Summary

The association between obesity and the fat mass and obesity associated (*FTO*) gene has been widely replicated among Caucasian populations. The limited number of studies assessing its significance in Asian populations have been somewhat conflicting. We performed a genetic association study of 51 tagging, GWAS, and imputed single nucleotide polymorphisms with twelve measures of adiposity and skeletal robustness in two Samoan populations of Polynesia. We included 465 and 624 unrelated American Samoan and Samoan individuals, respectively; these populations derive from a single genetic background traced to Southeast Asia and represent one socio-cultural unit, although they are economically disparate with distinct environmental exposures. American Samoans were significantly larger than Samoans in all measures of obesity and most measures of skeletal robustness. In separate analyses of American Samoa and Samoa, we found a total of 36 nominal associations between *FTO* variants and skeletal and obesity measures. The preponderance of these nominal associations (32 of 36) was observed in the Samoan population, and predominantly with skeletal rather than fat mass measures (28 of 36). All significance disappeared, however, following corrections for multiple testing. Based on these findings, it could be surmised that *FTO* is not likely a major obesity locus in Polynesian populations.

Authors' Contributions

The Samoan obesity study was conceived and designed by STM. The genetic study was designed by STM, DEW and RD. Field work, data collection and analysis of phenotypic traits were conducted under the supervision of STM. SV and JT provided guidance in the conduct of field work in Samoa and American Samoa, respectively. DEW provided supervision in statistical analysis. RK carried out the primary statistical analysis; RK and RD wrote much of the manuscript in consultation with STM and DEW. SG and HC performed genotyping under the supervision of RD. All the authors read and approved the final manuscript.

Keywords

obesity; *FTO*; association analysis; Samoa

Introduction

Genome-wide association studies (GWAS) have provided new insights into obesity genetics with the identification of sequence variants in several genes including *INSIG2*, *FTO*, *MC4R*, *BDNF*, *SH2B1* (Herbert et al. 2006; Frayling et al. 2007; Dina et al. 2007; Loos et al. 2008; Chambers et al. 2008; Thorleifsson et al. 2009). Among these genes, *FTO* has emerged as the strongest candidate conferring risk to obesity, with replication of common variants across populations of European and Hispanic descent (Dina et al. 2007; Frayling et al. 2007; Scuteri et al. 2007; Grant et al. 2008; Thorleifsson et al. 2009). Less certain and inconclusive, however, are the associations of *FTO* variants with body fatness measures in Asian populations (Cha et al. 2008; Ng et al. 2008; Tan et al. 2008; Li et al. 2008; Yajnik et al. 2009; Fang et al. 2010; Li et al. 2010). In comparison to most worldwide populations, levels of obesity are considerably higher in Oceanic populations (Collins et al. 1990) and associations of GWAS obesity-related loci among these populations are yet to be thoroughly explored. Based on a relatively smaller number of subjects, Ohashi et al. (2007) reported that *FTO* variants are not associated with obesity in six Oceanic populations, including one Polynesian group from Tonga. We conducted an association study of common *FTO* variants with obesity-related traits among Samoans of Polynesia who have a remarkably high prevalence of overweight and obesity (McGarvey 1991; Keighley et al. 2006).

Samoans of Polynesia are distributed in two polities, the independent nation of Samoa and the U.S. territory of American Samoa. Both groups share a common evolutionary history, form a single socio-cultural unit with frequent exchange of mates and genetically represent a single homogenous population without evidence of substructure (McGarvey 2001; Tsai et al. 2004). There is, however, substantial economic disparity between the two locales, which reflects the patterns of distribution of adiposity in the two groups. Based on the Polynesian body mass index (BMI) standards of 26–32 kg/m², and >32 kg/m² defining overweight and obesity, respectively (Swinburn et al. 1999), 59% of men and 71% of women are obese in American Samoa compared to 29% of men and 53% women in the less developed nation of Samoa (Keighley et al. 2006). To determine the significance of *FTO* variants in this population, we conducted a comprehensive association analysis of *FTO* tagging variants, supplemented with previously identified GWAS SNPs and SNPs imputed from the Phase III HapMap database with measures of obesity in adults residing in the Samoan islands. We expanded the phenotypic traits beyond those typically included in GWAS (classical measures including weight and BMI) to 12 anthropometric measures of body fatness and skeletal robustness. In all, we tested association of 51 *FTO* variants in a sample of 1,089 unrelated individuals.

