Summary. Comparative studies were made of semen samples from subfertile RR and normally fertile rr cockerels. These samples were obtained either by abdominal massage or directly from the tip of papillae. The numbers of collected sperm did not differ between genotypes and the sperm from RR cockerels were less motile than those from rr cockerels irrespective of the semen collection method. The uric acid concentration of seminal plasma was influenced by the semen collection method (massage > papillae) but no variations were induced by the genotypes. The ATP-ase and acid phosphatase activities found in the seminal plasma were influenced respectively by the genotype ($rr > RR$) and the semen collection method (papillae > massage). The fumarase and acrosin activities found in the sperm were not influenced by the semen collection methods while acrosin activity was found to be higher in RR than in rr cockerels. Correlations between these various characteristics are given in detail.

Introduction.

According to Cochez (1951) the low fecundity observed in the White Wyandotte breed is due to the subfertility of those cockerels which are homozygous for rose comb (RR). This male subfertility influences both the egg fertility level and the duration of the fertile period in the hen (Crawford and Smyth, 1961a, b, c). A deficiency in the semen quality of RR cockerels can explain their low fertility, because the sperm motility observed after dilution and storage of semen has been found to be subnormal (Petitjean and Cochez, 1966). The fumarase activity of sperm is also depressed in RR cockerels (Buckland *et al.*, 1968). In contrast, no anomaly has been found in the seminal plasma of these cockerels (Crawford and Smyth, 1964c ; Peyre *et al.*, 1968 ; Petitjean, 1970).

The present work reports a comparison of several biochemical constituents of semen collected from RR and rr cockerels : uric acid, ATP-ase, acid phosphatase fumarase and acrosine. Uric acid is a normal contaminant of semen collected by the

massage method. ATP-ase and acid phosphatase are particle-linked enzymes found in the seminal plasma itself, while fumarase is chiefly an intracellular enzyme associated with mitochondria. Its activity could therefore explain the depressed motility of the sperm collected from RR cockerels. Acrosin was studied as it is a component of the acrosome.

Materials and methods.

Animals. — Cockerels from two lines were used (M88 S = single comb ; M88 R = rose comb) derived from the M88 strain in which the males are *dw/dw*.

The experiments involved 29 cockerels of each line, at 22 weeks of age. They were raised under 16 hrs of light daily, individually caged, with food and water available *ad libitum*.

Each line was divided into 4 groups of 7-8 cockerels. The ejaculates were pooled for each group. After 3 days of habituation to pelvic massage, sperm collections were carried out once a day for 4 consecutive days (D1 to D4). On the following day, the cockerels were killed and their semen was collected directly on the tip of their ejaculatory papillae at autopsy.

In each semen sample, the volume, the sperm concentration, the total number of spermatozoa and their motility was determined.

Semen sample preparation. — After centrifugation ($1\,500 \times g$, 10 min, $0\text{ }^{\circ}\text{C}$) the seminal plasma was decanted, then filtered (Millipore, $0.45\ \mu\text{m}$) to eliminate any sperm debris. The sperm pellet was resuspended in phosphate buffer pH 7.0 and centrifuged again. The filtered plasmas and the washed pellets were frozen, then stored at $-18\text{ }^{\circ}\text{C}$ until assayed.

Assays.

1) In the filtered frozen-thawed seminal plasma fractions, uric acid was assayed by the uricase method (Praetorius, 1963). Other fractions from each seminal plasma were centrifuged again after thawing at $40\,000 \times g$, 30 min, at $0\text{ }^{\circ}\text{C}$ to separate a particle pellet in which acid phosphatase and ATP-ase were assayed by spectrophotometry. The first enzyme (E.C. : 3.1.3.2) was assayed at $\lambda = 400\text{ nm}$ in the presence of sodium paranitrophenyl phosphate ($4.75 \times 10^{-3}\text{ M}$) in citrate buffer (0.1 M, pH = 5.25, $25\text{ }^{\circ}\text{C}$). The second enzyme (E.C. 3.6.1.3) was assayed at $\lambda = 340\text{ nm}$, pH = 8.0, in the presence of ATP-Mg⁺⁺ ($5 \times 10^{-4}\text{ M}$) and the auxiliary enzymes pyruvate and lactico-dehydrogenase (Horgan *et al.*, 1972).

