### Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

## ABSTRACT

The interferon response suppression by the respiratory syncytial virus relies on two unique non-structural proteins, NS1 and NS2, that interact with cellular partners through high order complexes. We hypothesized that two conserved proline residues, P81 and P67, participate in the conformational change leading to oligomerization. We found that molecular dynamics of NS1 show a highly mobile C-terminal helix, which become rigid upon in silico replacement of P81. A soluble oligomerization pathway into regular spherical structures at low ionic strength competes with an aggregation pathway at high ionic strength upon temperature increase. P81A requires higher temperatures to oligomerize and has a small positive effect on aggregation, while P67A is largely prone to aggregation. Chemical denaturation shows a first transition, involving a large fluorescence and ellipticity change corresponding to both a conformational change and substantial effects on the environment of its single tryptophan, that is strongly destabilized in P67A but stabilized by P81A. The subsequent global cooperative unfolding corresponding to the main  $\beta$ -sheet core is not affected by the proline mutations. Thus, a clear link exists between the effect of P81 and P67 on the stability of the first transition and oligomerization/aggregation. Interestingly, both P67 and P81 are located

1  
2 far away in space and sequence from the C-terminal helix, indicating a marked global  
3  
4  
5  
6 structural dynamics. This provide a mechanism for modulating the oligomerization of NS1 by  
7  
8  
9 unfolding of a weak helix that exposes hydrophobic surfaces, linked to the participation of  
10  
11  
12 NS1 in multiprotein complexes.

## INTRODUCTION

RNA viruses require the innate immune response to be suppressed in order to attain a productive life cycle. Negative-sense single-stranded RNA viruses (*Mononegavirales*) use several different strategies mediated by different proteins <sup>1</sup>. *Paramyxoviruses* and *Pneumoviruses* suppress the IFN response by limiting the synthesis of IFN-inducing viral RNAs, inhibiting RNA sensors, using decoy substrates for cellular kinases, and by direct repressing the IFN promoter <sup>2</sup>. The IFN shut-down in these families of related viruses operate via targeted proteolysis and sequestering of signaling and cellular factors, and upregulation of cellular inhibitors related to IFN induction and IFN effector functions <sup>2,3,4</sup>.

The respiratory syncytial virus (RSV), formerly member of the *Paramyxoviridae* family and recently reclassified within the new *Pneumoviridae* family <sup>5</sup> is responsible for the majority of bronchiolitis and pneumonia cases in infants, elderly and immunocompromised <sup>6,7</sup>. Its 15 kb RNA genome encoding 11 proteins bears two unique 3' proximal genes encoding for two non-structural proteins, NS1 and NS2, that partake in suppressing the innate immune response <sup>3</sup>. These proteins have no sequence homologues among Mononegavirales and are responsible for the interferon (IFN) suppression activity of RSV, a function that is otherwise

1  
2 mediated by co-translational editing of the phosphoprotein P in paramyxoviruses and other  
3  
4  
5 pneumoviruses <sup>6,7</sup>. NS1 and NS2 are regarded as multifunctional, they are expressed  
6  
7  
8 abundantly immediately after cell entry <sup>8</sup> and were proposed to form heterodimers <sup>9,4</sup>. In  
9  
10  
11 addition, it was shown that NS1 has a strong inhibitory effect on RSV genomic and  
12  
13  
14 antigenomic RNA synthesis <sup>10</sup>. NS1 was reported to interact directly or indirectly with 221  
15  
16  
17 targets in a quantitative proteomic analysis <sup>11</sup> and its multiple functions were recently  
18  
19  
20 summarized in Chatterjee et al <sup>12</sup>. The first protein described to co-localize with NS1 was the  
21  
22  
23 mitochondrial signaling protein (MAVS), a critical molecule in the type I IFN pathway <sup>13</sup>. NS1  
24  
25  
26 can also bind directly to IRF- 3 and the CREB binding protein (CBP), both transcriptional  
27  
28  
29 activators of the type I IFN system <sup>14</sup>.

30  
31  
32  
33  
34  
35  
36  
37 Recombinant NS1 was shown to be a monomer in solution which unfolds following a  
38  
39  
40 highly cooperative two-state transition <sup>15,16</sup>. The native NS1 monomer follows a simple  
41  
42  
43 unfolding kinetics with a half-life of 45 min, in agreement with a highly stable core structure at  
44  
45  
46 equilibrium <sup>17</sup>. Refolding is a complex process that involves several slowly interconverting  
47  
48  
49 species compatible with proline isomerization. However, upon mild temperature variation,  
50  
51  
52 conformational changes are induced leading to the formation of regular ca 30 nm spherical  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 oligomers (NS1SOs) which are highly stable and homogeneous <sup>16</sup>. A substantial secondary  
3  
4  
5 structure change into increased  $\beta$ -sheet content and the formation of a dimeric nucleus  
6  
7  
8 precede polymerization by the sequential addition of monomers at a surprisingly low rate <sup>17</sup>.  
9  
10

11  
12  
13 NS1 transfected in lung epithelial cells was shown to form homo-oligomers and to  
14  
15  
16 interact with NS2 <sup>18</sup> suggesting that NS1 oligomerization is a likely event in the cell. In  
17  
18  
19 addition, a degradosome consisting of a large heterogeneous protein complex with a  
20  
21  
22 molecular mass in the range of 300–750 kDa, containing both NS1 and NS2 proteins as well  
23  
24  
25 as proteasome subunits, was described <sup>19</sup>. This degradosome also presents degradative  
26  
27  
28 activity for NS1 and NS2 cellular targets such as RIG-I, TRAF3, and STAT2 and was found to  
29  
30  
31 be important in innate immunity suppression in infected cells <sup>19</sup>. Overall, these findings  
32  
33  
34 strongly suggest that the NS1SOs formed quasi-spontaneously in vitro could be linked to the  
35  
36  
37 degradosome complex.  
38  
39  
40  
41  
42  
43  
44

45 The recently determined crystal structure of NS1 showed that the overall fold  
46  
47  
48 corresponds to a  $\beta$ -sandwich composed of seven  $\beta$ -strands and is completed by three  $\alpha$ -  
49  
50  
51 helices:  $\alpha$ 1, located between  $\beta$ 2 and  $\beta$ 3, the short  $\alpha$ 2 found right before  $\beta$ 5, and the C-terminal  
52  
53  
54  $\alpha$ 3 that lies against the  $\beta$ -sheet core of the protein <sup>12</sup> ( Figure S1). The multiple binding  
55  
56  
57  
58  
59  
60

1  
2 activities of NS1 can take place at a few binding interfaces at most, something to be  
3  
4  
5 considered remarkable given its small size (15 kDa). Therefore, conformational heterogeneity  
6  
7  
8 and in particular, oligomer formation, may explain such a promiscuous binding activity. Given  
9  
10 that oligomerization requires a conformational rearrangement, we hypothesize that  
11  
12  
13 oligomerization capacity may be linked to the stability or lack of thereof. We observe two  
14  
15  
16 conserved proline residues (P67 and P81) located at secondary structure boundaries (Figure  
17  
18  
19  
20 1 and Figure S1) which, together with the presence of proline type isomerizations in the  
21  
22  
23 refolding reaction <sup>17</sup>, made us consider analyzing the role of these residues in conformational  
24  
25  
26 stability and oligomerization. In addition, a recent report highlighted the role of prolines as  
27  
28  
29 conformational switches in amyloid oligomerization <sup>20</sup>. The fact that NS1 also undergoes a  
30  
31  
32 repetitive  $\beta$ -sheet type oligomerization, reinforced our hypothesis of conserved prolines as  
33  
34  
35 modulators of this process.  
36  
37  
38  
39  
40  
41  
42  
43