Materials and Methods

Subjects

A total of 1,089 adult individuals (465 American Samoan and 624 Samoan) were included in this study. The sample from American Samoa included 260 males and 205 females; the Samoan sample included 300 males and 324 females. These subjects were recruited in a previous longitudinal study of adiposity and cardiovascular disease risk factors performed from 1990 to 1995 (Galanis et al. 1999; McGarvey 2001). They were between the ages of 25 and 59 years with all four grandparents of Samoan ancestry. Anthropometric measurements of height (Ht), weight (Wt), waist circumference (WC), hip circumference (HC) were

obtained following standard protocols. Body mass index ($BMI = Wt \text{ in kg}/Ht \text{ in m}^2$), and waist-hip ratio ($WHR = WC/HC$) were calculated. A set of body fat measures including thigh circumference (THICIR), upper arm circumference (UAC), and calf circumference (CLFCIR) were obtained. In addition, three measures of skeletal mass and frame size were obtained according to Lohman et al. (1998), including the elbow breadth (distance between the epicondyles of the humerus), wrist breadth (distance between the medial aspect of ulna styloid and lateral aspect of radial styloid), and knee breadth (the distance between the most medial and lateral aspects of the femoral condyles). All data were collected at baseline, 1990 to 1991.

SNP Selection and Genotyping

A total of 32 SNPs, including 24 tagging SNPs within 30kb upstream and 30kb downstream of the original and potentially most significant *FTO* SNP (rs9939609) reported by Frayling et al (2007) and seven additional significant SNPs from previous GWAS (rs9939973, rs1421085, rs1121980, rs17817449, rs8050136, rs3751812, rs7190492) were genotyped. Tagging SNPs were selected based on pairwise r^2 (≥ 0.8) among all common SNPs with minor allele frequency ($MAF \geq 0.05$) using the approach of Carlson et al. (2004). These SNPs fall within introns 1 and 2 of the *FTO* gene. In addition, we imputed SNPs to increase the coverage of *FTO* variants within a 70 kb region containing the original SNPs. Imputation was performed using all available populations in HapMapIII as reference, since the inclusion of multiple reference haplotypes increases the performance and quality of the imputation in novel populations (Marchini & Howie, 2010). The final set of SNPs included in the study was 60, with 24 tagging, 8 GWAS and 28 imputed SNPs. The SNPlex protocol (Applied Biosystems) was used for SNP genotyping, which is a multiple oligonucleotide ligation/PCR assay with universal ZipChute probe detection. Six internal replicates and negative controls were included to assure genotypic quality control, the consistency rate was 100%. The overall genotype call rate of the 32 genotyped SNPs was $>99.5\%$.

Statistical Analysis

Descriptive statistics of the study sample were computed using SAS v.9.2 (SAS Institute, Inc. Cary, NC USA). All phenotypic traits were normalized using the Box-Cox method, and adjusted for age and gender. Linkage disequilibrium (LD; r^2) between markers was estimated in Haploview (v.4.1) (Barrett et al. 2005). Genotype imputation was performed in Mach1, a Markov chain-based haplotyper for unrelated populations (Li et al. 2009) and imputed SNPs were compiled with original SNPs prior to association testing. All genetic association analyses were performed using PLINK v1.07 (Purcell, 2007), using a 1 df linear model to assess the additive effects of the SNPs. A permutation test with 10,000 replications was used to assess significance after accounting for the presence of multiple markers. Association results were combined through fixed-effects meta analyses using PLINK v1.07. Genotype frequencies and their conformity to Hardy-Weinberg equilibrium (HWE) were also assessed in PLINK, using an exact test (Wigginton et al. 2005). SNPs that showed significant deviations from HWE with a P -value of $<.01$ and/or had an MAF of $<.05$ were excluded from analysis.

Results

Descriptive statistics of the 12 anthropometric measures from both polities are presented in Table 1. As previously stated, all measures were adjusted for the effects of age and gender due to their correlation with body fat. The American Samoans had significantly higher fat-related measures, were taller, and significantly larger skeletal measurements except elbow breadth in comparison to the Samoans.

