<sup>2</sup> Google Inc. and Columbia University (USA)

**Abstract.** Introduced by Micali, Rabin and Kilian (MRK), the basic primitive of zero-knowledge sets (ZKS) allows a prover to commit to a secret set  $S$  so as to be able to prove statements such as  $x \in S$  or  $x \notin S$ . Chase *et al.* showed that ZKS protocols are underlain by a cryptographic primitive termed *mercurial commitment*. A (trapdoor) mercurial commitment has two commitment procedures. At committing time, the committer can choose not to commit to a specific message and rather generate a dummy value which it will be able to softly open to any message without being able to completely open it. Hard commitments, on the other hand, can be hardly or softly opened to only one specific message. At Eurocrypt 2008, Catalano, Fiore and Messina (CFM) introduced an extension called trapdoor  $q$ -mercurial commitment (qTMC), which allows committing to a vector of  $q$  messages. These qTMC schemes are interesting since their openings w.r.t. specific vector positions can be short (ideally, the opening length should not depend on  $q$ ), which provides zero-knowledge sets with much shorter proofs when such a commitment is combined with a Merkle tree of arity  $q$ . The CFM construction notably features short proofs of *non-membership* as it makes use of a qTMC scheme with short soft openings. A problem left open is that hard openings still have size  $O(q)$ , which prevents proofs of membership from being as compact as those of non-membership. In this paper, we solve this open problem and describe a new qTMC scheme where hard and soft position-wise openings, both, have *constant size*. We then show how our scheme is amenable to constructing independent zero-knowledge sets (i.e., ZKS schemes that prevent adversaries from correlating their set to the sets of honest provers, as defined by Gennaro and Micali). Our solution retains the short proof property for this important primitive as well.

**Keywords.** Zero-knowledge databases, mercurial commitments, efficiency, independence.

## 1 Introduction

Introduced by Micali, Rabin and Kilian [21], zero-knowledge sets (ZKS) are fundamental secure data structures which allow a prover  $P$  to commit to a finite set  $S$  in such a way that, later on, he will be able to efficiently (and non-interactively) prove statements of the form  $x \in S$  or  $x \notin S$  without revealing anything else on  $S$ , not even its size. Of course, the prover should not be able to cheat and prove different statements about an element  $x$ . The more general notion of zero-knowledge elementary databases (ZK-EDB) generalizes zero-knowledge sets in that each element  $x$  has an associated value  $D(x)$  in the committed database.

In [21], Micali *et al.* described a beautiful construction of ZK-EDB based on the discrete logarithm assumption. The MRK scheme relies on the shared random string model (where a random string chosen by some trusted entity is made available to all parties) and suitably uses an extension of Pedersen's trapdoor commitment [23]. In 2005, Chase *et al.* [10] gave general constructions of zero-knowledge databases and formalized a primitive named *mercurial commitment* which they proved to give rise to ZK-EDB protocols. The MRK construction turned out to be a particular instance of a general design combining mercurial commitments with a Merkle tree [20], where each

internal node contains a mercurial commitment to its two children.

Informally speaking, mercurial commitments are commitments where the binding property is slightly relaxed in that the committer is allowed to *softly* open a commitment and say “if the commitment can be opened at all, then it opens to that message”. Upon committing, the sender has to decide whether the commitment will be a hard commitment, that can be hard/soft-opened to only one message, or a soft one that can be soft-opened to any arbitrary message without committing the sender to a specific one. Unlike soft commitments that cannot be hard-opened, hard commitments can be opened either in the soft or the hard manner but soft openings can never contradict hard ones. In addition, hard and soft commitments should be computationally indistinguishable.

RELATED WORK. Promptly after the work of Micali, Rabin and Kilian, Ostrovsky, Rackoff and Smith [22] described protocols for generalized queries (beyond membership/non-membership) for committed databases and also show how to add privacy to their schemes. Liskov [18] also extended the construction of Chase *et al.* [10] to obtain updatable zero-knowledge databases in the random oracle model. Subsequently, Catalano, Dodis and Visconti [8] gave simplified security definitions for (trapdoor) mercurial commitments and notably showed how to construct them out of one-way functions in the shared random string model.

In order to extend the properties of non-malleable commitments to zero-knowledge databases, Gennaro and Micali [15] formalized the notion of *independent* ZK-EDBs. Informally, this notion prevents adversaries from correlating their committed databases to those produced by honest provers.

More recently, Prabhakaran and Xue [24] defined the related notion of statistically hiding sets that requires the hiding property of zero-knowledge sets to be preserved against unbounded verifiers. At the same time, their notion of zero-knowledge was relaxed to permit unbounded simulators.

At Eurocrypt 2008, Catalano, Fiore and Messina [9] addressed the problem of compressing proofs in ZK-EDB schemes and significantly improved upon earlier proposals.

OUR CONTRIBUTION. The original construction of zero-knowledge database [21, 10] considers a binary Merkle tree of height  $O(\lambda)$ , where  $\lambda$  is the security parameter (in such a way that the upper bound on the database size is exponential in  $\lambda$  and leaks no information on its actual size). Each internal node contains a mercurial commitment to (a hash value of) its two children whereas each leaf node is a mercurial commitment to a database entry. The crucial idea is that internal childless nodes contain soft commitments, which keeps the commitment generation phase efficient (*i.e.*, polynomial in  $\lambda$ ). A proof of membership for the entry  $x$  consists of a sequence of hard openings for commitments appearing in nodes on the path from leaf  $x$  to the root. Proofs of non-membership proceed similarly but rather use soft openings along the path.

As noted in [9], the above approach often results in long proofs, which may be problematic in applications, like mobile Internet connections, where users are charged depending on the number of blocks that they send/receive. To address this issue, Catalano, Fiore and Messina (CFM) suggested to increase the branching factor  $q$  of the tree and to use a primitive called *trapdoor  $q$ -mercurial commitment* (qTMC). The latter is like an ordinary mercurial commitment with the difference that it allows committing to a vector of  $q$  messages at once. With regular mercurial commitments, increasing the arity of the tree is not appropriate as generating proofs entails to reveal  $q$  values (instead of 2) at each level of the tree. However, it becomes interesting with qTMC schemes that can be opened with respect to specific vector positions without having to disclose each one of the  $q$  committed messages. The CFM construction makes use of an elegant qTMC scheme where soft commitment openings consist of a single group element, which yields dramatically shorter proofs of non-membership. On the other hand, hard openings unfortunately comprise  $O(q)$  elements in the

qTMC scheme described in [9]. For this reason, proofs of membership remain significantly longer than proofs of non-membership.

In this paper, we solve a problem left open in [9] and consider a primitive called *concise* mercurial vector commitment, which is a qTMC scheme allowing to commit to a  $q$ -vector in such a way that (1) hard and soft position-wise openings *both* have constant (*i.e.*, independent of  $q$ ) size; (2) the committer can hard-open the commitment at position  $i \in \{1, \dots, q\}$  without revealing anything on messages at other positions in the vector. We describe a simple and natural example of such scheme. Like the CFM  $q$ -mercurial commitment, our realization relies on a specific number theoretic assumption in bilinear groups. Implementing the CFM flat-tree system with our scheme immediately yields very short proofs of membership and while retaining short proofs of non-membership. Assuming that  $2^\lambda$  is a theoretical bound on the database size, we obtain proofs comprising  $O(\lambda/\log(q))$  group elements for membership and non-membership. In the CFM system, proofs of membership grow as  $O(\lambda \cdot q/\log(q))$ , which prevents one from compressing proofs of non-membership without incurring a blow-up in the length of proofs of membership. Using our commitment scheme, both kinds of proof can be shortened by increasing  $q$  as long as the common reference string (which has size  $O(q)$  as in [9]) is not too large. With  $q = 128$  for instance, proofs do not exceed 2 kB in instantiations using suitable parameters.

In addition, we also show that our qTMC scheme easily lends itself to the construction of independent zero-knowledge databases. To construct such protocols satisfying a strong definition of independence, Gennaro and Micali [15] used *multi-trapdoor* mercurial commitments that can be seen as families of mercurial commitments (in the same way as multi-trapdoor commitments [14] are families of trapdoor commitments). Modulo appropriate slight modifications, our scheme can be turned into a concise multi-trapdoor qTMC scheme. It thus gives rise to the first ZK-EDB realization that simultaneously provides independence and short proofs.

ORGANIZATION. Section 2 recalls the definitions of qTMC schemes and zero-knowledge databases. We describe the new  $q$ -mercurial commitment scheme and discuss its efficiency impact in sections 3 and 4. Section 5 finally explains how the resulting ZK-EDB scheme can be made independent.

## 2 Background

### 2.1 Complexity Assumptions

We use groups  $(\mathbb{G}, \mathbb{G}_T)$  of prime order  $p$  with an efficiently computable map  $e : \mathbb{G} \times \mathbb{G} \rightarrow \mathbb{G}_T$  such that  $e(g^a, h^b) = e(g, h)^{ab}$  for any  $(g, h) \in \mathbb{G} \times \mathbb{G}$ ,  $a, b \in \mathbb{Z}$  and  $e(g, h) \neq 1_{\mathbb{G}_T}$  whenever  $g, h \neq 1_{\mathbb{G}}$ . In this mathematical setting, we rely on a computational assumption previously used in [5, 6].

**Definition 1 ([5]).** *Let  $\mathbb{G}$  be a group of prime order  $p$  and  $g \in \mathbb{G}$ . The  $q$ -Diffie-Hellman Exponent ( $q$ -DHE) problem is, given elements  $(g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q})$  such that  $g_i = g^{(\alpha^i)}$ , for  $i = 1, \dots, q, q+2, \dots, 2q$  and where  $\alpha \stackrel{R}{\leftarrow} \mathbb{Z}_p^*$ , to compute the missing group element  $g_{q+1} = g^{(\alpha^{q+1})}$ .*

As noted in [6], this problem is not easier than the one used in [5], which is to compute  $e(g, h)^{(\alpha^{q+1})}$  on input of the same values and the additional element  $h \in \mathbb{G}$ . The generic hardness of  $q$ -DHE is thus implied by the generic security of the family of assumptions described in [4].

### 2.2 Trapdoor $q$ -Mercurial Commitments

A trapdoor  $q$ -mercurial commitment (qTMC) consists of a set of efficient algorithms (qKeygen, qHCom, qHOpen, qHVer, qSCom, qSOpen, qSVer, qFake, qHEquiv, qSEquiv) with the following specifications.