44 In this work, we analyze the role of the two conserved proline residues in conformational  
45  
46  
47 dynamics and stability, and their participation in oligomerization and aggregation processes  
48  
49  
50 using biophysical techniques. We find that the proline mutations display minimum effect on  
51  
52  
53 the global unfolding but affect a first transition correlating chemical stability to oligomerization.  
54  
55  
56  
57  
58  
59  
60

1  
2 A novel insoluble aggregation route is uncovered, different and competing with the soluble  
3  
4  
5 oligomerization route. Both require a conformational change or local unfolding events that  
6  
7  
8 renders aggregation/oligomerization compatible species depending on the ionic strength. We  
9  
10  
11  
12 argue that this event involves the separation of the C-terminal  $\alpha$ 3 helix from the  $\beta$ -sheet core  
13  
14  
15  
16 with a dynamic fast exchanging equilibrium in native conditions. The distant location of the  
17  
18  
19 prolines from this  $\alpha$ 3-helix suggest global dynamics behind the modulation of oligomerization.  
20  
21  
22  
23 We discuss the results in the light of reports on the impact on oligomerization on its IFN  
24  
25  
26  
27 suppression activity.

## Materials and methods

### Protein Expression and Purification.

NS1 WT and proline mutants P67A, P81A and P67/81A were expressed and purified as previously described for the human RSV strain A NS1 WT protein<sup>16</sup>. Briefly, C41 cells were transformed with a pMal 2C plasmid, containing NS1 fused with the -maltose binding protein (MBP) with a thrombin cleavage site between the two proteins. Cells were grown in LB medium until an OD of 0.6 was reached and protein expression was induced adding 0.3 mM isopropyl  $\beta$ -D-1-thiogalactopyranoside and incubating the cells at 37 °C for 16 h. Cell pellets were resuspended in lysis buffer containing 20 mM Tris.HCl (pH 8.0), 200 mM NaCl, 2 mM 2-mercaptoethanol and 1 mM EDTA and lysed by sonication. Supernatants were precipitated with 50% ammonium sulphate and the pellet was resuspended and dialyzed against a buffer containing 10 mM Tris.HCl (pH 8.0), 200 mM NaCl, and 1 mM DTT. The fusion protein was purified by an affinity amylose resin (New England Biolabs, Hitchin, U.K.), followed by a thrombin cleavage and size exclusion chromatography to separate NS1 from MBP. Highly purified NS1 was dialyzed in 10 mM Tris.HCl (pH 8.0), 100 mM NaCl and 1 mM DTT. The

1  
2 protein concentration was determined spectrophotometrically using a molar extinction  
3  
4  
5  
6 coefficient ( $\epsilon_{280}$ ) of  $9970 \text{ M}^{-1} \text{ cm}^{-1}$ .  
7  
8  
9

### 14 Far-UV circular dichroism spectroscopy (CD).

15  
16  
17  
18  
19 Far-UV CD measurements were carried out on a Jasco J-810 spectropolarimeter using a  
20  
21  
22 Peltier temperature-controlled sample holder at  $25 \text{ }^\circ\text{C}$  in a  $0.1 \text{ cm}$  path length cell. Spectra  
23  
24  
25  
26 were recorded between  $200$  and  $260 \text{ nm}$ . All the spectra were obtained through an average of  
27  
28  
29 six scans. Mean residue molar ellipticity or  $[\theta]_{MRW}$  can be calculated applying the following  
30  
31  
32  
33 formula to the raw data:  
34  
35  
36  
37

$$38 \quad [\theta]_{MRW} (\text{degcm}^2/\text{dmol}) = \frac{m\text{deg}}{10 \times L \times [M] \times N}$$

39  
40  
41  
42  
43  
44 Where  $L$  is the path length (measured in  $\text{cm}$ ),  $[M]$  is the concentration (measured in molar  
45  
46  
47 units), and  $N$  is the number of peptide bonds (measured as: number of amino acids -1).  
48  
49  
50

51  
52  
53 *Thermal denaturation experiments by Far-UV CD spectroscopy.* Ellipticity was recorded at  
54  
55  
56  $225 \text{ nm}$  with a temperature increase of  $4^\circ\text{C}/\text{min}$ . Acquisition parameters were the following: 4  
57  
58  
59

1  
2 nm bandwidth, 4 s response time, and 0.2 °C data pitch. The protein concentration was 10  
3  
4  
5  
6  $\mu\text{M}$ . To calculate thermal transition midpoints, the thermal scans were fit to an irreversible  
7  
8  
9 denaturation model as was previously described <sup>21,22</sup>.

### 16 **Fluorescence Spectroscopy.**

17  
18  
19  
20 Fluorescence experiments were performed in a FluoroMax-4 (Horiba Scientific)  
21  
22  
23  
24 spectrofluorometer. Fluorescence emission spectra were recorded at 25 °C between 310 and  
25  
26  
27 450 nm with excitation wavelength of 295 nm using excitation and emission bandwidths of 5  
28  
29  
30  
31 nm. Fluorescence emission data were analyzed by first subtracting the buffer background.  
32  
33  
34  
35 The protein concentration was 10  $\mu\text{M}$ .

### 43 **Oligomerization Kinetics.**

44  
45  
46  
47  
48 Oligomerization was analyzed monitoring the changes occurring in the far-UV CD signal at  
49  
50  
51 225 nm. NS1 was added at 10  $\mu\text{M}$  to a cuvette containing 10 mM Tris.HCl (pH 8.0) and 2 mM  
52  
53  
54  
55 2-mercaptoethanol, equilibrated at 47°C. The oligomerization reaction was additionally  
56  
57  
58  
59  
60

1  
2 measured following the increase in ThT fluorescence in a Jasco FP-6500 spectrofluorometer.  
3  
4  
5  
6 It has been previously shown that NS1 Oligomers tightly bind ThT, while the monomeric form  
7  
8  
9 shows negligible binding. The ThT fluorescence was measured exciting at 446 nm a solution  
10  
11  
12 containing 20  $\mu\text{M}$  ThT and recording the emission intensity at 483 nm in a temperature-  
13  
14  
15 jumping experiment. The data were fitted to a single exponential process as the best  
16  
17  
18 approximation to the complex kinetics.  
19  
20  
21  
22  
23  
24  
25  
26  
27

### 28 **Unfolding Kinetics.**

30  
31  
32  
33 Native NS1 from a concentrated stock solution was diluted 10-fold by manual mixing in 10  
34  
35  
36 mM Tris.HCl (pH 8.0), 100 mM NaCl, 1mM DTT and 5.0 M Gdm.HCl, to a final protein  
37  
38  
39 concentration of 10  $\mu\text{M}$ . Unfolding kinetics was followed by changes in the CD signal at 220  
40  
41  
42 nm. Unfolding kinetics was also measured monitoring NS1 fluorescence, originated by its  
43  
44  
45 single tryptophan residue, with an excitation wavelength of 295 nm and an emission  
46  
47  
48 wavelength of 330 nm. The temperature was kept constant at 25 °C.  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58

## NMR measurements.

NMR measurements were performed at 25 °C on a Bruker Avance III spectrometer (Bruker Instruments, Inc., Bellerica, MA, USA) operating at a proton frequency of 600.2 MHz. The 1-1 Jump-and-return water suppression pulse sequence was used for 1H 1D NMR experiments<sup>23</sup>.