2) After thawing, the sperm pellet was washed at $0\text{ }^{\circ}\text{C}$ using Tris-HCl buffer (0.02 M, pH = 8.2), then sonicated ($5 \times 30\text{ sec}$ with 30 sec of delay between consecutive treatments). The sonicated sperm were then centrifuged (30 min, $40\,000 \times g$, $0\text{ }^{\circ}\text{C}$). Two enzymes were assayed in the supernatant : 1) Fumarase (E.C. : 4.2.1.2) in the presence of 1-malate 0.05 M (Hill and Bradshaw, 1969) ; 2) Acrosine (E.C. : 3.4.21.10) in the presence of α -N-benzoyl-dl-arginine para nitroaniline HCl (DL-Bapna) 10^{-3} M , dissolved in 10 p. 100 (V/V) dimethylsulfoxide and Tris-HCl buffer (0.1 M, pH = 8.2) (Erlanger *et al.*, 1961).

Furthermore, uric acid (mg/l), acid phosphatase ($\mu\text{M}/10^9$) and fumarase ($\mu\text{M}/10^9$) were also assayed after extraction from the sperm cells.

An analysis of variance was performed using the following model :

$$Y_{ijk1} = D_i + G_j + (DG)_{ij} + C_{jk} + (DC)_{ijk} + E_{ijk1}$$

where D_i is the day of the semen collection ($i = 1, 2, 3, 4$) ; G_j , the genotype of the cockerels (S or R) ; $(DG)_{ij}$, the day \times genotype interaction ; C_{jk} , the K^0 group of cockerels within the J^0 genotype ; $(DC)_{ijk}$, the day \times group interaction ; E_{ijk1} , residual assumed to be independent with a mean of zero and the same variance normally distributed ; Y_{ijk1} , factor to be analyzed, for example no. of spermatozoa.

Results.

1. Ejaculates collected from the 1st to the 4th day (tables 1 and 2).

a) *Biophysical observations.* — There was no significant day \times genotype interaction in the characteristics of ejaculates (volume, sperm concentration, total number of sperm per ejaculate, motility). The genotype strongly influenced the volume of ejacu-

lates (1.8 ml in *RR* vs 2.44 ml in *rr*) and sperm motility (14.7 vs 47.4). The day of collection, however, had no influence upon sperm motility, while the volume of the semen and the total number of sperm per ejaculate were significantly decreased from days 1 to 4. The differences found in the sperm concentration from days 1 to 4 were also significant but not clearly related to the day of semen collection.

b) *Biochemical assays.* — The day of collection significantly influenced the ATP-ase and the fumarase activities. The ATP-ase was highest on day 1 and then became relatively stable in both genotypes. The fumarase activity decreased from day 1 to day 4 in both genotypes but was exceptionally high on day 3 in *rr* cockerels, which explained the days \times genotype interaction for this semen characteristic,

Significant differences between genotypes were observed in the ATP-ase and acrosine activities, the first being higher in the *rr* cockerels while the second was, by contrast, lower in this strain.

2. *Comparison between the results of the two semen collection techniques.* — The following are the results obtained for semen collection by massage compared to those obtained for semen collected at the tip of the papillae. Between-genotype differences are also considered (table 3).

a) *Biophysical results.* — The volume of the semen collected at the tip of the papillae was significantly higher than that of samples collected by massage technique. The same trend was observed for sperm concentration, and thus, in the total number of sperm per sample (3.34 and 4.64×10^9 sperm vs 10.57 and 8.85×10^9 sperm in *RR* and *rr* cockerels, respectively). Interestingly, there were no significant differences between the techniques for motility results.

Irrespective of the semen collection technique, the volume of the semen samples was higher in *rr* than in *RR* cockerels, while the reverse was observed for the sperm

concentration results. This resulted in a non-significant difference between strains for the total number of sperm per sample. Sperm motility was more than three times higher in *rr* than in *RR* cockerels.

	<i>rr</i>	0.362	(0.063)	0.498	(0.127)	

b) *Biochemical assays.* — A considerable between-technique difference was observed for the uric acid concentration which was 3 to 4 times higher in the massage samples than in the papillae samples. The acid phosphatase activity was significantly higher in the latter case than in the former. No significant differences were observed for the other enzymes (ATP-ase, acrosine, fumarase).

Only one significant difference was observed between the genotypes : ATP-ase was 25 to 30 p. 100 higher in *rr* than in *RR* cockerels.