- $\text{qKeygen}(\lambda, q)$ : takes as input a security parameter  $\lambda$  and the number  $q$  of messages that can be committed to in a single commitment. The output is a pair of public/private keys  $(pk, tk)$ .
- $\text{qHCom}_{pk}(m_1, \dots, m_q)$ : takes as input an ordered tuple of messages. It outputs a hard commitment  $C$  to  $(m_1, \dots, m_q)$  under the public key  $pk$  and some auxiliary state information  $\text{aux}$ .
- $\text{qHOpen}_{pk}(m, i, \text{aux})$ : is a hard opening algorithm. Given a pair  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$ , it outputs a hard de-commitment  $\pi$  of  $C$  w.r.t. position  $i$  if  $m = m_i$ . If  $m \neq m_i$ , it returns  $\perp$ .
- $\text{qHVer}_{pk}(m, i, C, \pi)$ : is the hard verification algorithm. It outputs 1 if  $\pi$  gives evidence that  $C$  is a commitment to a sequence  $(m_1, \dots, m_q)$  such that  $m_i = m$ . Otherwise, it outputs 0.
- $\text{qSCom}_{pk}()$ : is a probabilistic algorithm that generates a soft commitment and some auxiliary information  $\text{aux}$ . Such a commitment is not associated with a specific sequence of messages.
- $\text{qSOpen}_{pk}(m, i, \text{flag}, \text{aux})$ : generates a soft de-commitment (a.k.a. “tease”)  $\tau$  of  $C$  to the message  $m$  at position  $i$ . The variable  $\text{flag} \in \{\mathbb{H}, \mathbb{S}\}$  indicates whether the state information  $\text{aux}$  corresponds to a hard commitment  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$  or a soft one  $(C, \text{aux}) = \text{qSCom}_{pk}()$ . If  $\text{flag} = \mathbb{H}$  and  $m \neq m_i$ , the algorithm returns the error message  $\perp$ .
- $\text{qSVer}_{pk}(m, i, C, \tau)$ : returns 1 if  $\tau$  is a valid soft de-commitment of  $C$  to  $m$  at position  $i$  and 0 otherwise. If  $\tau$  is valid and  $C$  is a hard commitment, its hard opening must be to  $m$  at index  $i$ .
- $\text{qFake}_{pk, tk}()$ : is a randomized algorithm that takes as input the trapdoor  $tk$  and generates a  $q$ -fake commitment  $C$  and some auxiliary information  $\text{aux}$ . The commitment  $C$  is not bound to any sequence of messages. The  $q$ -fake commitment  $C$  is similar to a soft de-commitment with the difference that it can be hard-opened using the trapdoor  $tk$ .
- $\text{qHEquiv}_{pk, tk}(m_1, \dots, m_q, i, \text{aux})$ : is a non-adaptive hard equivocation algorithm. Namely, given  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$ , it generates a hard de-commitment  $\pi$  for  $C$  at the  $i^{\text{th}}$  position of the sequence  $(m_1, \dots, m_q)$ . The algorithm is non-adaptive in that the sequence of messages has to be determined once-and-for-all before the execution of  $\text{qHEquiv}$ .
- $\text{qSEquiv}_{pk, tk}(m, i, \text{aux})$ : is a soft equivocation algorithm. Given the auxiliary information  $\text{aux}$  returned by  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$ , it creates a soft de-commitment  $\tau$  to  $m$  at position  $i$ .

Standard trapdoor mercurial commitments are a special case of qTMC schemes where  $q = 1$ .

**CORRECTNESS.** The correctness requirements are similar to those of standard mercurial commitments. For any sequence  $(m_1, \dots, m_q)$ , these statements must hold with overwhelming probability.

- Given a hard commitment  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$ , for all  $i \in \{1, \dots, q\}$ , we must have  $\text{qHVer}_{pk}(m_i, i, C, \text{qHOpen}_{pk}(m_i, i, \text{aux})) = 1$  and  $\text{qSVer}_{pk}(m_i, i, C, \text{qSOpen}_{pk}(m_i, i, \mathbb{H}, \text{aux})) = 1$ .
- If  $(C, \text{aux}) = \text{qSCom}_{pk}()$ , then  $\text{qSVer}_{pk}(m_i, i, C, \text{qSOpen}_{pk}(m_i, i, \mathbb{S}, \text{aux})) = 1$  for  $i = 1, \dots, q$ .
- Given  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$ , we must have  $\text{qSVer}_{pk}(m_i, i, C, \text{qSEquiv}_{pk, tk}(m_i, i, \text{aux})) = 1$  and  $\text{qHVer}_{pk}(m_i, i, C, \text{qHEquiv}_{pk, tk}(m_1, \dots, m_q, i, \text{aux})) = 1$  for all indices  $i \in \{1, \dots, q\}$ .

**SECURITY.** The security properties of a trapdoor  $q$ -mercurial commitment are stated as follows:

- **$q$ -Mercurial binding:** given the public key  $pk$ , it should be computationally infeasible to output a commitment  $C$ , an index  $i \in \{1, \dots, q\}$  and pairs  $(m, \pi), (m', \pi')$  that satisfy either of these two conditions which are respectively termed “hard collision” and “soft collision”:
  - $\text{qHVer}_{pk}(m, i, C, \pi) = 1, \text{qHVer}_{pk}(m', i, C, \pi') = 1$  and  $m \neq m'$ .
  - $\text{qHVer}_{pk}(m, i, C, \pi) = 1, \text{qSVer}_{pk}(m', i, C, \pi') = 1$  and  $m \neq m'$ .

- **$q$ -Mercurial hiding:** on input of  $pk$ , no PPT adversary can find a tuple  $(m_1, \dots, m_q)$  and an index  $i \in \{1, \dots, q\}$  for which it is able to distinguish  $(C, \text{qSOpen}_{pk}(m_i, i, \mathbb{H}, \text{aux}))$  from  $(C', \text{qSOpen}_{pk}(m_i, i, \mathbb{S}, \text{aux}'))$ , where  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$ ,  $(C', \text{aux}') = \text{qSCom}_{pk}()$ .
- **Equivocations:** given the public key  $pk$  and the trapdoor  $tk$ , no PPT adversary  $\mathcal{A}$  should be able to win the following games with non-negligible probability. In these games,  $\mathcal{A}$  aims to distinguish the “real” world from the corresponding “ideal” one. The kind of world that  $\mathcal{A}$  is faced with depends on a random  $b \stackrel{R}{\leftarrow} \{0, 1\}$  flipped by the challenger. If  $b = 0$ , the challenger plays the “real” game and provides  $\mathcal{A}$  with a real commitment/de-commitment tuple. If  $b = 1$ , the adversary  $\mathcal{A}$  rather receives a fake commitment and equivocations. More precisely,  $\mathcal{A}$  is required to guess the bit  $b \in \{0, 1\}$  with no better advantage than  $1/2$  in the following games:
  - **$q$ -HHEquivocation:** when  $\mathcal{A}$  chooses a message sequence  $(m_1, \dots, m_q)$ , the challenger computes  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$  if  $b = 0$  and  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$  if  $b = 1$ . In either case,  $\mathcal{A}$  receives  $C$ . When  $\mathcal{A}$  chooses an index  $i \in \{1, \dots, q\}$ , the challenger returns  $\pi = \text{qHOpen}_{pk}(m_i, i, \text{aux})$  if  $b = 0$  and  $\pi = \text{qHEquiv}_{pk, tk}(m_1, \dots, m_q, i, \text{aux})$  if  $b = 1$ .
  - **$q$ -HSEquivocation:** when  $\mathcal{A}$  chooses a message sequence  $(m_1, \dots, m_q)$ , the challenger computes  $(C, \text{aux}) = \text{qHCom}_{pk}(m_1, \dots, m_q)$  if  $b = 0$  and  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$  if  $b = 1$ . In either case,  $C$  is given to  $\mathcal{A}$  who then chooses  $i \in \{1, \dots, q\}$ . If  $b = 0$ , the challenger replies with  $\tau = \text{qSOpen}_{pk}(m_i, i, \mathbb{H}, \text{aux})$ . If  $b = 1$ ,  $\mathcal{A}$  receives  $\tau = \text{qSEquiv}_{pk, tk}(m_i, i, \text{aux})$ .
  - **$q$ -SSEquivocation:** if  $b = 0$ , the challenger creates a soft commitment  $(C, \text{aux}) = \text{qSCom}_{pk}()$  and hands  $C$  to  $\mathcal{A}$ . If  $b = 1$ ,  $\mathcal{A}$  rather obtains a fake commitment  $C$ , which is obtained as  $(C, \text{aux}) = \text{qFake}_{pk, tk}()$ . Then,  $\mathcal{A}$  chooses  $m \in \mathcal{M}$  and  $i \in \{1, \dots, q\}$  and gets back  $\tau = \text{qSOpen}_{pk}(m, i, \mathbb{S}, \text{aux})$  if  $b = 0$  and  $\tau = \text{qSEquiv}_{pk, tk}(m, i, \text{aux})$  if  $b = 1$ .

As noted in [8], giving the trapdoor  $tk$  to the adversary at the beginning of each game simplifies the definitions: security in the sense of the above atomic games then implies security in a more complex game where the adversary is playing an arbitrary composition of HHE, HSE and SSE games.

As was also pointed out in [8] in the case of ordinary trapdoor mercurial commitments, any qTMC scheme satisfying the  $q$ -HSEquivocation and  $q$ -SSEquivocation properties also satisfies the  $q$ -mercurial hiding requirement.

In the following, we say that a qTMC scheme is a *concise* mercurial vector commitment if the output sizes of qHOpen and qSOpen do not depend on  $q$  and if, when invoked on the index  $i \in \{1, \dots, q\}$ , qHOpen does not reveal any information on messages  $m_j$  with  $j \neq i$ .

### 2.3 Zero-Knowledge Sets and Databases

An elementary database  $D$  (EDB) is a set of pairs  $(x, y) \in \{0, 1\}^* \times \{0, 1\}^*$ , where  $x$  is called *key* and  $y$  is termed *value*. The support  $[D]$  of  $D$  is the set of  $x \in \{0, 1\}^*$  for which there exists  $y \in \{0, 1\}^*$  such that  $(x, y) \in D$ . When  $x \notin [D]$ , one usually writes  $D(x) = \perp$ . When  $x \in [D]$ , the associated value  $y = D(x)$  must be unique: if  $(x, y) \in D$  and  $(x, y') \in D$ , then  $y = y'$ . A zero-knowledge EDB allows a prover to commit to such a database  $D$  while being able to non-interactively prove statements of the form “ $x \in [D]$  and  $y = D(x)$  is the associated value” or “ $x \notin [D]$ ” without revealing any further information on  $D$  (not even the cardinality of  $[D]$ ). Zero-knowledge sets are specific ZK-EDBs where each key is assigned the value 1.

The prover and the verifier both take as input a string  $\sigma$  that can be a random string (in which case, the protocol stands in the common random string model) or have a specific structure (in

which case we are in the trusted parameters model). An EDB scheme is formally defined by a tuple  $(\text{CRS-Gen}, \text{P1}, \text{P2}, \text{V})$  such that:

- $\text{CRS-Gen}$  generates a common reference string  $\sigma$  on input of a security parameter  $\lambda$ .
- $\text{P1}$  is the commitment algorithm that takes as input the database  $D$  and  $\sigma$ . It outputs commitment and de-commitment strings  $(\text{Com}, \text{Dec})$ .
- $\text{P2}$  is the proving algorithm that, given  $\sigma$ , the commitment/de-commitment pair  $(\text{Com}, \text{Dec})$  and a key  $x \in \{0, 1\}^*$ , outputs a proof  $\pi_x$ .
- $\text{V}$  is the verification algorithm that, on input of  $\sigma$ ,  $\text{Com}$ ,  $x$  and  $\pi_x$ , outputs either  $y$  (which must be  $\perp$  if  $x \notin [D]$ ) if it is convinced that  $D(x) = y$  or *bad* if it believes that the prover is cheating.

The security requirements are formally defined in appendix A. In a nutshell, they are as follows. Correctness mandates that honestly generated proofs always satisfy the verification test. Soundness requires that provers be unable to come up with a key  $x$  and convincing proofs  $\pi_x, \pi'_x$  such that  $y = \text{V}(\sigma, \text{Com}, x, \pi_x) \neq \text{V}(\sigma, \text{Com}, x, \pi'_x) = y'$ . Finally, zero-knowledge means that each proof  $\pi_x$  only reveals the value  $D(x)$  and nothing else: for any computable database  $D$ , there must exist a simulator that outputs a simulated reference string  $\sigma'$  and a simulated commitment  $\text{Com}'$  that does not depend on  $D$ . For any key  $x \in \{0, 1\}^*$  and with oracle access to  $D$ , the simulator should be able to simulate proofs  $\pi_x$  that are indistinguishable from real proofs.

### 3 A Construction of Concise qTMC Scheme

Our idea is to build on the accumulator of Camenisch, Kohlweiss and Soriente [6], which is itself inspired by the Boneh-Gentry-Waters broadcast encryption system [5]. In the former, the public key comprises a sequence of group elements  $(g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q})$ , where  $q$  is the maximal number of accumulated values and  $g_i = g^{(\alpha^i)}$  for each  $i$ . Elements of  $\mathcal{V} \subseteq \{1, \dots, q\}$  are accumulated by computing  $V = \prod_{j \in \mathcal{V}} g_{q+1-j}$  and the witness for the accumulation of  $i \in \mathcal{V}$  consists of the group element  $W_i = \prod_{j \in \mathcal{V} \setminus \{i\}} g_{q+1-j+i}$ , which always satisfies  $e(g_i, V) = e(g, W_i) \cdot e(g_1, g_q)$ .