The following experimental parameters were used in all measurements: 256 scans, 1.85 s relaxation delay, 1.51 s acquisition time, 18 ppm spectral width, 131  $\mu$ s delay for binomial water suppression and 32 K acquisition points. The NMR data were zero-filled, Fourier transformed, phase corrected and converted to a Matlab-compatible format for further processing and analysis with NMRPipe<sup>24</sup>. All spectra were submitted to baseline correction and normalization.

## Molecular dynamics (MD) simulations.

*System set-up.* Initial NS1 WT structure was obtained from the PDB database, i.e. PDB 5VJ2

<sup>12</sup>. For simulation of monomeric NS1, molecule A of the asymmetric unit from the PDB was used. The P67A and P81A mutants were generated using FoldX<sup>25</sup>. Molecular dynamics (MD) simulations were performed using AMBER16<sup>26</sup> and the ff14SB force field was

1  
2 employed for all protein variants <sup>27</sup>. The Visual Molecular Dynamics (VMD) software was  
3  
4  
5  
6 employed for visualization and image rendering <sup>28</sup>.  
7

8  
9 *Explicit water simulations and periodic boundary conditions.* The production simulations for  
10  
11 each system were performed immersing each NS1 structure in a TIP3P water box with 20Å  
12  
13 separation between the protein structure and the box edge. In every case, after preliminary  
14  
15 rounds of minimization, an initial constant volume MD simulation was performed in order to  
16  
17 heat the system to 27 °C. Subsequently, a constant pressure simulation was carried out to  
18  
19 equilibrate the system density. The production MDs consisted of 100 ns simulations for each  
20  
21 analyzed variant. Temperature and pressure were kept constant using the Berendsen  
22  
23 thermostat and barostat respectively <sup>29</sup>. For the PBC simulations, Ewald summations were  
24  
25 used to compute the electrostatic energy terms using the default parameters in the Sander  
26  
27 module of the AMBER package <sup>26</sup>.  
28

35  
36  
37  
38  
39  
40  
41  
42  
43

44 *Trajectory analysis.* Trajectory analysis was performed using CCPTRAJ from the  
45  
46 AMBERTOOLS package <sup>30</sup> or the homemade scripts developed in Tcl running in VMD <sup>28</sup>  
47  
48  
49  
50

51 Calculations of RMSF per residue were performed against the average structure of the  
52  
53 production runs in explicit solvent. SASA values for W90 were calculated for the entire  
54  
55  
56  
57  
58  
59  
60

1  
2 production runs using a 1.4Å probe. The W90-Y88 reported distances were calculated as the  
3  
4  
5  
6 distances between the centers of mass of the sidechains for both residues. For the SASA  
7  
8  
9 calculations, a spherical probe of 1.4Å radius/diameter was used. The SASA of the folded  
10  
11  
12 state was calculated from the average of the production run of the MD simulation of wild-type  
13  
14  
15 NS1 using VMD software <sup>28</sup>. For the calculation of the SASA in the unfolded state, an  
16  
17  
18 ensemble of 2000 configurations of the NS1 sequence encompassing residues 5 to 139  
19  
20  
21 (corresponding to those present in the crystal structure <sup>12</sup> was obtained using a flexible  
22  
23  
24 meccano's Monte Carlo algorithm <sup>31</sup> using the ProtSA server <sup>28</sup>. Thus, the SASA for the  
25  
26  
27 unfolded state was calculated from the weighted average of the unfolded ensemble. The  
28  
29  
30 difference in solvent accessible surface area ( $\Delta$ SASA) between the folded and unfolded  
31  
32  
33 states was calculated using the average SASA values of both states <sup>32</sup>.

## 46 **Unfolding Data Analysis.**

47  
48  
49 *Unfolding Kinetics.* The observed rate constants for unfolding reaction were obtained by fitting  
50  
51  
52 the kinetic traces to a bi-exponential function:  
53  
54  
55  
56  
57  
58  
59  
60

$$F(t) = \sum A_n \exp(-k_n t) + F_\infty$$

where  $F(t)$  and  $F_\infty$  are the observed signal at time  $t$  and at infinite time, respectively, and  $A_n$  and  $k_n$  are the signal amplitude and rate constants, respectively (for each process). The criteria followed to choose the minimal number of exponentials that provide the best fit for each trace were (1) a random dispersion of residuals, (2) low standard deviation values, and (3) significant improvement in the fit  $\chi^2$  values.

*Equilibrium denaturation experiments.* The Gdm.HCl induced denaturation data were fitted to a two-state denaturation model that include linear slopes for the baselines, described in full in reference <sup>22</sup>.

## RESULTS

### Structural dynamics of wild-type NS1 and single proline mutants

The crystal structure revealed a particular fold that does not appear as highly compact, as revealed by the position of the C-terminal  $\alpha 3$ . To investigate the structural dynamics of NS1, we performed molecular dynamics (MD) simulations. We calculated the root mean squared fluctuation (RMSF) per residue and found that the most flexible regions correspond to the short loops (11-19, 52-54, 60-68, 82-83, and 98-110) that flank the  $\beta$  strands, and on  $\alpha 3$  (Figure 1). The fluctuations of  $\alpha 3$  arise from the concerted movement of the entire helix, which is displaced along its longitudinal axis in a back-and-forth movement along the surface of the core (not shown).

**Figure 1.** *Structure and flexibility of NS1 WT and proline mutants.* Left: The RMSF of WT and proline NS1 mutants was assessed analyzing the MD simulations obtained for WT NS1 (black), P67A (red) and P81A (green). The regions of higher motility correspond to loop and coil elements in the secondary structure (inset) and the  $\alpha 3$  helix. Proline positions are indicated with arrows. Right: Crystal structure of WT NS1 obtained from PDB 5VJ2. The highly flexible regions are displayed in red, and the proline residues are shown in a VdW representation, with the conserved prolines P67 and P81 displayed as blue spheres.

