether the same effect will be observed in patients treated with regimens containing ceftazidime-avibactam is unclear. In our cohort, ceftazidime-avibactam was used as monotherapy in 37% of patients.

Based on randomized controlled trials (RCTs), ceftazidime-avibactam was recently approved for complicated urinary tract infection and complicated intra-abdominal infections [10]. Another trial focused on ceftazidime-resistant pathogens in an open-label comparison with best-available therapy [28]. Nonetheless, an important unanswered question is how ceftazidime-avibactam performs overall in the treatment of CRE infections. Ideally, this question will be answered through an RCT. Unfortunately, results from any potential CRE-specific RCT are not imminently expected for ceftazidime-avibactam, although several carbapenem-resistant pathogen-specific RCT evaluating other novel therapeutic agents with in vitro activity against CRE are currently ongoing; examples include studies involving imipenem-relebactam (NCT02452047), meropenem-vaborbactam (NCT02168946), and cefiderocol (S-649266, NCT02714595).

The introduction of ceftazidime-avibactam during the study period of CRACKLE posed a unique opportunity to compare outcomes in patients treated with ceftazidime-avibactam versus colistin. Although important sources of bias remained, all data were collected in the same standardized, prospective manner. The relatively short study period decreases the likelihood that supportive, nonantibiotic treatment measures changed dramatically over the course of this study. For these reasons, this observational study represents a reasonable opportunity to inform the medical community about the relative efficacy and toxicity of ceftazidime-avibactam compared with colistin, while awaiting definitive RCT data.

Novel statistical methods such as DOOR and partial credit analyses were applied using ordinal outcomes. Ordinal outcomes allow for a more synthesized evaluation of benefits and harms, providing information on the overall effects on patients aligning with needs of clinicians when making treatment decisions and the priorities of patients. This is in contrast to segmented evaluation of treatment effects on outcomes where associations between component outcomes can be missed and competing risks can confound interpretation. This is particularly important when treatments have toxic effects that affect patient function and quality of life. Partial credit analyses allow for individual patient-clinician teams to apply their own values or preferences (ie, their own partial credit) regarding outcomes to obtain personalized estimates of treatment effects to guide decisions. Here, we observed that for all possible values of partial credit, ceftazidime-avibactam performed better than colistin. However, we included only disposition and renal failure in these analyses. Other potential adverse events associated with antibiotics, such as *Clostridium difficile* infection, rash, or hypersensitivity reactions, should be included in future studies.

Our study has several limitations. First, it was an observational study in which treatment was not randomly assigned. Confounding by indication is therefore a potential issue [29]. We have addressed this issue by applying IPTW. However, any confounding adjustment method can adjust only for measured variables and relies on correct specification of the adjustment models. Unmeasured variables associated with the outcomes of interest may have been unevenly distributed between patient groups, and, given the available sample, we could not adjust for all measured potential confounders. An indicator of lack of randomization of treatment allocation is the higher proportion of colistin-resistant CRE in the ceftazidime-avibactam group. Nonetheless, sensitivity analyses led to findings very similar to the ones presented here. Second, detailed data on dosing of colistin were not available for these patients. It is possible that the observed differences may in part be a consequence of relative underdosing of colistin. Third, the number of patients included in this study is relatively small. Nonetheless, this is the largest comparative study to date to address this question.

In summary, we report here evidence for superiority of ceftazidime-avibactam over colistin in the initial treatment of infections caused by *K. pneumoniae* carbapenemase–producing CRE. The use of ceftazidime-avibactam was associated with improved clinical outcomes, especially decreased all-cause hospital mortality rate and improved benefit-risk outcomes.