To obtain a commitment scheme, we modify this construction in order to accumulate messages  $m_i \in \mathbb{Z}_p^*$  in a position-sensitive manner and we also add some randomness  $\gamma \in \mathbb{Z}_p$  to have a hiding commitment. More precisely, we commit to  $(m_1, \dots, m_q)$  by computing  $V = g^\gamma \cdot \prod_{j=1}^q g_{q+1-j}^{m_j}$  and obtain a kind of generalized Pedersen commitment [23]. Thanks to the specific choice of base elements however,  $W_i = g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j}^{m_j}$  can serve as evidence that  $m_i$  was the  $i^{\text{th}}$  committed message as it satisfies the relation  $e(g_i, V) = e(g, W_i) \cdot e(g_1, g_q)^{m_i}$ . Moreover, the opening  $W_i$  at position  $i$  does not reveal anything about other components of the committed vector, which is a property that can be useful in other applications.

This commitment can be proved binding under the  $q$ -DHE assumption, which would be broken if the adversary was able to produce two distinct openings of  $V$  at position  $i$ . It is also a trapdoor commitment since anyone holding  $g_{q+1} = g^{(\alpha^{q+1})}$  can trapdoor open a commitment as he likes.

The scheme can further be made mercurial by observing that its binding property disappears if the verification equation is changed into  $e(g_i, V) = e(g_1, W_i) \cdot e(g_1, g_q)^{m_i}$ . The key idea is then to use commitments of the form  $(C, V)$  where  $C = g^\theta$ , for some  $\theta \in \mathbb{Z}_p$ , in hard commitments and  $C = g_1^\theta$  in soft commitments. The verification equation thus becomes  $e(g_i, V) = e(C, W_i) \cdot e(g_1, g_q)^{m_i}$ .

DESCRIPTION. We assume that committed messages are elements of  $\mathbb{Z}_p^*$ . In practice, arbitrary messages can be committed to by first applying a collision-resistant hash function with range  $\mathbb{Z}_p^*$ .

**qKeygen**( $\lambda, q$ ): chooses bilinear groups  $(\mathbb{G}, \mathbb{G}_T)$  of prime order  $p > 2^\lambda$  and  $g \xleftarrow{R} \mathbb{G}$ . It picks  $\alpha \xleftarrow{R} \mathbb{Z}_p^*$  and computes  $g_1, \dots, g_q, g_{q+2}, \dots, g_{2q}$ , where  $g_i = g^{(\alpha^i)}$  for  $i = 1, \dots, q, q+2, \dots, 2q$ . The public key is defined to be  $pk = \{g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q}\}$  and the trapdoor is  $tk = g_{q+1} = g^{(\alpha^{q+1})}$ .

**qHCom** <sub>$pk$</sub> ( $m_1, \dots, m_q$ ): to hard-commit to a sequence  $(m_1, \dots, m_q) \in (\mathbb{Z}_p^*)^q$ , this algorithm chooses  $\gamma, \theta \xleftarrow{R} \mathbb{Z}_p$  and computes the commitment as the pair

$$C = g^\theta \quad V = g^\gamma \cdot \prod_{j=1}^q g_{q+1-j}^{m_j} = g^\gamma \cdot g_q^{m_1} \cdots g_1^{m_q}.$$

The output is  $(C, V)$  and the auxiliary information is  $\text{aux} = (m_1, \dots, m_q, \gamma, \theta)$ .

**qHOpen** <sub>$pk$</sub> ( $m_i, i, \text{aux}$ ): parses  $\text{aux}$  as  $(m_1, \dots, m_q, \gamma, \theta)$  and calculates

$$W_i = \left( g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j} \right)^{1/\theta}. \quad (1)$$

The hard opening of  $(C, V)$  consists of  $\pi = (\theta, W_i) \in \mathbb{Z}_p \times \mathbb{G}$ .

**qHVer** <sub>$pk$</sub> ( $m_i, i, (C, V), \pi$ ): parses  $\pi$  as  $(\theta, W_i) \in \mathbb{Z}_p \times \mathbb{G}$  and returns 1 if  $C, V \in \mathbb{G}$  and it holds that

$$e(g_i, V) = e(C, W_i) \cdot e(g_1, g_q)^{m_i} \quad \text{and} \quad C = g^\theta. \quad (2)$$

Otherwise, it returns 0.

**qSCom** <sub>$pk$</sub> ( $\cdot$ ): chooses  $\theta, \gamma \xleftarrow{R} \mathbb{Z}_p$  and computes  $C = g^\theta, V = g_1^\gamma$ . The output is  $(C, V)$  and the auxiliary information is  $\text{aux} = (\theta, \gamma)$ .

**qSOpen** <sub>$pk$</sub> ( $m, i, \text{flag}, \text{aux}$ ): if  $\text{flag} = \mathbb{H}$ ,  $\text{aux}$  is parsed as  $(m_1, \dots, m_q, \gamma, \theta)$ . The algorithm returns  $\perp$  if  $m \neq m_i$ . Otherwise, it computes the soft opening as  $W_i = (g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j})^{1/\theta}$ . If  $\text{flag} = \mathbb{S}$ , the algorithm parses  $\text{aux}$  as  $(\theta, \gamma)$  and soft-de-commits to  $m$  using  $W_i = (g_i^\gamma \cdot g_q^{-m})^{1/\theta}$ . In either case, the algorithm returns  $\tau = W_i \in \mathbb{G}$ .

**qSVer** <sub>$pk$</sub> ( $m, i, (C, V), \tau$ ): parses  $\tau$  as  $W_i \in \mathbb{G}$  and returns 1 if and only if it holds that  $C, V \in \mathbb{G}$  and the first verification equation of (2) is satisfied.

**qFake** <sub>$pk, tk$</sub> ( $\cdot$ ): the fake commitment algorithm chooses  $\theta, \gamma \xleftarrow{R} \mathbb{Z}_p$  and returns  $(C, V) = (g^\theta, g^\gamma)$ . The auxiliary information is  $\text{aux} = (\theta, \gamma)$ .

**qHEquiv** <sub>$pk, tk$</sub> ( $m_1, \dots, m_q, i, \text{aux}$ ): parses  $\text{aux}$  as  $(\theta, \gamma) \in (\mathbb{Z}_p)^2$ . Using the trapdoor  $tk = g_{q+1} \in \mathbb{G}$ , it computes  $W_i = (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta}$ . The de-commitment consists of  $\pi = (\theta, W_i)$ .

**qSEquiv** <sub>$pk, tk$</sub> ( $m, i, \text{aux}$ ): parse  $\text{aux}$  as  $(\theta, \gamma)$  and returns  $W_i = (g_i^\gamma \cdot g_{q+1}^{-m})^{1/\theta}$ .

**CORRECTNESS.** In hard commitments, we can check that properly generated hard de-commitments always satisfy the verification test (2) since

$$\begin{aligned} \frac{e(g_i, V)}{e(C, W_i)} &= e(g^{(\alpha^i)}, g^{\gamma + \sum_{j=1}^q m_j (\alpha^{q+1-j})}) / e(g^\theta, g^{(\gamma(\alpha^i) + \sum_{j=1, j \neq i}^q m_j (\alpha^{q+1-j+i}))}) / \theta \\ &= e(g, g^{\gamma(\alpha^i) + \sum_{j=1}^q m_j (\alpha^{q+1-j+i})}) / e(g, g^{\gamma(\alpha^i) + \sum_{j=1, j \neq i}^q m_j (\alpha^{q+1-j+i})}) \\ &= e(g, g)^{m_i (\alpha^{q+1})} = e(g_1, g_q)^{m_i}. \end{aligned}$$

As for soft commitments, soft de-commitments always satisfy the first relation of (2) since

$$\begin{aligned} e(C, W_i) \cdot e(g_1, g_q)^{m_i} &= e(g_1^\theta, (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta}) \cdot e(g_1, g_q)^{m_i} \\ &= e(g_1, g_i^\gamma \cdot g_{q+1}^{-m_i}) \cdot e(g_1, g_q)^{m_i} = e(g_1^\gamma, g_i) = e(g_i, V). \end{aligned}$$

We finally observe that, in any fake commitment  $(C, V) = (g^\theta, g^\gamma)$ , the hard de-commitment  $(\theta, W_i)$  successfully passes the verification test as

$$\begin{aligned} e(C, W_i) \cdot e(g_1, g_q)^{m_i} &= e(g^\theta, (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta}) \cdot e(g_1, g_q)^{m_i} \\ &= e(g, g_i^\gamma \cdot g_{q+1}^{-m_i}) \cdot e(g_1, g_q)^{m_i} = e(g_i, g^\gamma) = e(g_i, V). \end{aligned}$$

**SECURITY.** To prove the security of the scheme, we first notice that it is a “proper” qTMC [8] since, in hard commitments, the soft de-commitment is a proper subset of the hard de-commitment.

**Theorem 1.** *The above scheme is a secure concise qTMC if the q-DHE assumption holds in  $\mathbb{G}$ .*

*Proof.* We first show the  $q$ -mercurial binding property. Let us assume that, given the public key, an adversary  $\mathcal{A}$  is able to generate soft collisions (since the scheme is “proper”, the case of hard collisions immediately follows). That is,  $\mathcal{A}$  comes up with a commitment  $(C, V) \in \mathbb{G}^2$ , an index  $i \in \{1, \dots, q\}$ , a valid hard de-commitment  $\pi = (\theta, W_i) \in \mathbb{Z}_p \times \mathbb{G}$  to  $m_i$  at position  $i$  and a valid soft de-commitment  $\tau = W'_i \in \mathbb{G}$  to  $m'_i$  such that  $m_i \neq m'_i$ . We must have

$$e(g_i, V) = e(g^\theta, W_i) \cdot e(g_1, g_q)^{m_i} \quad e(g_i, V) = e(g^\theta, W'_i) \cdot e(g_1, g_q)^{m'_i},$$

so that  $e(g^\theta, W_i/W'_i) = e(g_1, g_q)^{m_i - m'_i}$  and  $e(g, (W_i/W'_i)^{\theta/(m'_i - m_i)}) = e(g_1, g_q)$ . Since  $m_i \neq m'_i$ , the latter relation implies that  $g_{q+1} = (W_i/W'_i)^{\theta/(m'_i - m_i)}$  is revealed by the soft collision, which contradicts the  $q$ -DHE assumption.

We now turn to the  $q$ -HHE,  $q$ -HSE and  $q$ -SSE equivocation properties (which imply  $q$ -mercurial hiding). A fake commitment has the form  $(C, V) = (g^\theta, g^\gamma)$  and its hard equivocation to  $(m_i, i)$  is the pair  $(\theta, W_i = (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta})$ . For any sequence of messages  $(m_1, \dots, m_q) \in (\mathbb{Z}_p^*)^q$ , there always exists  $\gamma' \in \mathbb{Z}_p$  such that

$$V = g^{\gamma'} \cdot \prod_{j=1}^q g_{q+1-j}^{m_j}. \quad (3)$$

Then, the corresponding hard opening of  $(C, V)$  w.r.t.  $m_i$  at position  $i$  should be obtained as  $W'_i = (g_i^{\gamma'} \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j})^{1/\theta}$ . Since  $V$  also equals  $g^\gamma$ , if we raise both members of (3) to the power  $\alpha^i$ , we find that

$$g_i^\gamma = g_i^{\gamma'} \cdot \prod_{j=1}^q g_{q+1-j+i}^{m_j}.$$

Therefore, the element  $W_i = (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta}$  returned by the hard equivocation algorithm can also be written  $W_i = (g_i^{\gamma'} \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j})^{1/\theta}$ . It comes that fake commitments and hard equivocations have exactly the same distribution as hard commitments and their hard openings.