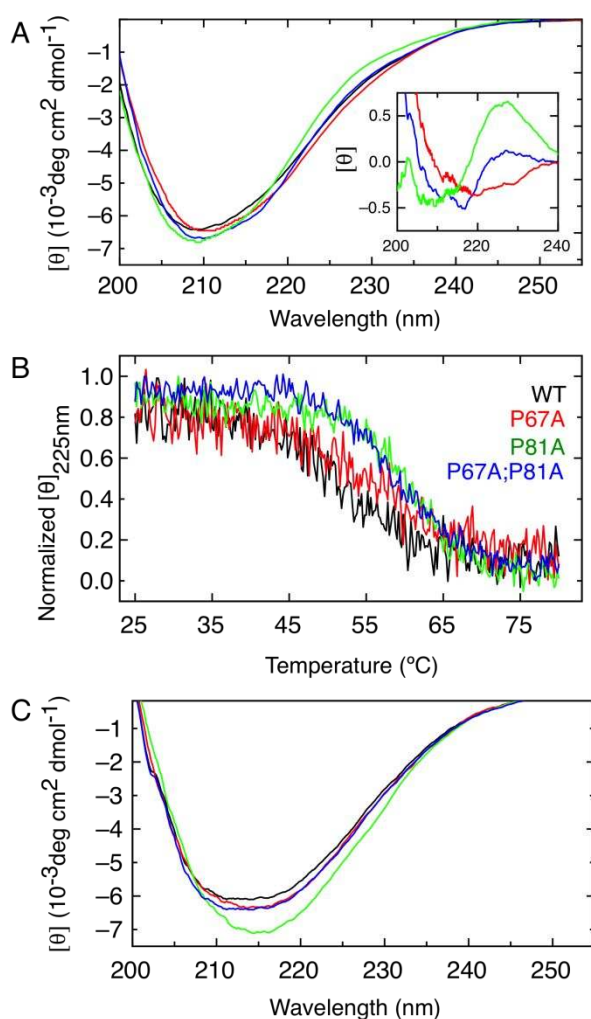

Inspection of the secondary structure elements and RMSF show that the proline residues (P67, P81, P101 and P139) are located in regions of maximum mobility at the boundaries of secondary structural elements. However, P67 and P81 exhibit sequence conservation between human and bovine NS1 while P101 and P139 do not, where the latter is one residue away from the C-terminus. The role of the conserved prolines on the structure and dynamics of NS1 was addressed by generating the mutants P67A and P81A in silico.

1  
2 MD simulations reveal that these mutations do not impact on the protein fold substantially, but  
3  
4  
5  
6 affect the dynamics both locally and non-locally. Both P67A and P81A exhibit an increased  
7  
8  
9 mobility of  $\alpha 3$ . The P67A variant exhibits increased a mobility in the 11-19 and 60-68 loops.  
10  
11  
12 On the other hand, P81A exhibits a different behavior, where aside from the  $\alpha 3$  helix, the rest  
13  
14  
15 of the protein displays a decreased RMSF, even in the flexible loops. Thus, although there is  
16  
17  
18 some local increase in flexibility in certain regions for this variant, the compact elements  
19  
20  
21 constituting the main  $\beta$ -sheet fold of the core <sup>12</sup> are more rigid.

24  
25  
26  
27

### 28 **Effect of conserved prolines on the conformation and oligomerization of NS1**

29  
30  
31  
32 Although the overall fold appears to be unmodified, as the 1D NMR spectra indicates  
33  
34  
35 (Figure S2) there are some small changes on the CD spectra that can be pointed out.  
36  
37  
38  
39 Mutation of P67 to alanine does not affect the secondary structure, as judged by an identical  
40  
41  
42 CD spectrum to wild type NS1 (Figure 2A). However, the single P81A mutant shows a  
43  
44  
45 significant secondary structure change, clearly evidenced in the difference spectrum (Figure  
46  
47  
48 2A inset). This change cannot be ascribed to a particular structural element, but only  
49  
50  
51 describe a change at around 225 nm.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 P67A shows no difference from wild-type in terms of the tendency to form NS1SOs  
3  
4  
5  
6 after temperature perturbation, as the oligomerization  $T_{m,app}$  (Thermal transition midpoint)  
7  
8  
9 indicates, while P81A and the double mutant are more resistant to oligomerization with a 10  
11  
12 °C increase in the  $T_{m,app}$  (Figure 2B, 2C and Table 1). Consistent with previous results <sup>16,17</sup>,  
13  
14  
15  
16 the far UV CD spectra of the NS1SOs formed at the endpoint of the heating process shows  
17  
18  
19 an increase in  $\beta$ -sheet content, and this is particularly noticeable for the P81A mutant (Figure  
20  
21  
22  
23 2C and Figure S3).

Normalized thermal scans of protein samples followed at 225 nm by far-UV CD. (C) CD spectra of wild-type and mutants at 80°C taken at the end of the thermal scan (C). All the experiments were carried out in 10 mM Tris.HCl (pH 8.0), 100 mM NaCl and 1 mM DTT at 10  $\mu$ M protein concentration. The same color code for the mutants is used in all figures.

**Table 1. Oligomerization and aggregation parameters <sup>a</sup>.**

	$T_{m, \text{agg}}$	$T_{m, \text{olig}}$	$k_{\text{app}} \times 10^3 \text{ (s}^{-1}\text{)}$	
			Fluo. ThT	Far UV-CD
	(°C)	(°C)		
<b>Wild-type</b>	65.2	46.9	$1.2 \pm 0.003$	$8.8 \pm 0.31$
<b>P67A</b>	60.3	49.9	$0.8 \pm 0.004$	$10.4 \pm 0.39$
<b>P81A</b>	67.6	56.7	$0.5 \pm 0.001$	$3 \pm 0.23$
<b>P67A;P81A</b>	64.6	54.7	$0.8 \pm 0.003$	$6.7 \pm 0.22$

<sup>a</sup>Data obtained from figures 3 and 4. Thermal scans were fit to an irreversible denaturation model <sup>21,22</sup>.

We have previously shown that the actual NS1SOs oligomerization process can be monitored by ThT binding which reports the formation of anti-parallel  $\beta$ -sheet. This process is preceded by a marked secondary structure change evidenced by a decrease of ellipticity signal at 225 nm indicative of an increase in the  $\beta$ -sheet content of the NS1 monomer <sup>16</sup>. We analyzed the oligomerization kinetics of the proline mutants by temperature jump (see materials and methods) and compared to the wild-type NS1 (Figure 3 and Figure S4). We found that P81A is significantly slower than wild-type, while P67A and the double mutant

1  
2 show similar kinetics, suggesting that P67 counterbalances the effect of P81. The nucleation  
3  
4  
5  
6 lag is observed for all variants, but it is more pronounced in P81A. In any case, as we  
7  
8  
9 previously described, the oligomerization process is complex and multiple events may coexist  
10  
11  
12 within the  $k_{app}$ , which we now use to compare the global process.

40 **Figure 3.** *Kinetics of NS1SOs formation.* Oligomerization kinetics were measured after  
41 transferring WT or NS1 mutants to a pre-equilibrated buffer at 47 °C (Temperature jump) in  
42 four independent experiments. The final protein concentration was 10  $\mu\text{M}$ . Oligomerization  
43 kinetics was assessed following changes in ThT fluorescence (A) and in the far-UV CD signal  
44 at 225 nm (B). Traces were fitted to a single exponential function. The rate constants are  
45 shown in table 1.

1  
2 As in the case of WT, the kinetics of the secondary structure change of the mutants by  
3  
4  
5  
6 CD precedes the oligomerization reaction as measured by ThT fluorescence, indicating an  
7  
8  
9 overall similar mechanism (Figure S4). Because the first-order nature of the conformational  
10  
11  
12 change, a single exponential fit yields a true constant  $k_{app}$ . P81A is substantially slower than  
13  
14  
15  
16 WT while P67A shows a faster change. The double mutant shows an intermediate rate (Table  
17  
18  
19 1).