Two genotyped SNPs and seven imputed SNPs were excluded from the analysis due to low MAF ($<.05$) and deviations from HWE ($P <.01$). The pairwise LD plot of the remaining 51 SNPs was identical for American Samoa and Samoa (data not shown). There were no significant differences in allele frequencies between American Samoa and Samoa; compiled SNP statistics with comparative minor allele frequencies from Asian (CHB) and Caucasian (CEU) HapMaps are presented in Table 2. In general, Samoan allele frequencies were relatively closer to those of the Asian population than those of the Caucasian population. Of note, MAFs of the previously reported eight GWAS SNPs were significantly lower in both Samoan groups (0.161–0.239) than the CEU (0.292–0.478).

We tested associations of 51 SNPs with the anthropometric traits adjusted for age and gender. The analysis was performed separately for American Samoan and Samoan samples due to significant differences in phenotypic traits between the two polities (see Table 1). Thirty-six out of 1,224 P -values were nominally significant, though none were previous GWAS SNPs (Table 3; all data with the nominal P -values are presented in Supplementary Tables 1 and 2). Thirty-two of the thirty six nominal associations were observed in Samoan sample. Of these, 26 were associated with measures of skeletal robustness (height and knee, wrist, and elbow breadth). No significant association, however, was found with any SNP after correction for multiple testing. A combined analysis and gender-specific analysis of the *FTO* SNPs in the American Samoa and Samoa did not uncover any further associations (data not shown). Finally, a meta analysis was performed to uncover any consistent signals of association observed in both polities, but the results did not change (Supplementary Table 3). A second meta analysis was performed to combine the association signals of rs9939609 in both Samoan polities and the Tongan population reported by Ohashi et al (2007), but the signal remained insignificant ($P=0.424$).

Since the majority of previous *FTO* reports have included BMI as the principal phenotype, we have estimated the effect sizes of nominally significant SNPs on BMI in the American Samoa and Samoan samples. There was no commonly associated SNP with BMI between the two polities; the effect size estimates for the two SNPs in Samoa (rs1861869, $\beta = -0.347$; rs7186521, $\beta = -0.586$) were lower than the SNP effect size estimate in American Samoa (rs1164281, $\beta = -0.931$). The confidence intervals of these estimates (Table 3) overlapped with reported point estimates in previous GWAS.

Discussion

We investigated the association of 51 tagging, GWAS and imputed SNPs with an expanded set of obesity-related anthropometric measures among Samoans and American Samoans. With respect to the phenotypic traits, there were significant differences in all measures of fatness and skeletal robustness (except elbow breadth) between the two Samoan groups, with the American Samoans showing significantly higher mean values of these traits. This likely reflects the effect of differential exposure to modernization with relatively higher affluence in American Samoa and a more neo-traditional life in Samoa (Keighley et al. 2006; McGarvey 1991, 1994). There was, however, no difference in allele frequency distributions and LD patterns between the two groups reaffirming that the American Samoans and Samoans share a common genetic background as reported previously (Deka et al. 1994; Tsai et al. 2004).

Although *FTO* has emerged as a major gene influencing obesity particularly in populations of European descent, results from Asian populations have been less conclusive. Our study does not provide replication among the Samoans, which can be attributed to several reasons. First, our sample size (465 American Samoans and 624 Samoans) may not have adequate power to capture the effect of the variants. For example, we have 80% power to detect a