The  $q$ -HSEquivocation property follows from the above arguments (since the scheme is “proper”). To prove the indistinguishability in the  $q$ -SSEquivocation game, we note that fake commitments  $(C, V) = (g^\theta, g^\gamma)$  have the same distribution as soft ones as they can be written  $(C, V) = (g_1^{\tilde{\theta}}, g_1^{\tilde{\gamma}})$  where  $\tilde{\theta} = \theta/\alpha$  and  $\tilde{\gamma} = \gamma/\alpha$ . Their soft equivocation  $W_i = (g_i^\gamma \cdot g_{q+1}^{-m_i})^{1/\theta}$  can be written  $(g_i^{\alpha\tilde{\gamma}} \cdot g_{q+1}^{-m_i})^{1/(\alpha\tilde{\theta})} = (g_i^{\tilde{\gamma}} \cdot g_{q+1}^{-m_i})^{1/\tilde{\theta}}$  and has the distribution of a soft opening.  $\square$

INSTANTIATION WITH ASYMMETRIC PAIRINGS. It is simple<sup>3</sup> to describe the construction in terms of asymmetric pairings  $e : \mathbb{G} \times \hat{\mathbb{G}} \rightarrow \mathbb{G}_T$ , where  $\mathbb{G} \neq \hat{\mathbb{G}}$  and an isomorphism  $\psi : \hat{\mathbb{G}} \rightarrow \mathbb{G}$  is efficiently computable. The public key comprises generators  $\hat{g} \in \hat{\mathbb{G}}$  and  $\hat{g}_i$  for  $i = 1, \dots, q, q+2, \dots, 2q$ . Then, hard (resp. soft) commitments  $(C, V) \in \hat{\mathbb{G}} \times \mathbb{G}$  are pairs of group elements obtained as  $C = \hat{g}^\theta$  and  $V = \psi(\hat{g})^\gamma \cdot \prod_{j=1}^q \psi(\hat{g}_{q+1-j})^{m_j}$  (resp.  $C = \hat{g}_1^\theta$  and  $V = \psi(\hat{g}_1)^\gamma$ ). Hard openings are pairs  $(\theta, W_i) \in \mathbb{Z}_p^* \times \mathbb{G}$ , where  $W_i = \psi(\hat{g}_i)^{\gamma/\theta} \cdot \prod_{j=1, j \neq i}^q \psi(\hat{g}_{q+1-j+i})^{m_j/\theta}$  and they are verified by checking that  $C = \hat{g}^\theta$  and  $e(V, \hat{g}_i) = e(W_i, C) \cdot e(\psi(\hat{g}_1), \hat{g}_q)^{m_i}$ . Using the trapdoor  $\hat{g}_{q+1}$ , fake commitments  $(C, V) = (\hat{g}^\theta, \psi(\hat{g})^\gamma)$  can be equivocated by outputting  $\theta$  and  $W_i = \psi(\hat{g}_i)^{\gamma/\theta} \cdot \psi(\hat{g}_{q+1})^{-m_i/\theta}$ .

## 4 Implications on the Efficiency of ZK-EDBs

The construction [9] of ZK-EDB from qTMC schemes is detailed in appendix B and goes as follows. Each key  $x$  is assigned to a leaf of a  $q$ -ary tree of height  $h$  (and can be seen as the label of the leaf, expressed in  $q$ -ary encoding), so that  $q^h$  is the theoretical bound on the size of the EDB.

The committing phase is made efficient by pruning subtrees where all leaves correspond to keys that are *not* in the database. Only the roots (called “frontier nodes” and at least one sibling of which is an ancestor of a leaf in the EDB) of these subtrees are kept in the tree and contain soft  $q$ -commitments. For each key  $x$  such that  $D(x) \neq \perp$ , the corresponding leaf contains a standard hard mercurial commitment to a hash value of  $D(x)$ . As for remaining nodes, each internal one contains a hard  $q$ -commitment to messages obtained by hashing its children. The  $q$ -commitment at the root then serves as a commitment to the entire EDB.

To convince a verifier that  $D(x) = v \neq \perp$  for some key  $x$ , the prover generates a proof of membership consisting of hard openings for commitments in nodes on the path connecting leaf  $x$  to the root. At each level of the tree, the  $q$ -commitment is hard-opened with respect to the position determined by the  $q$ -ary encoding of  $x$  at that level.

To provide evidence that some key  $x$  does not belong to the database (*i.e.*,  $D(x) = \perp$ ), the prover first generates the missing portion of the subtree where  $x$  lies. Then, it reveals soft openings for all (hard or soft) commitments contained in nodes appearing in the path from  $x$  to the root.

As in the original zero-knowledge EDB construction [21], only storing commitments in subtrees containing leaves  $x$  for which  $D(x) \neq \perp$  (and soft commitments at nodes that have no descendants) is what allows committing with complexity  $O(h \cdot |D|)$  instead of  $O(q^h)$ .

The advantage of using qTMC schemes and  $q$ -ary (with  $q > 2$ ) trees lies in that proofs can be made much shorter if, at each level, commitments can be opened w.r.t. the required position  $i \in \{1, \dots, q\}$  without having to reveal  $q$  values. The qTMC scheme of [9] features soft openings consisting of a single group element and, for an appropriate branching factor  $q$ , allows reducing proofs of non-membership by 73% in comparison with [21]. On the other hand, hard openings still have length  $O(q)$  and proofs of membership thus remain significantly longer than proofs of non-membership. If  $h$  denotes the height of the tree, the former consist of  $h(q+4) + 5$  elements of  $\mathbb{G}$  (in an implementation with asymmetric pairings) while the latter only demand  $4h + 4$  such elements.

If we plug our qTMC scheme into the above construction, proofs of membership become essentially as short as proofs of non-membership. At each internal node, each hard opening only requires to reveal  $(C, V) \in \hat{\mathbb{G}} \times \mathbb{G}$  and  $(\theta, W_i) \in \mathbb{Z}_p \times \mathbb{G}$ . At the same time, proofs of non-membership remain as short as in [9] since, at each internal node, the prover only discloses  $(C, V)$  and  $W_i$ .

<sup>3</sup> The security then relies on the hardness of computing  $\psi(\hat{g})^{(\alpha^{q+1})}$  on input of  $(\hat{g}, \hat{g}_1, \dots, \hat{g}_q, \hat{g}_{q+2}, \dots, \hat{g}_{2q}) \in \hat{\mathbb{G}}^{2q}$ , where  $\hat{g}_i = \hat{g}^{(\alpha^i)}$  for each  $i$ .

To concretely assess proof sizes, we assume (as in [9]) that elements of  $\hat{\mathbb{G}}$  count as two elements

$q$	$h$	Membership	Non-Membership	Membership in [9]
8	43	220	176	521
16	32	165	132	643
32	26	135	108	941
64	22	115	92	1501
128	19	100	80	2513
256	16	85	68	4165

**Fig. 1.** Required number of group elements per proof

of  $\mathbb{G}$  (since their representation is usually twice as large using suitable parameters and optimizations such as those of [2]), each one of which costs  $|p|$  bits to represent. Then, we find that proofs of membership and non-membership eventually amount to  $5h + 5$  and  $4h + 4$  elements of  $\mathbb{G}$ , respectively. These short hard openings allow us to increase the branching factor of the tree as long as the length of the common reference string is deemed acceptable.

The table of figure 1 summarizes the proof lengths (expressed in numbers of  $\mathbb{G}$  elements and in comparison with [9]) for various branching factors and assuming that  $q^h \approx 2^{128}$  theoretically bounds the EDB’s size. In the MRK construction, membership (resp. non-membership) can be proved using 773 (resp. 644) group elements. The best tradeoff achieved in [9] was for  $q = 8$ , where proofs of non-membership could be reduced to 176 elements but proofs of membership still took 521 elements. With  $q = 8$ , we have equally short proofs of non-membership and only need 220 elements to prove membership, which improves CFM [9] by about 57% and MRK [21] by 71%.

Moreover, we can shorten both kinds of proof by increasing  $q$ : with  $q = 128$  for instance, no more than 100 group elements (or 13% of the original length achieved in [21]) are needed to prove membership whereas 2513 elements are necessary in [9]. Instantiating our scheme with Barreto-Naehrig curves [2] yields proofs of less than 2 kB when  $q = 128$ . For such relatively small values of  $q$ , Cheon’s attack [12] does not require to increase the security parameter  $\lambda$  and it is reasonable to use groups  $(\mathbb{G}, \hat{\mathbb{G}})$  where elements of  $\mathbb{G}$  have a 161-bit representation.

## 5 Achieving Strong Independence

In [15], Gennaro and Micali formalized the notion of *independent zero-knowledge* EDBs which requires that adversaries be unable to correlate their database to those created by honest provers.

The strongest flavor of independence considers two-stage adversaries  $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ . First,  $\mathcal{A}_1$  observes  $\ell$  honest provers’ commitments  $(Com_1, \dots, Com_\ell)$  and queries proofs for keys of her choice in underlying databases  $D_1, \dots, D_\ell$  before outputting her own commitment  $Com$ . Then, two copies of  $\mathcal{A}_2$  are executed: in the first one,  $\mathcal{A}_2$  is given oracle access to provers that “open”  $Com_i$  w.r.t  $D_i$  whereas, in the second run,  $\mathcal{A}_2$  has access to provers for different<sup>4</sup> databases  $D'_i$  that agree with  $D_i$  for the set  $Q_i$  of queries made by  $\mathcal{A}_1$ . Eventually, both executions of  $\mathcal{A}_2$  end with  $\mathcal{A}_2$  outputting a key  $x$ , which is identical in both runs, and a proof  $\pi_x$ . The resulting database value  $D(x)$  is required to be the same in the two copies, meaning that it was fixed at the end of the committing stage.

<sup>4</sup> For this reason, commitments  $(Com_1, \dots, Com_\ell)$  are produced using the ZK-EDB simulator, whose definition is recalled in appendix A, as the two executions of  $\mathcal{A}_2$  proceed as if underlying databases were different.

In the strongest definition of [15],  $\mathcal{A}_1$  is allowed to copy one of the honest provers' commitment (say  $Com_i$ ) as long as the key  $x$  returned by  $\mathcal{A}_2$  is never queried to  $\text{Sim}_2(St_i, Com_i)$  by  $\mathcal{A}_1$  or  $\mathcal{A}_2$ : in other words,  $\mathcal{A}_2$ 's answer must be fixed on all values  $x$  that were not queried to the  $i^{\text{th}}$  prover.

**Definition 2.** [15] *A ZK-EDB protocol is strongly independent if, for any polynomial  $\ell$ , any PPT adversary  $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$  and any databases  $D_1, \dots, D_\ell, D'_1, \dots, D'_\ell$ , the following probability is negligible.*

$$\Pr \left[ (\sigma, St_0) \leftarrow \text{Sim}_0(\lambda); (Com_i, St_i) \leftarrow \text{Sim}_1(St_0) \forall i = 1, \dots, \ell; \right. \\ (Com, \omega) \leftarrow \mathcal{A}_1^{\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)}(\sigma, Com_1, \dots, Com_\ell); \\ (x, \pi_x) \leftarrow \mathcal{A}_2^{\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)}(\sigma, \omega); (x, \pi'_x) \leftarrow \mathcal{A}_2^{\text{Sim}_2^{D'_i \dashv_{Q_i} D_i(\cdot)}(St_i, Com_i)}(\sigma, \omega); \\ (bad \neq \mathbb{V}(\sigma, Com, x, \pi_x) \neq \mathbb{V}(\sigma, Com, x, \pi'_x) \neq bad) \wedge \left( (\forall i : Com \neq Com_i) \right. \\ \left. \vee (\exists i : (Com = Com_i) \wedge (x \notin Q_i \cup Q'_i)) \right) \Big],$$

where  $Q_i$  (resp.  $Q'_i$ ) stands for the list of queries made by  $\mathcal{A}_1$  (resp.  $\mathcal{A}_2$ ) to  $\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)$  (resp.  $\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)$  and  $\text{Sim}_2^{D'_i \dashv_{Q_i} D_i(\cdot)}(St_i, Com_i)$ ) and  $D'_i \dashv_{Q_i} D_i$  denotes a database that agrees with  $D'_i$  on all keys but those in  $Q_i$  where it agrees with  $D_i$ .