25

### 26 **Competing soluble oligomerization and insoluble aggregation routes**

27  
28  
29  
30 Partial protein losses during the purification process, possibly due to aggregation,  
31  
32  
33 prompted us to test the effect of ionic strength on the NS1 monomer. Increasing the  
34  
35  
36 concentration of NaCl does not affect the secondary structure at 25 °C (not shown), but leads  
37  
38  
39 to aggregation upon increasing the temperature, as indicated by the complete loss of CD  
40  
41  
42 signal, increase in absorbance light scattering (not shown), and visual inspection after  
43  
44  
45 heating. We carried out thermal scanning experiments followed by CD and observed a drastic  
46  
47  
48 change in the scans from low to high salt (Figure 4A), where the salt effect on aggregation  
49  
50  
51 saturates at 0.2 M NaCl (Figure 4A, inset). The aspect of the scans clearly shows a shift from  
52  
53  
54  
55  
56  
57  
58  
59  
60

soluble oligomerization (NS1SOs species) at low salt characterized by a decrease in ellipticity due to the increase in  $\beta$ -sheet (Figure 2B and Figure 4A), to the extreme insoluble aggregation, which we refer to as NS1Agg (Figure 4A). At intermediate salt concentrations, the opposed signal changes cancel out to different extents, indicating the presence of competing routes. Since there is no effect of the ionic strength on the CD of the NS1 monomer at 25 °C, we propose that the effect is after the formation of the oligomerization monomeric nucleus, i.e., during the oligomerization or aggregation processes.

**Figure 4.** Effect of ionic strength in oligomerization and aggregation routes for WT NS1 and proline mutants. (A) Thermal scans, from 25°C to 80°C followed at 225 nm by far-UV CD, at

1  
2 different concentrations of NaCl for NS1 WT ([NaCl]: 0, 25, 50, 100, 200 and 400 mM of  
3 NaCl). Inset: dependence of the CD signal as function of the NaCl concentration at 80°C (B)  
4 Thermal scans of NS1 WT and mutants at 250 mM of NaCl concentration followed by far-UV  
5 CD at 225 nm. Inset: difference between the  $T_m$  obtained for mutants relative to WT NS1  
6 protein. All experiments were performed at 10  $\mu$ M final protein concentration.  
7  
8  
9  
10

11  
12 In order to test the effect of the proline mutants on the aggregation process, we carried  
13 out thermal scans followed by CD. The P81A mutant is slightly but significantly more resistant  
14 to thermal aggregation when compared to wild-type, but P67A is substantially more  
15 aggregation prone, as a 5 °C decrease in  $T_{m,app}$  indicates (Figure 4B and Table 1).

### 30 Folding of proline variants

31  
32 We have previously shown that NS1 unfolds reversibly and its chemical unfolding  
33 transition can be followed by its single buried tryptophan residue, an excellent reporter for  
34 global unfolding <sup>16</sup>. Upon progression of the unfolding process the exposure to the solvent,  
35 the maximum emission wavelength ( $\lambda_{max}$ ) of the single Trp90 shifts from 332 to 356 nm  
36 (Figure S5). The process is also accompanied by a large change in fluorescence intensity  
37 ( $F_{int}$ ), likely because of quenching of its unique trp residue, since we use an excitation  
38 wavelength of 295 nm to eliminate possible contributions from tyrosine residues.

51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 The transition can also be also followed by far-UV circular dichroism which shows the  
3  
4  
5  
6 disappearance of the signal corresponding to folded secondary structure, with maximum  
7  
8  
9 ellipticity change between 215 and 225 nm (Figure S5). Performing both measurements in  
10  
11  
12 the same experiment with a protein concentration that yields an optimal signal provides  
13  
14  
15  
16 maximum accuracy for dissecting a complex transition. Based on both fluorescence and  
17  
18  
19 ellipticity transitions, we monitored the  $F_{\text{int}}$  at 325 nm and the molar ellipticity  $[\theta]$  at 225 nm.  
20  
21  
22  
23 The ellipticity change upon unfolding of wild-type and mutants show a large pre-transition  
24  
25  
26 slope from zero to ca 2.5 M denaturant, indicative of a substantial change of secondary  
27  
28  
29 structure, an anomalous signal of an aromatic residue, or both (Figure 5A). This linear  
30  
31  
32  
33 transition is followed subsequently by a cooperative transition similar to what was previously  
34  
35  
36  
37 observed <sup>16</sup>, with a apparent similar behavior for the mutants. However, two salient features  
38  
39  
40 can be observed of this first transition: in P81A it takes place at higher denaturant than the  
41  
42  
43  
44 other species and the P67A/P81A double mutant shows the largest change in secondary  
45  
46  
47 structure (Figure 5A).  
48  
49  
50

51 When both  $F_{\text{int}}$  and  $[\theta]$  are represented for each species an evident uncoupling  
52  
53  
54 between the two signals is observed (Figure 5B), strongly suggesting a non two-state  
55  
56  
57  
58  
59  
60

1 transition, with the largest uncoupling corresponding to P67A (Figure 5B, Figure S5). The  
 2  
 3  
 4  
 5  
 6 partial overlapping of the two transitions, the absence of a significant  $F_{\text{int}}$  change in the  
 7  
 8  
 9 second transition, and the fact that the first secondary structure transition is large and opposed  
 10  
 11  
 12 to the second more stable and cooperative one, makes fitting the data to a three-state model  
 13  
 14  
 15 very difficult and therefore not quantitatively reliable. As an approximation, since the first  
 16  
 17  
 18 ellipticity transition is linear, we fit it as a slope preceding the main cooperative/second  
 19  
 20  
 21 transition treated as two-state in all four proteins and the data are presented in Table 2.  
 22  
 23  
 24 Using the P67A as an example of the uncoupling between both signals (Figure 5B), we fitted  
 25  
 26  
 27 the  $F_{\text{int}}$  to a two-state model in a range where the second transition has either not started or  
 28  
 29  
 30 can be approximated as linear within the transition midpoint range. The resulting data are  
 31  
 32  
 33 presented in Table 2.  
 34  
 35  
 36  
 37  
 38  
 39  
 40

41 **Table 2.** Thermodynamic parameters obtained by fitting the fluorescence or far-UV CD data to  
 42  
 43 a two-state model.  
 44

	First fluorescence transition			Second Ellipticity transition		
	$\Delta G$ (kcal.mol <sup>-1</sup> )	$m$ (kcal.mol <sup>-1</sup> .M <sup>-1</sup> )	$D_{50\%}$	$\Delta G$ (kcal.mol <sup>-1</sup> )	$m$ (kcal.mol <sup>-1</sup> .M <sup>-1</sup> )	$D_{50\%}$
Wild-type	3.21 ± 0.51	1.32 ± 0.25	2.4	3.50 ± 0.31	1.02 ± 0.12	3.4
P67A	1.98 ± 0.48	1.29 ± 0.19	1.5	2.36 ± 0.41	0.69 ± 0.15	3.4