BMI effect size of 1.01 kg/m² in the American Samoan sample, 0.88 kg/m² in the Samoan sample, and 0.664 kg/m² in the combined sample, based on the allele frequency in our study populations of the widely replicated obesity-related *FTO* SNP (rs9939609) at alpha equal to 0.05. We have the power to detect only effect sizes that are somewhat larger than those reported in previous studies of *FTO* in Asian and Oceanic populations (Ohashi et al. 2007); therefore, we cannot conclusively rule out the involvement of *FTO* with obesity. Although we have greater power to detect smaller effect sizes in the combined sample, there were significant differences in phenotypic measurements between the two groups, and as noted above a meta analysis combining the two samples did not reveal significant associations after correcting for multiple testing. Effect size confidence intervals of SNPs nominally associated with BMI in our study population include the point estimates of previous GWAS reports, which might indicate inadequate power to maintain significance following adjustment for multiple testing. The effect size of *FTO* SNPs on BMI was stronger in the American Samoa sample than the Samoan sample, which may reflect the decreased power to detect smaller effects due to lower sample size, or the environmental component of excess caloric intake and sedentary lifestyles may obscure the direct genetic impact. Second, Samoan allele frequencies are significantly different from those in the reported GWAS and replication studies, particularly the European populations. Corollary to this is the evolutionary history of the Polynesians, who migrated from Southeast Asia about 4,000 to 5,000 years ago (Kirch 2000; Soares 2011). This together with a likely founder effect followed by genetic drift resulting in allele frequency changes could have masked the contribution of the *FTO* variants on obesity-related phenotypes among the Polynesians. Third, body compositions of contemporary Samoans are different from the Europeans with higher body and subcutaneous fat mass, bone mineral density as well as higher proportion of fat-free soft tissue (Swinburn et al, 1999). This may suggest that mechanisms underlying energy balance in Polynesians are different. This could implicate instead other genetic loci with stronger influence on obesity-related traits that may be influenced by physiological and anthropometric differences between Asian and Caucasian populations. In addition, the high BMI of the population per se may contribute to the non-replication, which could account in part for the limited signal detection in the American Samoan sample. A study among six Oceanic populations that included 116 Tongans from Polynesia also did not replicate the association of *FTO* variants with BMI (Ohashi et al. 2007); though this study was somewhat underpowered, these and the combined results from our second meta analysis substantiate our non-replication. Based on inconclusive studies, it could be surmised that *FTO* is not likely a major obesity locus in populations of Asian descent.

Tsai H-J, Sun G, Smelser D, Viali S, Tufa J, Jin L, Weeks DE, McGarvey ST, Deka R. Distribution of genome-wide linkage disequilibrium based on microsatellite loci in the Samoan population. *Hum Genomics.* 2004; 1:327–334. [PubMed: 15588493]

Wigginton JE, Cutler DJ, Abecasis GR. A Note on Exact Tests of Hardy-Weinberg Equilibrium. *Am J Hum Genet.* 2005; 76:887–893. [PubMed: 15789306]

Yajnik CS, Janipalli CS, Bhaskar S, Kulkarni SR, Freathy RM, Prakash S, Mani KR, Weedon MN, Kale SD, Deshpande J, Krishnaveni GV, Veena SR, Fall CHD, McCarthy MI, Frayling TM, Hattersley AT, Chandak GR. FTO gene variants are strongly associated with type 2 diabetes but only weakly with obesity in South Asian Indians. *Diabetologia.* 2009; 52:247–252. [PubMed: 19005641]

Table 1

Descriptive statistics of the phenotypic measures

Trait	American Samoa (N = 465)	Samoa (N = 624)	P
	Mean ± S.D.	Mean ± S.D.	
Age (years)	38.58 ± 7.83	38.09 ± 8.82	0.34
Height* (cm)	166.86 ± 8.02	164.97 ± 8.03	0.0001
Body Mass Index* (kg/m ²)	34.71 ± 6.16	29.90 ± 5.22	< .0001
Weight* (kg)	97.24 ± 19.72	81.43 ± 15.22	< .0001
Waist Circumference* (cm)	108.04 ± 15.01	95.10 ± 13.37	< .0001
Hip Circumference* (cm)	114.74 ± 12.71	103.48 ± 10.20	< .0001
Waist-Hip-Ratio*	0.94 ± .06	0.92 ± .07	< .0001
Calf Circumference (cm)	42.59 ± 4.47	39.47 ± 3.80	< .0001
Thigh Circumference* (cm)	48.38 ± 6.08	44.54 ± 5.37	< .0001
Upper Arm Circumference* (cm)	37.65 ± 4.85	34.03 ± 4.11	< .0001
Elbow (cm)	6.88 ± .76	6.94 ± 0.66	0.16
Wrist* (cm)	5.68 ± .58	5.57 ± .44	0.0004
Knee* (cm)	10.41 ± 1.21	10.05 ± 1.08	<.0001

* Denotes American Samoa mean values are significantly greater than Samoa mean values