An efficient construction of independent ZK-EDB was proved in [15] to satisfy the above definition under the strong RSA assumption. It was obtained by extending Gennaro's multi-trapdoor commitment scheme [14] and making it mercurial.

We show how to turn our qTMC scheme into a multi-trapdoor  $q$ -mercurial commitment scheme that yields strongly independent EDBs with short proofs.

**MULTI-TRAPDOOR Q-MERCURIAL COMMITMENTS.** A multi-trapdoor qTMC can be seen as extending qTMC schemes in the same way as multi-trapdoor commitments generalize ordinary trapdoor commitments. It can be defined as a family of trapdoor  $q$ -mercurial commitments, each member of which is identified by a string  $tag$  and has its own trapdoor  $tk_{tag}$ . The latter is generated from  $tag$  using a master trapdoor  $TK$  that matches the master public key  $PK$ .

$\text{qKeygen}(\lambda, q)$ : has the same specification as in section 2.2 but, in addition to the master key pair  $(PK, TK)$ , it outputs the description of a tag space  $\mathcal{T}$ .

$\text{qHCom}_{PK}(m_1, \dots, m_q, tag)$ : given an ordered tuple  $(m_1, \dots, m_q)$  and  $tag \in \mathcal{T}$ , this algorithm outputs a hard commitment  $C$  under  $(PK, tag)$  and some auxiliary state information  $aux$ .

$\text{qHOpen}_{PK}(m, i, tag, aux)$ : given a pair  $(C, aux) = \text{qHCom}_{PK}(m_1, \dots, m_q, tag)$ , this algorithm outputs a hard de-commitment  $\pi$  of  $C$  w.r.t. position  $i$  if  $m = m_i$ . If  $m \neq m_i$ , it returns  $\perp$ .

$\text{qHVer}_{PK}(m, i, C, tag, \pi)$ : outputs 1 if and only if  $\pi$  gives evidence that, under the tag  $tag$ ,  $C$  is bound to a sequence  $(m_1, \dots, m_q)$  such that  $m_i = m$ .

$\text{qSCom}_{PK}()$ : generates a soft commitment and some auxiliary information  $aux$ . Such a commitment is not associated with any specific messages or tag.

$\text{qSOpen}_{PK}(m, i, flag, tag, aux)$ : generates a soft de-commitment  $\tau$  of  $C$  to  $m$  at position  $i$  and w.r.t.  $tag$ . The variable  $flag \in \{\mathbb{H}, \mathbb{S}\}$  indicates whether  $\tau$  pertains to a hard commitment  $(C, aux) = \text{qHCom}_{PK}(m_1, \dots, m_q, tag)$  or a soft commitment  $(C, aux) = \text{qSCom}_{PK}()$ . If  $flag = \mathbb{H}$  and  $m \neq m_i$ , the algorithm returns  $\perp$ .

$\text{qSVer}_{PK}(m, i, C, \tau, tag)$  returns 1 if, under  $tag \in \mathcal{T}$ ,  $\tau$  is deemed as a valid soft de-commitment of  $C$  to  $m$  at position  $i$  and 0 otherwise.

$\text{qTrapGen}_{PK,TK}(tag)$ : given a string  $tag \in \mathcal{T}$ , this algorithm generates a tag-specific trapdoor  $tk_{tag}$  using the master trapdoor  $TK$ .

$\text{qFake}_{PK,tk_{tag}}()$ : outputs a  $q$ -fake commitment  $C$  and some auxiliary state information  $\text{aux}$ .

$\text{qHEquiv}_{PK,tk_{tag}}(m_1, \dots, m_q, i, tag, \text{aux})$ : given  $(C, \text{aux}) = \text{qFake}_{PK,tk_{tag}}()$ , this algorithm generates a hard de-commitment  $\pi$  for  $C$  and  $tag \in \mathcal{T}$  at the  $i^{\text{th}}$  position of the sequence  $(m_1, \dots, m_q)$ . The sequence of messages has to be determined once-and-for-all before the execution of  $\text{qHEquiv}$ .

$\text{qSEquiv}_{PK,tk_{tag}}(m, i, tag, \text{aux})$ : using the trapdoor  $tk_{tag}$  and the state information  $\text{aux}$  returned by  $(C, \text{aux}) = \text{qFake}_{PK,tk_{tag}}()$ , this algorithm creates a soft de-commitment  $\tau$  to  $m$  at position  $i$  and w.r.t.  $tag \in \mathcal{T}$ .

Again, we call such a scheme *concise* if it satisfies the same conditions as those mentioned at the end of section 2.2.

The security properties are expressed by naturally requiring the  $q$ -mercurial hiding and equivocation properties to hold for each  $tag \in \mathcal{T}$ . In equivocation games, the adversary should be unable to distinguish the two games even knowing the master trapdoor  $TK$ . As for the  $q$ -mercurial binding property, it states that no PPT adversary  $\mathcal{A}$  should have non-negligible advantage in this game:

**$q$ -Mercurial binding game:**  $\mathcal{A}$  chooses strings  $tag_1, \dots, tag_\ell \in \mathcal{T}$ . Then, the challenger generates a master key pair  $(TK, PK) \leftarrow \text{qKeygen}(\lambda, q)$  and gives  $PK$  to  $\mathcal{A}$  who starts invoking a trapdoor oracle  $\mathcal{TG}$ : the latter receives  $tag \in \{tag_1, \dots, tag_\ell\}$  and returns  $tk_{tag} \leftarrow \text{qTrapGen}_{PK,TK}(tag)$ . Eventually,  $\mathcal{A}$  chooses a family  $tag^* \in \mathcal{T} \setminus \{tag_1, \dots, tag_\ell\}$  for which she aims to generate a collision: she wins if she outputs  $C$ , an index  $i \in \{1, \dots, q\}$  and pairs  $(m, \pi)$ ,  $(m', \pi')$  (resp.  $(m, \pi)$  and  $(m', \tau)$ ) such that  $\text{qHVer}_{PK}(m, i, C, tag^*, \pi) = 1$  and  $\text{qHVer}_{PK}(m', i, C, tag^*, \pi') = 1$  (resp.  $\text{qHVer}_{PK}(m, i, C, tag^*, \pi) = 1$  and  $\text{qSVer}_{PK}(m', i, C, tag^*, \tau) = 1$ ) but  $m \neq m'$ .

As in [14], the latter definition captures security in a non-adaptive sense in that the adversary chooses  $tag_1, \dots, tag_\ell$  before seeing the public key  $PK$ . As noted in [13, 19] in the case of ordinary multi-trapdoor commitments, some applications might require to consider a notion of adaptive security where, much in the fashion of identity-based trapdoor commitments [1, 7], the adversary can query  $\mathcal{TG}$  in an adaptive fashion. In the present context, non-adaptive security suffices.

A CONSTRUCTION OF MULTI-TRAPDOOR qTMC. The construction combines the qTMC scheme of section 3 with a programmable hash function  $H_{\mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  and techniques that were introduced in [3]. Programmable hash functions, as formalized by Hofheinz and Kiltz [17], are designed in such a way that a trapdoor information makes it possible to relate the output  $H_{\mathbb{G}}(M)$ , which lies in a group  $\mathbb{G}$ , to computable values  $a_M, b_M \in \mathbb{Z}_p$  satisfying  $H_{\mathbb{G}}(M) = g^{a_M} \cdot h^{b_M}$ . Informally (see appendix C for a formal definition), a  $(m, n)$ -programmable hash function is such that, for any  $M_1, \dots, M_m, M'_1, \dots, M'_n$  such that  $M_i \neq M'_j$ , there is a non-negligible probability that  $b_{M_i} = 0$  and  $b_{M'_j} \neq 0$  for  $i = 1, \dots, m$  and  $j = 1, \dots, n$ . The number theoretic hash function used in [11, 25] is an example of such a  $(1, \ell)$ -programmable hash function, for some polynomial  $\ell$ .

**qKeygen** $(\lambda, q)$ : is as in section 3 but the algorithm also chooses a tag space  $\mathcal{T} = \{0, 1\}^L$  and a  $(1, \ell)$ -programmable hash function  $H_{\mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  for some polynomials  $\ell, L$ . The public key is  $PK = \{\mathcal{T}, g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q}, H_{\mathbb{G}}\}$  and the master trapdoor is  $TK = g_{q+1} = g^{(\alpha^{q+1})}$ .

**qHCom**<sub>PK</sub>( $m_1, \dots, m_q, tag$ ): to hard-commit to a sequence  $(m_1, \dots, m_q) \in (\mathbb{Z}_p^*)^q$ , this algorithm chooses  $\gamma, \theta \xleftarrow{R} \mathbb{Z}_p$  and computes  $(C, V) = (g^\theta, g^\gamma \cdot \prod_{j=1}^q g_{q+1-j}^{m_j})$ . The output is  $(C, V)$  and the auxiliary information is  $\mathbf{aux} = (m_1, \dots, m_q, \gamma, \theta)$ .

**qHOpen**<sub>PK</sub>( $m_i, i, tag, \mathbf{aux}$ ): parses  $\mathbf{aux}$  as  $(m_1, \dots, m_q, \gamma, \theta)$ , chooses  $r \xleftarrow{R} \mathbb{Z}_p^*$  and computes

$$(W_i, Z_i) = \left( (g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j} \cdot H_{\mathbb{G}}(tag)^r)^{1/\theta}, g^{-r} \right), \quad (4)$$

The hard opening of  $(C, V)$  with respect to  $tag \in \mathcal{T}$  is the triple  $\pi = (\theta, W_i, Z_i) \in \mathbb{Z}_p \times \mathbb{G}^2$ .

**qHVer**<sub>PK</sub>( $m_i, i, (C, V), tag, \pi$ ): parses  $\pi$  as  $(\theta, W_i, Z_i) \in \mathbb{Z}_p \times \mathbb{G}^2$  and returns 1 if  $C, V \in \mathbb{G}$  and relations (5) are both satisfied. Otherwise, it returns 0.

$$e(g_i, V) = e(C, W_i) \cdot e(g_1, g_q)^{m_i} \cdot e(H_{\mathbb{G}}(tag), Z_i) \quad C = g^\theta. \quad (5)$$

**qSCom**<sub>PK</sub>( $\cdot$ ): chooses  $\theta, \gamma \xleftarrow{R} \mathbb{Z}_p$  and computes  $C = g_1^\theta, V = g_1^\gamma$ . The output is  $(C, V)$  and the auxiliary information is  $\mathbf{aux} = (\theta, \gamma)$ .

**qSOpen**<sub>PK</sub>( $m, i, \mathbf{flag}, tag, \mathbf{aux}$ ): if  $\mathbf{flag} = \mathbb{H}$ ,  $\mathbf{aux}$  is parsed as  $(m_1, \dots, m_q, \gamma, \theta)$ . The algorithm returns  $\perp$  if  $m \neq m_i$ . Otherwise, the soft opening  $\tau = (W_i, Z_i)$  is generated as per (4). If  $\mathbf{flag} = \mathbb{S}$ , the algorithm parses  $\mathbf{aux}$  as  $(\theta, \gamma)$  and soft-decommits to  $m$  using

$$(W_i, Z_i) = \left( (g_i^\gamma \cdot g_q^{-m} \cdot H_{\mathbb{G}}(tag)^r)^{1/\theta}, g_1^{-r} \right), \quad (6)$$

where  $r \xleftarrow{R} \mathbb{Z}_p^*$ . In either case, the algorithm returns  $\tau = (W_i, Z_i) \in \mathbb{G}^2$ .