P81A	5.03 ± 0.76	1.70 ± 0.25	2.9	5.88 ± 0.74	1.60 ± 0.21	3.6
P67;81A <sup>a</sup>	nd	nd	2.5 <sup>b</sup>	nd	nd	3.3 <sup>b</sup>

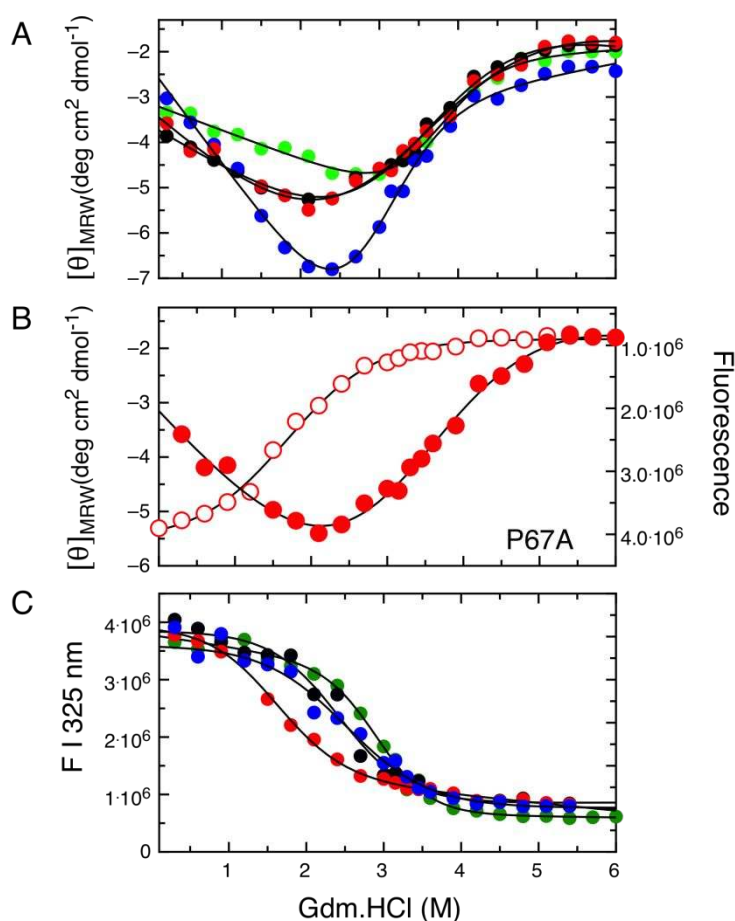

<sup>a</sup> This mutant showed partial reversibility (Figure S7) and therefore its stability is expressed as the apparent  $D_{50\%}$ . <sup>b</sup>

The fact that the  $m$  values are different suggest that there are differences in the exposure of solvent accessible surface area ( $\Delta$ ASA) across this first transition to an intermediate state, and renders the  $\Delta G$  values not comparable (Table 2). Under these circumstances we use the denaturation midpoint  $[D]_{50\%}$ , calculated from the  $\Delta G$  and  $m$  of each protein, as the best estimation for stability of this first transition. The P81A mutant is more stable than wild type, whereas P67A is less stable and the double mutant appears to compensate both single mutants, **based on its apparent  $[D]_{50\%}$  of 2.5 M**(Table 2). These results are also visually confirmed when  $F_{int}$  is represented in a normalized plot (Figure 5C).

Similarly, we approach the first secondary structure transition as a linear process and treat the second part of the curve as a two-state process. Once again, difference in  $m$  values hampers the use of the  $\Delta G$  for comparing the different proteins (Table 2). This allow us to conclude that the wild-type, P67A and P81A show similar stability in this cooperative transition, indicated by  $[D]_{50\%}$  between 3.4 and 3.6 M, which we ascribe to the folded  $\beta$ -sheet core described in the X-ray structure <sup>12</sup>. The complexity of the double mutant is revealed by

1  
2 the partial reversibility as opposed to the complete secondary and tertiary structure  
3  
4  
5  
6 reversibility for the single mutants and the wild-type protein (Figure S7). The partial  
7  
8  
9 reversibility preclude the extraction of accurate thermodynamic parameters. Irrespective of  
10  
11  
12 the degree of reversibility and its structural basis, we use the apparent  $[D]_{50\%}$  (3.3 M, Table 2  
13  
14  
15  
16 and Figure S6) for an approximation to stability.  
17

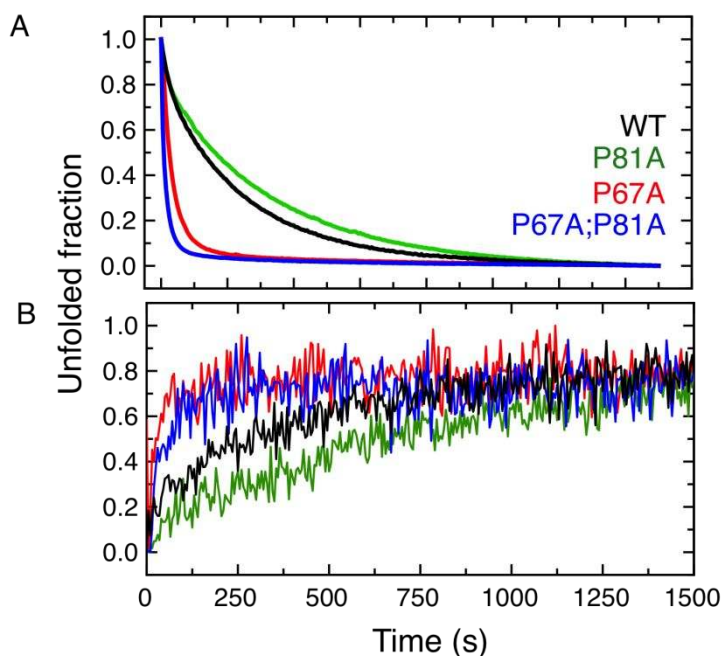

**Figure 5.** *Gdm.HCl* equilibrium denaturation of wild-type and proline mutants. (A) Denaturation followed by changes in molar ellipticity. (B) Denaturation followed by ellipticity at 225 nm and  $F_{int}$  at 325 nm changes for the P67A mutant, shown as an example (see Figure S6). The fits to a two-state denaturation model are represented. (C) Comparison of  $F_{int}$  of all proteins. All the measurements were carried out at 10  $\mu$ m protein concentration, and fluorescence and ellipticity data collected from the same experiments.

Given the impact of having very different  $m$  values on overall stability, we tackled a kinetic analysis of the unfolding rates in order to obtain another assessment of stability. We have previously shown that unfolding shows a monoexponential decay with a minimal effect

1  
2 of the denaturant on the rate. We analyzed the unfolding rates ( $k_{\text{obs}}$ ) of the mutants at 5.0 M  
3  
4  
5  
6 Gdm.HCl well after the completion of the unfolding transition, and compared them to the wild-  
7  
8  
9 type protein (Figure 5C, Figure S5 and Table S1). All proteins showed a single phase, but a  
10  
11  
12 faster fluorescence change cannot be determined because of the experimental dead time of  
13  
14  
15  
16 manual mixing. P81A unfolds slightly slower than wild type but P67A unfolds 10-fold faster  
17  
18  
19 (Figure 6A). The double mutant also unfolds 10-fold faster, which indicates that the unfolding  
20  
21  
22 rate is governed by P67, different from the effect at the equilibrium. These results suggest an  
23  
24  
25  
26 effect at the level of the transition state ensemble that requires further investigation. In the  
27  
28  
29  
30 second transition detected in the three mutants, secondary and tertiary structure unfold  
31  
32  
33 together similar to wild-type (Figure 6B and Table 2), where only a single phase can be  
34  
35  
36  
37 detected because of CD noise and also the experimental deadtime of manual mixing.