3. Correlations between semen characteristics (table 4).

a) *Particle-linked enzymes.* — Positive correlations were observed between the activities of the particle-linked enzymes in the seminal plasma and the volume of the semen samples for *RR* cockerels and for *RR* + *rr* cockerels taken together.

* 0.05 > P > 0.01; ** P < 0.01.

The ATP-ase activity was negatively correlated with the sperm concentration, but positively correlated with motility in $RR + rr$ cockerels taken together. However, no significant correlation was found within individual genotypes.

Acid phosphatase was significantly correlated with the total number of sperm per semen sample but not with the sperm concentration.

b) *Intraspermic enzymes*. — In the case of rr cockerels only, there was a negative correlation between acrosine activity and either the volume of the semen samples or the total number of sperm in these samples. The fumarase activity was positively correlated with the semen sample volume, but only in the RR cockerels.

Discussion.

The present results agree with previous observations (Petitjean and Cochez, 1966). While the RR genotype has no significant influence upon the amount of semen, this genotype strongly depresses the sperm motility observed after dilution and storage. In the present work, similar results were found for semen directly collected from the papillae. The lower motility found in the sperm from RR cockerels is therefore not due to contamination of the semen at the time of collection.

The concentration of uric acid found in the seminal plasma from semen collected by either the massage method (350 vs 375 mg/l in RR vs rr cockerels, respectively) or directly from the papillae (124 vs 97 mg/l, respectively) are the same or slightly higher than those found by Lake (1971) in semen samples either contaminated (375 mg/l) or uncontaminated (78 mg/l) with transparent fluid. As the difference between RR and rr cockerels for uric acid concentration is not statistically significant, this component would not appear to be implicated in the low fertility found in RR cockerels.

It is known (Lake, 1962) that acid phosphatases are secreted throughout the genital tract of the cockerel but the relationships between these enzymes and the spermatozoa are still obscure. Our observations on particle-linked acid phosphatase cannot clarify the relationship between the activity of this enzyme and the subnormal motility and fertility found in the spermatozoa from RR cockerels. It was found that the acid phosphatase activity is 1.5 higher in semen samples collected directly from papillae than in those collected by massage. For the latter, there are positive correlations between the activity of acid phosphatase and either the volume of ejaculates or their total number of spermatozoa. However, ATP-ase activity varied independently of acid phosphatase activity yet both enzymes are particle-linked. ATP-ase activity depends upon the semen collection method and its activity is positively correlated with the volume of ejaculates but negatively correlated with their sperm concentration. Although ATP-ase activity and motility was less in RR than in rr cockerels, no correlation was found between ATP-ase activity and motility.

No consistent relationships were found between acrosin activity and either genotype or fertilizing ability or semen collection method. The same was true for fumarase activity, despite a previous report of depressed fumarase activity in RR cockerels (Buckland *et al.*, 1968). Differences between strains and techniques (extraction and assay of the enzyme) might explain the discrepancy.

Conclusion.

This work has confirmed that the motility of the spermatozoa is depressed in *RR* cockerels. This depression is not due to the semen collection method, although this modifies the semen characteristics.

ATP-ase activity, like motility, is depressed in *RR* cockerels : this activity could therefore be useful in predicting the fertilizing ability of the spermatozoa or for diagnosing the status of the genital tract of cockerels.

Résumé. Les spermatozoïdes de coqs *RR* (subfertiles) et *rr* (fertiles) sont étudiés comparative-ment. Les échantillons sont obtenus d'une part, par massage abdominal, d'autre part, directement à la papille. Les quantités de spermatozoïdes collectées ne diffèrent pas significativement entre les génotypes et ceci pour les deux modes de collecte mis en œuvre. La motilité subnormale des spermatozoïdes des coqs *RR* est très nette quelle que soit la technique de prélèvement du sperme. Le mode de collecte influe considérablement le taux d'acide urique (massage > papille), mais sans effet significatif du génotype. L'activité de l'ATP-ase est significativement influencée par le génotype (*rr* > *RR*) tandis que le mode de collecte a une action significative sur l'activité de la phosphatase acide (papille > massage). Le mode de collecte et le génotype n'ont pas d'effet significatif sur l'activité de la fumarase. Il en est de même pour le mode de collecte de l'acrosine, mais une différence significative de l'activité de cette enzyme est observée entre les génotypes (*RR* > *rr*). Les corrélations entre les caractères observés sont étudiées.