**qSVer**<sub>pk</sub>( $m, i, (C, V), \tau, tag$ ): parses  $\tau$  as  $(W_i, Z_i) \in \mathbb{G}$  and returns 1 if and only if  $C, V \in \mathbb{G}$  and the first verification equation of (5) is satisfied.

**qTrapGen**<sub>PK,TK</sub>( $tag$ ): given the master trapdoor  $TK = g_{q+1}$ , a trapdoor for  $tag \in \mathcal{T}$  is computed  $tk_{tag} = (t_{tag,1}, t_{tag,2}) = (g_{q+1} \cdot H_{\mathbb{G}}(tag)^s, g^{-s})$  for a random  $s \xleftarrow{R} \mathbb{Z}_p^*$ .

**qFake**<sub>PK,tk<sub>tag</sub></sub>( $\cdot$ ): outputs a pair  $(C, V) = (g^\theta, g^\gamma)$ , where  $\theta, \gamma \xleftarrow{R} \mathbb{Z}_p^*$ , and retains the state information  $\mathbf{aux} = (\theta, \gamma)$ .

**qHEquiv**<sub>PK,tk<sub>tag</sub></sub>( $m_1, \dots, m_q, i, tag, \mathbf{aux}$ ): parses  $\mathbf{aux}$  as  $(\theta, \gamma) \in (\mathbb{Z}_p^*)^2$  and the trapdoor  $tk_{tag}$  as  $(t_{tag,1}, t_{tag,2}) \in \mathbb{G}^2$ . It picks  $r \xleftarrow{R} \mathbb{Z}_p^*$  and computes

$$(W_i, Z_i) = \left( (g_i^\gamma \cdot t_{tag,1}^{-m_i} \cdot H_{\mathbb{G}}(tag)^r)^{1/\theta}, t_{tag,2}^{-m_i} \cdot g^{-r} \right).$$

The de-commitment is  $\pi = (\theta, W_i, Z_i) = \left( \theta, (g_i^\gamma \cdot g_{q+1}^{-m_i} \cdot H_{\mathbb{G}}(tag)^{r'})^{1/\theta}, g^{-r'} \right)$ , where  $r' = -sm_i + r$ .

**qSEquiv**<sub>PK,tk<sub>tag</sub></sub>( $m, i, tag, \mathbf{aux}$ ): parse  $\mathbf{aux}$  as  $(\theta, \gamma)$  and computes  $(W_i, Z_i)$  as in **qHEquiv**<sub>PK,tk<sub>tag</sub></sub>.

**Theorem 2.** *The scheme is a concise multi-trapdoor qTMC if the q-DHE assumption holds.*

*Proof.* Given in appendix D. □

STRONGLY INDEPENDENT ZK-EDBs FROM MULTI-TRAPDOOR qTMC. Following [15], a multi-trapdoor qTMC can be combined with a digital signature and a collision-resistant hash function  $H : \{0, 1\}^* \rightarrow \mathcal{T}$  to give a strongly independent ZK-EDB. To commit to a database  $D$ , the prover first generates a key pair  $(\mathbf{SK}, \mathbf{VK})$  for an existentially unforgeable (as defined in appendix C)

signature scheme  $\Sigma = (\mathcal{G}, \mathcal{S}, \mathcal{V})$  [16]. The commitment string is  $(Com, VK)$ , where all commitments are produced using the qTMC family (with  $q = 1$  at the leaves and  $q > 1$  at internal nodes) indexed by the tag  $H(VK)$ . To generate a proof for some key  $x$ , the prover generates a proof  $\pi_x$  (by opening the appropriate commitments using  $Dec$ ) and outputs  $\pi_x$  and  $\text{sig}_x = \mathcal{S}(\text{SK}, (Com, x))$ . Verification entails to check  $\pi_x$  and that  $\mathcal{V}(\text{sig}_x, VK, (Com, x)) = 1$ . The security proof of this scheme (detailed in appendix E) is similar to that of theorem 3 in [15].

## A Security Properties of Zero-Knowledge Databases

The completeness, soundness and zero-knowledge properties of ZK-EDBs are formally stated as follows.

**Completeness:** For all databases  $D$  and for all keys  $x$ , it must hold that

$$\Pr\left[\sigma \leftarrow \text{CRS-Gen}(\lambda); (Com, Dec) \leftarrow \text{P1}(\sigma, D); \right. \\ \left. \pi_x \leftarrow \text{P2}(\sigma, D, Com, Dec, x) : \forall(\sigma, Com, x, \pi_x) = D(x) \right] = 1 - \nu.$$

for some negligible function  $\nu$ .

**Soundness:** For all keys  $x$  and for any probabilistic poly-time algorithm  $\text{P}'$ , the following probability is negligible:

$$\Pr\left[\sigma \leftarrow \text{CRS-Gen}(\lambda); (Com, x, \pi_x, \pi'_x) \leftarrow \text{P}'(\sigma, D); \right. \\ \left. \forall(\sigma, Com, x, \pi_x) = y \neq bad \wedge \forall(\sigma, Com, x, \pi'_x) = y' \neq bad \wedge (y \neq y') \right].$$

**Zero-knowledge:** for any PPT adversary  $\mathcal{A}$  and any efficiently computable database  $D$ , there must exist an efficient simulator  $(\text{Sim}_0, \text{Sim}_1, \text{Sim}_2^D)$  such that the outputs of the following experiments are indistinguishable:

*Real experiment:*

1. Set  $\sigma \leftarrow \text{CRS-Gen}(\lambda)$ ,  $(Com, Dec) \leftarrow \text{P1}(\sigma, D)$  and  $s_0 = \varepsilon$ ,  $\pi_0 = \varepsilon$ .
2. For  $i = 1, \dots, n$ ,  $\mathcal{A}$  outputs  $(x_i, s_i) \leftarrow \mathcal{A}(\sigma, Com, \pi_0, \dots, \pi_{i-1}, s_{i-1})$  and obtains a real proof  $\pi_i = \text{P2}(\sigma, D, Com, Dec, x_i)$ .

The output is  $(\sigma, x_1, \pi_1, \dots, x_n, \pi_n)$ .

*Ideal experiment:*

1. Set  $(\sigma', St_0) \leftarrow \text{Sim}_0(\lambda)$ ,  $(Com', St_1) \leftarrow \text{Sim}_1(St_0)$  as well as  $s_0 = \varepsilon$ ,  $\pi'_0 = \varepsilon$ .
2. For  $i = 1, \dots, n$ ,  $\mathcal{A}$  outputs  $(x_i, s_i) \leftarrow \mathcal{A}(\sigma', Com', \pi'_0, \dots, \pi'_{i-1}, s_{i-1})$  and gets a simulated proof  $\pi'_i \leftarrow \text{Sim}_2^D(\sigma', St_1, x_i)$ .

The output of the experiment is  $(\sigma', x_1, \pi'_1, \dots, x_n, \pi'_n)$ .

In the above,  $\text{Sim}_2^D$  is an oracle that is permitted to invoke a database oracle  $D(\cdot)$  and obtain values  $D(x)$  for the keys  $x$  chosen by  $\mathcal{A}$ .

## B Zero-Knowledge Elementary Databases from qTMC Schemes

The common reference string  $\sigma = (pk, pkm, H)$  consists of the public key  $pk$  of a trapdoor  $q$ -mercurial commitment scheme  $QTM$ , the public key  $pkm$  of an ordinary trapdoor mercurial commitment  $\mathcal{MC}$  (which can be an instance of the qTMC with  $q = 1$ ) and the description of a collision-resistant hash function  $H$ , the domain of which does *not* include 0.

The notations of this section are close to the ones of [21, 9]: we denote by  $T_h$  the complete  $q$ -ary tree of height  $h$  and  $q^h$  leaves. If  $\mathcal{U}_h$  is a universe of size  $q^h$ , its associated tree  $T_h$  is obtained by assigning each element  $x \in \mathcal{U}_h$  to a leaf of  $T_h$  and by labeling each node using the  $q$ -ary encoding of  $x \in \mathcal{U}_h$ . The label of the root is the empty string  $\epsilon$  and, if  $v$  is a non-leaf node, its children are labeled as  $v1, \dots, vq$ . For each node  $v$ ,  $\text{parent}(v)$  denotes  $v$ 's father in the tree and,

when  $u = \text{parent}(v)$ ,  $\text{index}_u(v)$  is the index of  $v$  when numbering  $u$ 's children from 1 to  $q$  in a left-to-right order. For each leaf node  $H(x)$ , we also call  $\text{PATH}(H(x))$  the set of nodes on the path from  $H(x)$  to the root, not counting  $H(x)$  and  $\epsilon$  themselves. For any  $S \subseteq \mathcal{U}_h$ ,  $\text{TREE}(S)$  denotes the subtree of  $T_h$  containing nodes on paths that connect elements of  $S$  to the root (in other words,  $\text{TREE}(S) = S \cup \{\text{PATH}(v) | v \in S\}$ ). Also,  $\text{FRONTIER}(S)$  will be used to denote the set  $\{v : v \notin S \wedge \text{parent}(v) \in \text{TREE}(S)\}$ .

In [9], Catalano *et al.* generalize the ZK-EDB construction of [10] as follows.

**CRS-Gen**( $\lambda$ ) : runs  $(pk, tk) \leftarrow \text{qKeygen}(\lambda, q)$ ,  $(pkm, tkm) \leftarrow \text{qKeygen}(\lambda, 1)$  and discards  $(tk, tkm)$ .

It also chooses a collision-resistant hash function  $H$  and sets  $\sigma = (pk, pkm, H)$ .

**P1**( $\sigma, D$ ) : the committer conducts the following steps.

1. Let  $S = \{H(x) : x \in \mathcal{U}_h \text{ s.t. } D(x) \neq \perp\}$  and let  $T = \text{TREE}(S) \cup \text{FRONTIER}(S)$ .
2. For each leaf node  $H(x)$  of  $T$ , compute

$$n_{H(x)} = \begin{cases} H(y) & \text{if } D(x) = y \\ 0 & \text{if } D(x) = \perp, \end{cases}$$

compute  $(C_{H(x)}, \text{aux}_{H(x)}) = \text{qHCom}_{pkm}(n_{H(x)})$  and set  $m_{H(x)} = H(C_{H(x)})$ .

3. For each internal node  $u \in T$  such that  $u \in \text{FRONTIER}(S)$ , set  $(C_u, \text{aux}_u) = \text{qSCom}_{pk}()$ .
4. For each internal node  $u \in \text{TREE}(S)$  and in a bottom-up order, compute a hard  $q$ -commitment  $(C_u, \text{aux}_u) = \text{qHCom}_{pk}(m_{u1}, \dots, m_{uq})$  and, if  $u \neq \epsilon$ , set  $m_u = H(C_u)$ . For each  $u \in \text{TREE}(S)$ , retain the state information  $\text{aux}_u$ .
5. Output the commitment string  $Com = C_\epsilon$  and  $Dec = \{\text{aux}_u | u \in T\}$ .

**P2**( $\sigma, Com, Dec, x$ ) : to generate a proof for the key  $x \in \mathcal{U}_h$ ,

1. If  $D(x) \neq \perp$ , the proof  $\pi_x$  consists of commitments and their hard openings for all nodes on the path from leaf  $H(x)$  to the root  $\epsilon$ :

$$\pi_x = \{y, C_{H(x)}, \text{qHOpen}_{pkm}(H(y), \text{aux}_{H(x)}), \{C_u, \text{qHOpen}_{pk}(m_v, i, \text{aux}_u)\}_{v \in \text{PATH}(H(x))}\},$$

where  $u = \text{parent}(v)$  and  $i = \text{index}_u(v)$ .