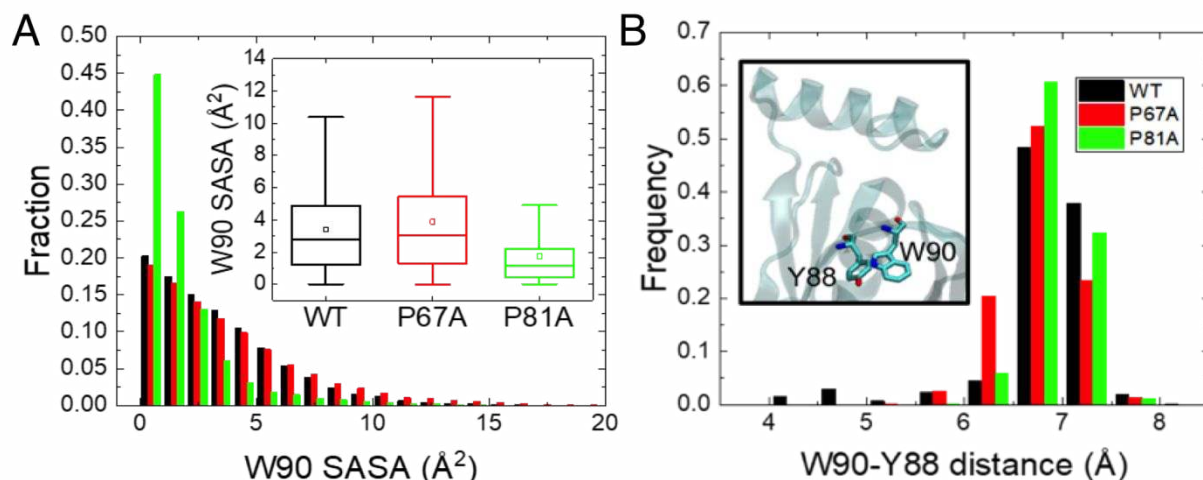

**Figure 6.** *Gdm.HCl* unfolding of wild-type and mutant NS1s. Each protein was added to a cuvette containing 5.0 M *Gdm.HCl* in buffer and either fluorescence (A) or ellipticity (B) was followed in similar conditions to equilibrium unfolding experiments (Figure 5).

### Fluorescence changes reveal local dynamics at the C-term helix/ $\beta$ -sheet core interface.

We have shown that the fluorescence intensity at the  $\lambda_{\max}$  (360 nm) shows a marked change prior to the global unfolding transition reported by changes in  $\lambda_{\max}$  with a differential effect depending on the mutant, reflecting a highly sensitive reporter for local events (Figure 5B, Figure S5). In order to understand the basis for this phenomenon, we carried out MD simulation analysis of the single tryptophan 90. Although the calculations of the SASA on the

1  
2 crystal structure of NS1 yields this Trp side chain as buried, trajectory analysis reveal that the  
3  
4  
5 exposure of the residue oscillates, from 0 to ca 26 Å<sup>2</sup> in WT NS1. This large fluctuation  
6  
7  
8  
9 shows Trp90 as partly exposed, and the level of exposure correlates with the position of α-  
10  
11  
12 helix 3 along the trajectory, as in some arrangements it completely occludes the Trp side  
13  
14  
15  
16 chain. P67A follows a similar pattern to that of WT NS1, although with a slightly higher mean  
17  
18  
19 and a broader distribution (Figure 7B). P81A clearly shows both a lower mean accessibility  
20  
21  
22 and less variability, correlating with an overall lower flexibility of the protein as assessed by  
23  
24  
25  
26 RMSF calculations (Figure 1).

**Figure 7.** Solvent accessibility for WT and NS1 proline mutants by MD dynamics. (A) Solvent accessibility of W90 in NS1 variants. Frequency of the solvent accessible surface area (SASA) distribution was obtained calculating the SASA of W90, along the 100ns trajectories, for WT NS1 (black), P67A (red) and P81A (green). Inset: Box-and-whiskers plot, showing the mean, median, interquartile range (IQR) Q3-Q1 that represents the data range between 25%

1  
2 and 75% of the data, and data range within 1.5 IQR calculated as  $Q1-1.5IQR$  to  $Q3+1.5IQR$ .  
3  
4 (B) Distance distribution between W90 and Y88 in NS1 variants. The distances along the  
5 trajectories were calculated between the center of mass of the sidechains of residues W90  
6 and Y88 (inset). The frequency of the distances distribution is plotted using the calculations  
7 performed along the 100ns trajectories for WT NS1 (black), P67A (green) and P81A (red)  
8  
9  
10  
11  
12  
13

14  
15 Another factor that can affect fluorescence is quenching, whether collisional or due to  
16  
17 Förster Resonance energy transfer (FRET). Visual inspection of NS1 structure shows that  
18 tyrosine 88 side chain lies on top of Trp90, rendering it a suitable candidate as the  
19 fluorescence quencher (Figure 7B). We analyzed the distance between both residues,  
20  
21 calculating the distance between the respective centers of mass of the side chains along the  
22  
23 dynamics for WT NS1 and both mutants. The displacement of  $\alpha$ -helix along the trajectories for  
24  
25 WT NS1 modulates the Trp90-Tyr88 distance distribution, showing a bimodal distribution with  
26  
27 the maxima centered around  $7\text{\AA}$  and  $4.5\text{\AA}$ , respectively, where the latter distribution being  
28  
29 much less populated. Both mutants display the same trend, evidenced in the RMSF and  
30  
31 SASA calculations. They also display Trp90-Tyr88 distance distribution centered around  $7\text{\AA}$ ,  
32  
33 with P67A exhibiting a broader distribution, favoring closer distances while P81A presents a  
34  
35 narrower distribution skewed towards larger distances.

## DISCUSSION

In previous work we showed that NS1 from human RSV, although a stable monomer in solution, shows a marked tendency to form soluble, stable and regular spherical oligomers at physiological temperatures, which we termed NS1SOs<sup>16</sup>. This process involves a slow conformational change corresponding to an increased  $\beta$ -sheet content prior to oligomerization. We hypothesized that such change may originate in conformational isomerizations from two highly conserved proline residues and at the same time gain more insight into the mechanism. The recently determined crystallographic structure provides structural grounds for interpretation of our current and previous results.