2. If  $D(x) = \perp$ , the prover checks if  $H(x)$  is in the tree  $T$  constructed by **P1**. If not, let  $w \in \text{FRONTIER}(S)$  be the root of the missing subtree of  $T_h$  containing  $H(x)$ . Let the prover construct the subtree rooted at  $w$  by executing steps 2 and 4 of **P1** for that subtree (instead of  $T$ ). Then, the proof of non-membership consists of commitments and soft-openings for all nodes on the path from  $H(x)$  to the root  $\epsilon$ :

$$\pi_x = \{C_{H(x)}, \text{qSOpen}_{pkm}(0, \mathbb{H}, \text{aux}_{H(x)}), \{C_u, \text{qSOpen}_{pk}(m_v, i, \mathbb{H}/\mathbb{S}, \text{aux}_u)\}_{v \in \text{PATH}(H(x))}\},$$

where  $u = \text{parent}(v)$  and  $i = \text{index}_u(v)$ .

**V**( $\sigma, Com, x, \pi_x$ ) :

- a. If  $D(x) \neq \perp$ , parse  $\pi_x$  as  $\{y, C_{H(x)}, HO_{H(x)}, \{C_u, HO_v\}_{v \in \text{PATH}(H(x)), u = \text{parent}(v)}\}$ .

1. Return *bad* if  $\text{qHVer}_{pkm}(H(y), C_{H(x)}, HO_{H(x)}) = 0$ .
2. Compute  $m_{H(x)} = H(C_{H(x)})$ .
3. Let  $v = \text{parent}(H(x))$ ,  $i = \text{index}_v(H(x))$ . Return *bad* if  $\text{qHVer}_{pk}(m_{H(x)}, i, C_v, HO_v) = 0$ .

4. For each  $v \in \text{PATH}(H(x))$ , let  $u = \text{parent}(v)$  and  $i = \text{index}_u(v)$ . Compute  $m_v = H(C_v)$  and return *bad* if  $\text{qHVer}_{pk}(m_v, i, C_u, HO_v) = 0$ .

If none of the above checks failed, return  $y$ .

- b. If  $D(x) = \perp$ , parse  $\pi_x$  as  $\{C_{H(x)}, SO_{H(x)}, \{C_u, SO_v\}_{v \in \text{PATH}(H(x)), u = \text{parent}(v)}\}$ .
  1. Return *bad* if  $\text{qSVer}_{pkm}(0, C_{H(x)}, SO_{H(x)}) = 0$ .
  2. Compute  $m_{H(x)} = H(C_{H(x)})$ .
  3. Let  $v = \text{parent}(H(x))$ ,  $i = \text{index}_v(H(x))$ . Return *bad* if  $\text{qSVer}_{pk}(m_{H(x)}, i, C_v, SO_v) = 0$ .
  4. For each  $v \in \text{PATH}(H(x))$ , let  $u = \text{parent}(v)$ ,  $i = \text{index}_u(v)$  and  $m_v = H(C_v)$ . Return *bad* if  $\text{qSVer}_{pk}(m_v, i, C_u, SO_v) = 0$ .

If none of the above checks fails, return  $\perp$  (meaning that  $x \notin [D]$ ).

## C Digital Signatures and Programmable Hash Functions

**DIGITAL SIGNATURES.** A signature scheme consists of a triple of algorithms  $\Sigma = (\mathcal{G}, \mathcal{S}, \mathcal{V})$  such that, on input of a security parameter  $\lambda$ ,  $\mathcal{G}$  generates a key pair  $(\text{SK}, \text{VK})$  while, for any message  $M$ ,  $\mathcal{V}(\text{sig}, \text{VK}, M)$  outputs 1 whenever  $\text{sig} = \mathcal{S}(\text{SK}, M)$  and 0 otherwise.

As in [15], we need existentially unforgeable digital signatures. Namely, given  $\text{VK}$  and access to a signing oracle, no PPT adversary must be able to create a signature for a previously unsigned message (according to the security definition of [16]).

**Definition 3.** A signature scheme  $\Sigma = (\mathcal{G}, \mathcal{S}, \mathcal{V})$  is existentially unforgeable under chosen-message attacks if, for any PPT adversary  $\mathcal{F}$ , the probability

$$\Pr[(\text{SK}, \text{VK}) \leftarrow \mathcal{G}(\lambda); (M^*, \text{sig}^*) \leftarrow \mathcal{F}^{\mathcal{O}_{\text{sig}(\cdot)}}(\text{VK}) : \mathcal{V}(\text{sig}^*, \text{VK}, M^*) = 1 \wedge M^* \notin Q]$$

is negligible as a function of  $\lambda$ . In the above,  $\mathcal{O}_{\text{sig}(\cdot)}$  is an oracle taking as input arbitrary messages  $M$  and returns  $\text{sig} = \mathcal{S}(\text{SK}, M)$  while  $Q$  denotes the list of messages that were queried to  $\mathcal{O}_{\text{sig}(\cdot)}$ .

**PROGRAMMABLE HASH FUNCTIONS.** A group hash function  $H = (\text{PHF.Gen}, \text{PHF.Eval})$  is a pair of algorithms such that, for a security parameter  $\lambda \in \mathbb{N}$ , a key  $\kappa \leftarrow \text{PHF.Gen}(\lambda)$  is generated by the key generation algorithm. This key is used to evaluate the deterministic evaluation algorithm that, on input of a string  $X \in \{0, 1\}^L$ , computes  $H_{\kappa, \mathbb{G}}(X) = \text{PHF.Eval}(\kappa, X) \in \mathbb{G}$ .

**Definition 4.** [17] A group hash function  $H_{\mathbb{G}} : \{0, 1\}^* \rightarrow \mathbb{G}$  is  $(m, n, \gamma, \delta)$ -programmable if there exists PPT algorithms  $(\text{PHF.TrapGen}, \text{PHF.TrapEval})$  such that:

- For  $g, h \in \mathbb{G}$ , the trapdoor key generation algorithm  $(\kappa', tk) \leftarrow \text{PHF.TrapGen}(\lambda, g, h)$  generates a key  $\kappa'$  and a trapdoor  $tk$  such that, for any  $X \in \{0, 1\}^L$ ,  $(a_X, b_X) \leftarrow \text{PHF.TrapEval}(tk, X)$  produces integers  $a_X, b_X$  such that  $H_{\kappa', \mathbb{G}}(X) = \text{PHF.Eval}(\kappa', X) = g^{a_X} h^{b_X}$ .
- For all  $g, h \in \mathbb{G}$  and for  $\kappa \leftarrow \text{PHF.Eval}(\lambda)$ ,  $(\kappa', tk) \leftarrow \text{PHF.TrapGen}(\lambda, g, h)$ , the distributions of  $\kappa$  and  $\kappa'$  are statistically  $\gamma$ -close to each other.
- For all generators  $g, h \in \mathbb{G}$  and all  $\kappa'$  produced by  $\text{PHF.TrapGen}$ , for all  $X_1, \dots, X_m \in \{0, 1\}^L$ ,  $Z_1, \dots, Z_n \in \{0, 1\}^L$  such that  $X_i \neq Z_j$ , the corresponding  $(a_{X_i}, b_{X_i}) \leftarrow \text{PHF.TrapEval}(tk, X_i)$ ,  $(a_{Z_i}, b_{Z_i}) \leftarrow \text{PHF.TrapEval}(tk, Z_i)$  are such that

$$\Pr[b_{X_1} = \dots = b_{X_m} = 0 \wedge b_{Z_1}, \dots, b_{Z_n} \neq 0] \geq \delta,$$

where the probability is taken over the trapdoor  $tk$  produced along with  $\kappa'$ .

The hash function of Chaum *et al.* [11], that hashes  $L$ -bit strings  $M = m_1 \cdots m_L \in \{0, 1\}^L$  by mapping them onto  $H_{\kappa, \mathbb{G}}(M) = u_0 \cdot \prod_{k=1}^L u_k^{m_k}$  using public group elements  $(u_0, \dots, u_L)$ , is known [25] to provide such a  $(1, \ell, 0, \delta)$ -programmable hash function where  $\delta = 1/(8\ell(L+1))$ , for some polynomial  $\ell$ . Using a different technique, Hofheinz and Kiltz [17] showed how to increase the probability  $\delta$  to  $O(1/(\ell\sqrt{L}))$ .

## D Proof of Theorem 2

We first show the correctness of the scheme. Hard commitments  $(C, V) = (g^\theta, g^\gamma \cdot \prod_{j=1}^q g_{q+1-j}^{m_j})$  are hard-opened by revealing  $\theta$ ,  $W_i = (g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j} \cdot H_{\mathbb{G}}(\text{tag})^r)^{1/\theta}$  and  $Z_i = g^{-r}$ , for a random  $r \xleftarrow{R} \mathbb{Z}_p^*$ , which satisfy the verification (5) since

$$\begin{aligned} e(C, W_i) \cdot e(g_1, g_q)^{m_i} \cdot e(H_{\mathbb{G}}(\text{tag}), Z_i) &= e(g, g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j} \cdot H_{\mathbb{G}}(\text{tag})^r) \cdot e(g_1, g_q)^{m_i} \cdot e(H_{\mathbb{G}}(\text{tag}), g^{-r}) \\ &= e(g, g_i^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j+i}^{m_j}) \cdot e(g_1, g_q)^{m_i} \\ &= e(g_i, g^\gamma \cdot \prod_{j=1, j \neq i}^q g_{q+1-j}^{m_j}) \cdot e(g_i, g_{q+1-i})^{m_i} = e(g_i, V). \end{aligned}$$

In soft commitments  $(C, V) = (g_1^\theta, g_1^\gamma)$ , a soft de-commitment to message  $m$  consists of a pair  $(W_i, Z_i) = ((g_i^\gamma \cdot g_q^{-m} \cdot H_{\mathbb{G}}(\text{tag})^r)^{1/\theta}, g_1^{-r})$ , which is easily seen to pass the verification test as

$$\begin{aligned} e(C, W_i) \cdot e(g_1, g_q)^m \cdot e(H_{\mathbb{G}}(\text{tag}), Z_i) &= e(g_1, g_i^\gamma \cdot g_q^{-m} \cdot H_{\mathbb{G}}(\text{tag})^r) \cdot e(g_1, g_q)^m \cdot e(H_{\mathbb{G}}(\text{tag}), g_1^{-r}) \\ &= e(g_1, g_i^\gamma) = e(g_i, V). \end{aligned}$$

Regarding fake commitments  $(C, V) = (g^\theta, g^\gamma)$ , they are hard-equivocated by revealing a triple of the form  $\pi = (\theta, W_i, Z_i) = (\theta, (g_i^\gamma \cdot g_{q+1}^{-m_i} \cdot H_{\mathbb{G}}(\text{tag})^r)^{1/\theta}, g^{-r})$ , for some  $r \in \mathbb{Z}_p^*$ . We can check that such a triple satisfies

$$\begin{aligned} e(C, W_i) \cdot e(g_1, g_q)^m \cdot e(H_{\mathbb{G}}(\text{tag}), Z_i) &= e(g, g_i^\gamma \cdot g_{q+1}^{-m} \cdot H_{\mathbb{G}}(\text{tag})^r) \cdot e(g_1, g_q)^m \cdot e(H_{\mathbb{G}}(\text{tag}), g^{-r}) \\ &= e(g, g_i^\gamma) = e(g_i, V). \end{aligned}$$

We now turn to the binding property and prove that the scheme is actually an adaptive multi-trapdoor  $q$ -mercurial commitment scheme (which is a stronger property than what we need) if the hash function  $H_{\mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  is  $(1, \ell)$ -programmable, where  $\ell$  denotes the number of tags (*i.e.*, the number of members in the family of multi-trapdoor commitments) that  $\mathcal{A}$  queries the trapdoor of.

We construct an algorithm  $\mathcal{B}$  that solves a  $q$ -DHE instance  $(g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q})$  using its interaction with an adversary  $\mathcal{A}$  that breaks the adaptive  $q$ -mercurial binding property after  $\ell$  trapdoor queries. To this end,  $\mathcal{B}$  includes in  $PK$  the description of a  $(1, \ell, 0, \delta)$ -programmable

hash function  $H_{\mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  such that, for any  $tag \in \mathcal{T}$ ,  $H_{\mathbb{G}}(tag) = g^{a_{tag}} \cdot g_1^{b_{tag}}$  for integers  $a_{tag}, b_{tag}$  that it can compute. Moreover, for any  $tag_1, \dots, tag_{\ell}$  and  $tag^* \notin \{tag_1, \dots, tag_{\ell}\}$ , it holds with non-negligible probability  $\delta$  that  $b_{tag_i} \neq 0$  for  $i = 1, \dots, \ell$  whereas  $b_{tag^*} = 0$ . Therefore, if  $tag_1, \dots, tag_{\ell}$  are the tags that  $\mathcal{A}$  adaptively queries to the  $\mathcal{TG}$  oracle,  $\mathcal{B}$  is able to compute  $tk_{tag_i} = (t_{tag_i,1}, t_{tag_i,2}) = (g_{q+1} \cdot H_{\mathbb{G}}(tag_i)^{\tilde{r}}, g^{-\tilde{r}})$  using the technique of [3]: it picks  $r \xleftarrow{R} \mathbb{Z}_p^*$  and sets  $(t_{tag_i,1}, t_{tag_i,2}) = (H_{\mathbb{G}}(tag_i)^r \cdot g_q^{-a_{tag_i}/b_{tag_i}}, g^{-r} \cdot g_q^{1/b_{tag_i}})$ , which is easily seen to have the correct distribution if we set  $\tilde{r} = r - \frac{\alpha^q}{b_{tag_i}}$ , where  $\alpha = \log_g(g_1)$ .

In addition, the  $q$ -commitment family  $tag^*$  which is the target of the attack also satisfies  $H_{\mathbb{G}}(tag^*) = g^{a_{tag^*}}$ , for some known  $a_{tag^*} \in \mathbb{Z}_p$ , with non-negligible probability. Let us assume that the attack is a soft collision  $(m_i, \theta, W_i, Z_i)$ ,  $(m'_i, W'_i, Z'_i)$ , where  $m_i \neq m'_i$ , for some  $q$ -commitment  $(C, V)$  at some position  $i \in \{1, \dots, q\}$ . We must have

$$\begin{aligned} e(g_i, V) &= e(C, W_i) \cdot e(g_1, g_q)^{m_i} \cdot e(H_{\mathbb{G}}(tag^*), Z_i) \\ &= e(C, W'_i) \cdot e(g_1, g_q)^{m'_i} \cdot e(H_{\mathbb{G}}(tag^*), Z'_i). \end{aligned}$$

which implies  $e(g, (W_i/W'_i)^{\theta/(m'_i-m_i)} \cdot (Z_i/Z'_i)^{a_{tag^*}/(m'_i-m_i)}) = e(g_1, g_q)$  since  $H_{\mathbb{G}}(tag^*) = g^{a_{tag^*}}$  and  $C = g^{\theta}$ . Therefore,  $\mathcal{B}$  is able to compute  $g_{q+1} = (W_i/W'_i)^{\theta/(m'_i-m_i)} \cdot (Z_i/Z'_i)^{a_{tag^*}/(m'_i-m_i)}$  and thus breaks the  $q$ -DHE assumption with probability  $\delta \cdot \varepsilon$  if  $\varepsilon$  is  $\mathcal{A}$ 's probability of success.  $\square$

## E From Multi-Trapdoor $q$ TMC to Strongly Independent ZK-EDB

Let us assume that an adversary  $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$  has non-negligible chance of breaking the strong independence property of the ZK-EDB scheme outlined at the end of section 5. We show that it implies a breach either in the  $q$ -mercurial binding property of the multi-trapdoor  $q$ TMC scheme, the unforgeability of the signature scheme  $\Sigma$  or in the collision-resistance of the hash function.

Recall that  $\mathcal{A}$  is such that, after having obtained  $((Com_1, VK_1), \dots, (Com_{\ell}, VK_{\ell}))$  and queried some proofs for underlying databases  $D_1, \dots, D_{\ell}$ ,  $\mathcal{A}_1$  outputs a commitment of her own  $(Com, VK)$  and some state information  $\omega$ . Then, in two independent executions on the same input  $(\sigma, \omega)$ ,  $\mathcal{A}_2$  is given access to oracles  $\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)$  and  $\text{Sim}_2^{D'_i \dashv Q_i D_i}(St_i, Com_i)$ , respectively. These executions are expected to yield convincing proofs  $\pi_x, \pi'_x$  for different statements about the same key  $x$ . As in the proof of theorem 3 in [15], we distinguish the following cases:

- If  $VK = VK_{i^*}$  for some  $i^* \in \{1, \dots, \ell\}$ , it must hold that either  $Com \neq Com_{i^*}$  or  $x$  was never queried by  $\mathcal{A}_1$  or  $\mathcal{A}_2$  to oracles  $\text{Sim}_2^{D_{i^*}(\cdot)}$  or  $\text{Sim}_2^{D'_{i^*} \dashv Q_{i^*} D_{i^*}(\cdot)}$ . Then, the security of the signature scheme can be broken with probability  $1/\ell$ . When generating  $\mathcal{A}_1$ 's input, the forger  $\mathcal{B}$  chooses  $j \xleftarrow{R} \{1, \dots, \ell\}$ . It sets  $VK_j = VK^*$ , where  $VK^*$  is a signature verification key supplied by a challenger, and generates  $VK_1, \dots, VK_{j-1}, VK_{j+1}, \dots, VK_{\ell}$  itself. To generate  $Com_1, \dots, Com_{\ell}$ ,  $\mathcal{B}$  generates fake  $q$ -commitments and, using the master trapdoor  $TK = g_{q+1}$  (that it also chose itself), can equivocate them as needed to simulate  $\text{Sim}_2^{D_i(\cdot)}(St_i, Com_i)$  and  $\text{Sim}_2^{D'_i \dashv Q_i D_i}(St_i, Com_i)$  in the two runs of  $\mathcal{A}_2$ . To simulate these two oracles,  $\mathcal{B}$  also needs to query its own challenger and obtain signatures w.r.t. the verification key  $VK_j = VK^*$ . With probability  $1/\ell$ , we have  $i^* = j$  (since  $j$  is independent of  $\mathcal{A}$ 's view) and  $\mathcal{A}_2$  must have come up with a forgery since either  $Com \neq Com_{i^*}$  or the key  $x$  was not queried to the  $j^{\text{th}}$  prover.

- If  $\text{VK} \neq \text{VK}_i$ , we can break the  $q$ -mercurial binding security of the multi-trapdoor qTMC or find a collision on the hash function. Let  $\mathcal{B}$  be an adversary taking as input the master qTMC public key  $PK$  and the description of a hash function  $H$ . At the beginning of the mercurial binding game,  $\mathcal{B}$  generates  $\ell$  digital signature key pairs  $(\text{SK}_i, \text{VK}_i)$ , for  $i = 1, \dots, \ell$ , and hands  $\text{tag}_1 = H(\text{VK}_1), \dots, \text{tag}_\ell = H(\text{VK}_\ell)$  to its mercurial binding challenger. The latter replies with a master public key  $PK$  and  $\mathcal{B}$  is then allowed to query  $\mathcal{TG}$  and obtain trapdoors  $tk_{\text{tag}_1}, \dots, tk_{\text{tag}_\ell}$  for commitment families indexed by  $\text{tag}_1, \dots, \text{tag}_\ell$ . Using these, it can feed  $\mathcal{A}_1$  with  $(\text{Com}_1, \text{VK}_1), \dots, (\text{Com}_\ell, \text{VK}_1)$  that are all generated using fake  $q$ -commitments in the appropriate families. Thanks to  $tk_{\text{tag}_1}, \dots, tk_{\text{tag}_\ell}$ , it can equivocate such fake commitments at will and, for each  $i \in \{1, \dots, \ell\}$ , it can perfectly simulate oracles  $\text{Sim}_2^{D_i(\cdot)}(St_i, \text{Com}_i)$  and  $\text{Sim}_2^{D'_i \dashv Q_i D_i}(St_i, \text{Com}_i)$  in the two executions of  $\mathcal{A}_2$ . For the commitment string  $(\text{Com}, \text{VK})$  produced by  $\mathcal{A}_1$ , the two runs of  $\mathcal{A}_2$  must output  $(x, (\pi_x, \text{sig}_x))$  and  $(x, (\pi'_x, \text{sig}'_x))$  such that  $\pi_x \neq \pi'_x$  (since they trick the verifier into accepting two distinct values  $D(x)$  for the key  $x$ ). Moreover,  $\pi_x$  and  $\pi'_x$  consist of two sequences of commitments and hard/soft openings that are all valid w.r.t. the tag  $H(\text{VK})$  and converge to the same commitment string  $\text{Com}$  at the root of the tree. It comes that these sequences necessarily “fork” at some point on the path from the root to  $x$ . Using the same arguments as those that establish the soundness property in the proof of theorem 2 in [9], we end up with either a hard/soft collision for the qTMC family member indexed by the tag  $H(\text{VK})$  (which  $\mathcal{B}$  never queried to its  $\mathcal{TG}$  oracle) or a collision on  $H$ . □

In the construction of strongly independent ZK-EDB outlined at the end of section 5, two distinct multi-trapdoor qTMC instances are needed: an instance with  $q > 1$  must be used at each internal node while another instance with  $q = 1$  is needed at the leaves of the tree. Each one of these instances makes use of its own programmable hash function and we call these two functions  $H_{q, \mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  and  $H_{1, \mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$ , respectively.

In the case  $\text{VK} \neq \text{VK}_i$  in the above proof, the adversary  $\mathcal{A}$  breaks the binding property of the second qTMC instance (with  $q = 1$ ) if the “forking” occurs at a leaf. If the forking appears at an internal node,  $\mathcal{A}$  rather defeats the security of the first instance (where  $q > 1$ ). To keep the proof simple, we need to make sure that the adversary breaks one-out-of-two  $q$ -DHE problem instances (where  $q > 1$  or  $q = 1$ ) regardless of whether the forking is located at a leaf or an internal node. To this end, existing implementations [11, 25, 17] of programmable hash functions make it possible to instantiate  $H_{q, \mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  and  $H_{1, \mathbb{G}} : \mathcal{T} \rightarrow \mathbb{G}$  so as to have  $H_{q, \mathbb{G}}(\text{tag}) = g^{a_{\text{tag}}} \cdot g_1^{b_{\text{tag}}}$  and  $H_{1, \mathbb{G}}(\text{tag}) = g^{a'_{\text{tag}}} \cdot h_1^{b_{\text{tag}}}$  for independent values  $a_{\text{tag}}, a'_{\text{tag}} \in_R \mathbb{Z}_p$  and where  $g_1, h_1$  are part of a  $q$ -DHE instance  $(g, g_1, \dots, g_q, g_{q+2}, \dots, g_{2q})$  and 1-DHE instance (*i.e.*, a “squared Diffie-Hellman” instance where one has to find  $g^{(\alpha^2)}$  given  $(g, h_1 = g^\alpha)$ ), respectively. By doing so, even though outputs of  $H_{q, \mathbb{G}}(\text{tag})$  and  $H_{1, \mathbb{G}}(\text{tag})$  are independent for each  $\text{tag} \in \mathcal{T}$ , it holds that  $H_{q, \mathbb{G}}(\text{tag}) = g^{a_{\text{tag}}}$  whenever  $H_{1, \mathbb{G}}(\text{tag}) = g^{a'_{\text{tag}}}$  and, whenever  $H_{q, \mathbb{G}}(\text{tag}) = g^{a_{\text{tag}}} \cdot g_1^{b_{\text{tag}}}$  for some  $b_{\text{tag}} \neq 0$ , we also have  $H_{1, \mathbb{G}}(\text{tag}) = g^{a'_{\text{tag}}} \cdot h_1^{b_{\text{tag}}}$ . Then, the simulator  $\mathcal{B}$  will be able to solve one of the two  $q$ -DHE instances with a probability  $\delta$  proportional to  $1/\ell$  (as explained at the end of appendix D), no matter where the forking lies in the sequence of commitments/openings.