The experimental results and MD simulations show that the overall structure is not affected by the proline to alanine substitutions. However, the calculations expose some important details of the protein dynamics and the role of the conserved prolines. These mutations elicit both local and non-local effects on the protein dynamics, that in turn affect overall protein stability and more importantly soluble and insoluble aggregation routes. MD simulations show several flexible  $\beta$ -strand flanking loops which become rigid upon mutation of proline 81 to alanine, particularly in the 60-68 loop. Interestingly, a digitization observed for

1  
2 most regions strongly suggests a global structural impact of this proline residue. MD also  
3  
4  
5  
6 reveals a fluctuation of its C-terminal  $\alpha 3$  helix which displaces along the main  $\beta$ -strand barrel-  
7  
8  
9 type core <sup>12</sup>.

10  
11  
12 In experimental terms, the P81A mutant shows a significant increase in ellipticity at 225  
13  
14  
15 nm, although the 1D, although no large differences are observed in 1D-NMR. This mutant  
16  
17  
18  
19 also leads to a decrease in oligomerization propensity as indicated by an increased  $T_{m,app}$ .  
20  
21  
22  
23 Both the CD of the monomer and decreased tendency to oligomerization by temperature are  
24  
25  
26 identical for P81A and the double mutant P67A;P81A, strongly suggesting that the effect at  
27  
28  
29  
30 the equilibrium is governed by P81. The oligomerization rate of P81A is also slower than the  
31  
32  
33  
34 WT and the other variants for both temperature induced conformational change and the  
35  
36  
37 subsequent oligomerization reaction. We propose that the slower conformational change  
38  
39  
40  
41 responds to the rigidization and stabilization caused by P81 on the overall structure resulting  
42  
43  
44 in a higher energy barrier. The protein is a monomer at low concentrations in solution, but the  
45  
46  
47 oligomerization mechanism and the crystallographic structure support the existence of a  
48  
49  
50  
51 dimeric species which we believe is the immediate product of the conformational change  
52  
53  
54 required for oligomerization to take place <sup>12,17</sup>. An interesting observation is that P67A reverts  
55  
56  
57  
58  
59  
60

1  
2 the effect of P81 on the oligomerization kinetics but not on the equilibrium temperature  
3  
4  
5  
6 transition suggesting a differential role in ground and transition states.  
7  
8

9 In this work, we uncover insoluble aggregation pathway (NS1Agg) that takes place at  
10  
11 increasing salt concentration which competes with the NS1SOs soluble oligomerization route  
12  
13 peaking at 0.2 M NaCl. This process is marginally affected by P81, but strongly increased by  
14  
15  
16 P67, suggesting that both soluble oligomerization and insoluble aggregation routes respond  
17  
18  
19 to different intermediate conformers, supported by the lack of correlation of the effect of  
20  
21  
22 mutation on both processes (Figure 4B, inset). It also suggests that depending on its  
23  
24  
25 concentration levels in the host cell and its ligands, it may be a preferred pathway for  
26  
27  
28 unbound NS1, a possible scenario of high levels of the protein <sup>8</sup>. In any case, the fact that the  
29  
30  
31 ionic strength favors the aggregation route (NS1Agg), suggests a very sensitive electrostatic  
32  
33  
34 component on the soluble oligomerization NS1SOs route screened by the addition of 0.2 M  
35  
36  
37 salt. This explains the apparent contradiction observed in the lack of effect of residues F17,  
38  
39  
40 F56, Y125 in which structure clearly links them to the stabilization of the C-terminal helix,  
41  
42  
43 since the thermal denaturation reported therein is in fact insoluble aggregation <sup>12</sup>.  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 Chemical denaturation experiments show a first weaker transition with a large change  
3  
4  
5  
6 in fluorescence intensity, but an otherwise small change in  $\lambda_{\max}$ , and a second transition where  
7  
8  
9 the  $\lambda_{\max}$  change is that expected from a fully unfolded tryptophan. Circular dichroism also  
10  
11  
12 shows two marked transitions, strongly suggesting that the first transition is of significant  
13  
14  
15 structural magnitude. However, we believe that anomalous contribution of aromatics to the  
16  
17  
18 ellipticity signal in that wavelength range plays an important role. P81A shows the most  
19  
20  
21 stabilizing effect on this transition, P67A is destabilizing compared to wild-type, and the  
22  
23  
24 double mutant appears to compensate the individual single mutations. Neither of the  
25  
26  
27 mutants appear to significantly affect the second stronger and more cooperative transition.  
28  
29  
30 We propose that this first weak transition corresponds to unfolding of the alpha-helix-3<sup>12</sup>,  
31  
32  
33 which leaves an intermediate species corresponding to the main folding  $\beta$ -sheet core. In the  
34  
35  
36 absence of denaturant this species is not soluble as a monomer and oligomerizes as the  
37  
38  
39 temperature jump experiments indicate. Both P81 and P67 residue plays opposing but  
40  
41  
42 otherwise similar roles in chemical partial unfolding and temperature stabilization.  
43  
44  
45  
46  
47  
48  
49  
50

51 We have previously shown that, as opposed to the single phase unfolding reaction, the  
52  
53  
54 refolding kinetics is a complex multiphasic reaction based on oligomerization of its proline  
55  
56  
57  
58  
59  
60

1  
2 residues prior to the global refolding <sup>17</sup>. This implies that elements of structure in the unfolded  
3  
4  
5 state must isomerize for the refolding to take place, and this isomerization would modulate the  
6  
7  
8 formation or disruption of a folding nucleus. P67 exists as the *trans* isomer in the folded state,  
9  
10 and its replacement by alanine appears to favor the formation of local structure. The local  
11  
12 residual structure is probed by a strong quenching of Trp90, supporting the hypothesis. On  
13  
14  
15 the other hand, P81 populates the *cis* isomer in the native folded state, and its mutation  
16  
17  
18 favors rigidization and opposes to oligomerization. The absence of the WT P81 would  
19  
20  
21 preclude an isomerization dependent conformational change, but further interpretation  
22  
23  
24 requires NMR analysis.  
25  
26  
27  
28  
29  
30  
31  
32

33 The overall picture shows a weak and highly mobile C-terminal  $\alpha$ -helix that is readily  
34  
35 affected by mild temperature perturbation that leads to either oligomerization or aggregation  
36  
37 routes depending on the ionic strength. This helix weakens upon chemical unfolding, as  
38  
39 reported by its single and highly sensitive Trp90, preceding the global unfolding transition  
40  
41 corresponding to the main  $\beta$ -sheet core <sup>12</sup>. Although there is no specific protein target defined  
42  
43  
44 in terms of binding affinity or structure, this mobile C-terminal helix might have important  
45  
46  
47 implications in structure <sup>33</sup>. The conserved proline residues, in particular P81, maintain the  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 global structure dynamic in order for the oligomerization to be modulated. Thus, they appear  
3  
4  
5  
6 to tune the exposure of SASA in order to either bind to the many interaction partners reported  
7  
8  
9 so far, or partake in those interactions involving oligomerization. Further functional analysis  
10  
11  
12 with the infection model aiming at the role of the oligomerization routes and interaction  
13  
14  
15 partners should be addressed by probing the C-terminal helix with biophysical and structural  
16  
17  
18 methods. The final goal is understanding the molecular basis of its interferon inhibiting activity  
19  
20  
21 in concerted action with NS2, both unique to RSV, particularly through the numerous  
22  
23  
24 interaction partners identified by proteomic studies, where oligomerization appears as a  
25  
26  
27 prominent feature for the biological activity this protein.
